The converse effect, the drawing away of attention from motion, has been observed by Rees et al. (1997). The authors showed that attention to central visual stimulus substantially reduced the motion activity of hMT/V5. Rees et al. presented words in the center of the display and asked subjects to detect bisyllabic words compared to a low-load condition in which they detected uppercase words. We made similar observations in a control experiment for our initial monkey fMRI experiments, in which fixation was controlled by requiring the monkey to detect orientation changes of a very small, light bar. We measured the effect of a 32% reduction in the hMT/V5+ motion activation as the result of attention to this central bar (Sunaert et al., unpublished). Rees et al. (2001) subsequently showed that a similar task requiring attention to auditorily presented words had little effect on motion activation in hMT/V5+, hV3A, and KO.

ATTENTION TO DIRECTION OF MOTION Rather than asking subjects to attend to a moving versus stationary stimulus, one can draw the subjects' attention to a given aspect of motion, thus manipulating featural attention. This is usually done with a task requiring the subject to judge some aspect of motion (e.g., speed or direction). The manipulation of featural attention (Corbetta et al., 1991) should not be confused with task manipulation, in which the feature remains constant but the task performed with the attribute varies (Dupont et al., 1993; Fias et al., 2002; Orban et al., 1997). As O'Craven et al. (1997) noted, the use of a discrimination task does not allow for a pure attention manipulation, since either featural attention or decision factors can explain the differences in activation between the discrimination task and the control task. However, a conjunction analysis might provide that distinction (Peuskens et al., 2001a).

Figure 83.9 shows one of the most simple discrimination tasks, that of opposed motion discrimination, which has

been studied extensively in single-cell studies by Newsome and coworkers (Britten et al., 1992; Newsome and Paré, 1988). Compared to a dimming detection control task, discrimination of opposite directions of motion activates hMT/V5+ and hV3A but also parietal and premotor cortex. The parietal activation, and a fortiori the premotor one, may well reflect decision-related processes, according to single-cell studies (Shadlen and Newsome, 1996). In contrast, the activation of hMT/V5+ and hV3A most likely reflects featural attention. While the discrimination of opposite directions of motion does activate hMT/V5+, fine discriminations of direction, compared to the same dimming control task, fails to activate this area (Cornette et al., 1998a) but activates hV3A and parietal cortex. It is worth noting that the computations involved in these two tasks are very different. In the case of opposite direction of motion, direction-selective cells tuned to those directions are required (Britten et al., 1992). For fine discrimination, it may well be that the slope of the direction-tuning curve is important if one extrapolates from orientation discrimination (Schoups et al., 2001). For these fine discriminations, directional (tuned to a single direction) and nondirectional (tuned to opposite directions) cells then become equally useful.

Still related to direction processing is the heading task, in which the spatial distribution of directions contains the information about the direction of self-motion. This task, again with reference to the same dimming control task, activates hMT/V5+, as well as parietal and premotor cortex, but not hV3A (Peuskens et al., 2001a). Here the single-cell studies (Duffy and Wurtz, 1991; Lagae et al., 1994; Saito et al., 1986) have shown that neurons selective to expansion occur in MSTd, the homolog of which is included in the hMT/V5+ complex. Finally, expectations about the direction of motion elicited by a stationary cue (arrow) activate hMT/V5+ and also parietal motion-sensitive regions along the IPS (VIPS, DIPSM/L, and DIPSA; Shulman et al., 1999).

ATTENTION TO SPEED The aspect of motion which has received most attention is speed of motion. In their seminal study, Corbetta et al. (1991) compared same-different judgments of speed to a divided attention condition. They observed a strong activation over what is now known as hV3A, but also a weaker one over hMT/V5+. In a subsequent study, Beauchamp et al. (1997) compared hMT/V5+ activation by an identical stimulus, an annulus of coherently moving dots, under two attention conditions. Subjects either compared speeds in the two halves of the annulus or compared the colors in these halves, resulting in a 35% reduction of hMT/V5+ activity when attention was drawn away from the speed. Huk and Heeger (2000) again reported a 10% increase in activation of hMT/V5+, but not of V1 or hV3A, when comparing a speed discrimination to a contrast discrimination. In contrast, we (Orban et al., 1998; Sunaert et al., 2000b) observed an activation of hV3A (and V3) but not of hMT/V5+ when speed identification and a successive speed discrimination task were compared to a dimming control task. This result does not depend on the psychophysical performance level (Sunaert et al., 2000b). It remains unclear which of the small differences in stimulus and task explain the differences between these studies. It should be noted that in our last study (Sunaert et al., 2000b), we also observed a very small increase (5%) in the activity of hMT/V5+ in speed discrimination versus dimming detection. The frequently quoted observation that speed discrimination is impaired in monkeys after lesioning that includes MT/V5 (Orban et al., 1995b) simply indicates that MT/V5 is critical to speed discrimination, not that its activity level needs to be influenced by attention to speed. Finally, it is worthwhile to mention another peculiarity of speed discriminations. While all discriminations involving direction of motion engage parietal regions, this is not the case for speed discriminations (Sunaert et al., 2000a; but see Lewis et al., 2000).

Other behavioral functions of motion-sensitive regions

CONTROL OF MOVEMENTS Up to now, we have concentrated on the use of motion processing to judge motion in the outside world. Motion processing, however, has a much wider role (Nakayama, 1985). One additional function is the control of eye movements. It has been shown that optokinetic nystagmus, elicited by a rotating drum compared to fixating a stationary drum, activates hMT/V5+ but also V1 and FEF (Dieterich et al., 1998). Similarly, activation of hMT/V5+ has been observed during pursuit eye movements (Barton et al., 1996; O'Driscoll et al., 1998). In both cases, the effects of visual stimulation and of eye movements were difficult to distinguish. Finally, it has been shown that the FEF contains two subregions, the more lateral and inferior

of which is activated by pursuit rather than by saccades (Petit and Haxby, 1999; Petit et al., 1997).

It has been noted that hMT/V5+ is active when subjects view hand movements (Decety et al., 1994), even when this is compared to random motion (Bonda et al., 1996). Clearly, the role of motion regions in the control of eye and body movements needs more work, but the immobilization of the subject in the scanner, required for quality imaging, renders those studies more difficult.

KINETIC BOUNDARIES Motion processing can also be used to extract shape information from motion displays, both a two-dimensional (2D) (flat) shape that is extracted from the discontinuities in the velocity distribution and a three-dimensional (3D) shape derived from the speed gradients. Differences in motion direction produce the percept of kinetic boundaries, which are perceptually as sharp as luminance-defined boundaries. In comparing orientation discrimination using kinetic gratings rather than luminance-defined gratings, we (Orban et al., 1995a) observed an activation in a region posterior to hMT/V5+ rather than in hMT/V5+ itself. Subsequent studies (Dupont et al., 1997; Van Oostende et al., 1997) with passive subjects viewing kinetic gratings compared to luminance gratings, uniform motion (coherently translating dots), and transparent motion confirmed that this region, which we now refer to as the *kinetic occipital* (KO) region, is specifically involved in the processing of kinetic contours. It is located close to the lateral occipital sulcus, between hMT/V5+ anteriorly and hV3A and V3 posteriorly (Fig. 83.104). In this region, activation can be obtained by comparing scenes and objects to uniform textures (Malach et al., 1995), but this "lateral occipital" activation extends well beyond the KO region. Subsequent studies (Grill-Spector et al., 1998) have shown that LO is indeed activated by both luminance- and motion-defined objects. Using larger stimuli with radial kinetic contours, Reppas et al. (1997) failed to observe hMT/V5+ activation, as was the case in most of the subjects in our studies, but they did observe activation in early retinotopic regions rather than in KO. The activation of cortex representing the peripheral field observed by Reppas et al. may have been due to the fixed position of boundaries which, when compared to uniform motion, may induce differences in activity in neurons with surrounds (Jones et al., 2001). Failure to observe any activation over KO may have been due to the lack of resolvable contours in the center of the display, since KO responded to small kinetic gratings in our studies. A later study from the same laboratory using our stimuli did indeed observe KO activation along with hMT/V5+ activation (Tootell and Hadjikhani, 2001). It is worth noting that in all these studies the kinetic boundaries were stationary. This is very different from another type of

FIGURE 83.10. *A*, Location of the KO (red diamond) region compared to hMT/V5+ (green), V3A (blue), V3 dorsal (orange), and LO (yellow) diamonds. *B*, Nodes of the 3D from motion processing network on rendered brain; red, nodes from group and single-subject analysis; yellow, single-subject analysis; black circles, bilateral nodes; 1, hMT/V5+; 2, DIPSA; 3, lateral occipital sulcus; 5, POIPS; 6, TRIPS (junction transverse occipital and intraparietal sulci); 11, DIPSL; 12, VIPS; 14, lingual node; 15, fusiform node. (*A* from Van Oostende et al., 1997; *B* from Orban et al., 1999.) (See color plate 71.)

form-from-motion where the whole envelop (contour) moves. This has been shown to activate hMT/V5+ (Wang et al., 1999).

THREE-DIMENSIONAL STRUCTURE FROM MOTION Relatively little work has been done on the extraction of 3D shape from motion. Comparing 3D dynamic displays, in which 3D objects (random lines) are perceived, to 2D dynamic displays, in which flat objects are perceived, we (Orban et al., 1999) observed activation, across rigid and nonrigid conditions, of hMT/V5+, a lateral occipital region, and a series of regions along the IPS, as well as, in at least half of the subjects, lingual and fusiform cortex. Control experiments revealed that this activation was due neither to the differences in lower- and higher-order motion characteristics as such nor to attention. The activation of hMT/V5+ is in agreement with single-cell studies showing that MT neurons are selective for the direction of speed gradients, which correspond to the direction of tilt in depth (Xiao et al., 1997; see also Bradley et al., 1998). Using a different stimulus (a half-3D sphere created from random dots) and a different control (incoherently moving dots), Paradis et al. (2000) obtained quite a different result: activation of ventral lingual cortex and of a PO region. The reasons for this difference are unclear. On the one hand, their control condition is known to activate hMT/V5+ strongly; on the other hand, moving dots may not be as efficient for producing 3D motion activation as random lines (Sunaert et al., 2000a).

BIOLOGICAL MOTION A related phenomenon is biological motion, in which a set of moving dots create the impression of a moving human figure (Johansson, 1973). This stimulus compared to a scrambled control activates the STS motion region (Bonda et al., 1996; Grossman et al., 2000). This same STS region has been shown to be more strongly activated by facial movements than by simple, coherent motion of random dots (Puce et al., 1998). How specific that region is for biological motion compared to other complex motion displays is presently under investigation (Grèzes et al., 2001; Grossman and Blake, 2001; Peuskens et al., 2001b).

Conclusions

Many regions in human and monkey cortex are motion sensitive, the most prominent of these being the MT/V5 motion complex. This diversity is likely to reflect the different computations that can be performed on the retinal motion signals rather than distinct pathways for different types of motion stimuli. The different computations performed on the motion signals relate both to the many aspects of motion perception and to the many other behavioral functions of motion processing. Indeed, the most important function of the visual motion regions, like that of the visual system in general, is not to analyze the retinal motion signals,

and indirectly motion in the outside world, but to adapt the results of this analysis to the needs of other brain systems that have to make use of the visual information.

The advent of fMRI in the awake monkey holds the promise of rapid progress in understanding the function of the cerebral motion networks, which can now be studied at both the population and the single-neuron level

84 Optic Flow

WILLIAM H. WARREN

OPTIC FLOW IS THE PATTERN of motion present at the eye of a moving observer. Such flow patterns contain information about self-motion, moving objects, and the three-dimensional (3D) layout of the environment, and could potentially be exploited to control locomotion. The term was first used by Gibson (1950) to generalize Helmholtz's notion of *motion parallax* from single objects to the continuous environment surrounding the observer. He developed the concept during World War II while working on methods for pilot testing and training, after he concluded that the classical depth cues were inadequate to explain a pilot's practical ability to land an airplane. But little research was done on the subject until the 1980s, when its relevance to robot and vehicle guidance was recognized and computer animation made it amenable to study.

Optic flow is a key example of Gibson's (1979) *ecological approach* to perception and action. This functionalist approach emphasizes that the task of vision is to guide successful behavior in the natural environment, and stresses the importance of higher-order optical information that specifies complex properties of that environment and its relationship to the observer. The nervous system is viewed as providing causal support for the detection of informational variables and the modulation of action variables. Optic flow offers a case study of a higher-order variable that has been formally analyzed and empirically investigated in some detail. In what follows, we will trace optic flow through the cycle of perception and action.

The past 20 years have seen intensive research on the topic, with parallel developments in the domains of human perception, primate neurophysiology, and computational vision. This chapter aims to integrate these perspectives to address both mechanistic questions about how optic flow patterns are extracted by the visual cortex and functional questions about how this information is used to perceive self-motion and control behavior. (For related reviews see Lappe et al., 1999; Warren, 1998; regarding structure from motion, see Todd, 1995.)

The optic flow field

Optic flow is typically represented as an instantaneous velocity field in which each vector corresponds to the optical motion of a point in the environment, as in Figure 84.1A. It is immediately apparent that this flow field has a radial struc-

ture, with a *focus of expansion* (FOE) lying in the direction of self-motion. When one views the moving display, it is also apparent that the environment is a planar surface receding in depth. The radial pattern of vector directions depends solely on the observer's direction of translation, or *heading*, and is independent of the 3D structure. The magnitude of each vector, on the other hand, depends on both heading and depth and decreases quickly with distance. The radial flow pattern thus specifies one's current heading, whether or not the local FOE itself is visible. This was Gibson's fundamental hypothesis about the perception of self-motion from optic flow, and was the starting point for both psychophysical and neurophysiological experiments.

Although the velocity field description is compatible with the motion selectivity of cortical areas V1 and MT, it does not represent higher-order temporal components of the optic flow such as acceleration, or the trajectories of points over time. This appears to be a reasonable approximation, for the visual system is relatively insensitive to acceleration and relies primarily on the first-order flow to determine heading (Paolini et al., 2000; Warren et al., 1991a).

OBSERVER ROTATION However, the detection of optic flow by a moving eye is complicated by the fact that the eye can also rotate (Gibson, 1950, pp. 124–127). If the observer simply translates on a straight path, the flow pattern on the retina is radial (Fig. 84.1A). This is called the *translational component* of retinal flow, and recovery of heading from it is straightforward. A rotation of the observer, such as a pursuit eye or head movement, merely displaces the image on the retina, producing the *rotational component* of retinal flow.¹ Specifically, pitch or yaw of the eye create patterns of vertical or horizontal lamellar flow (Fig. 84.1B), and roll about the line of sight creates a pattern of rotary flow. But if the eye is simultaneously translating and rotating, which commonly occurs when one fixates a point in the world during locomotion, the retinal flow is the vector sum of these two components (Fig. 84.1C). The resulting flow field is more complex, without a qualitative feature corresponding to

¹To keep these distinctions clear, I will consistently use *translation* and *rotation* to describe observer movement and *lamellar* and *rotary* to describe flow patterns.

FIGURE 84.1. Retinal flow field for a ground plane with rotation about a diagonal axis. *a*, Translational component produced by observer translation toward the \mathbf{x} : radial flow from the heading point. *b*, Rotational component produced by eye rotation downward and to the right: lamellar flow upward and to the left. *c*, Flow field

produced by the sum of *a* and *b* due to heading toward the \mathbf{x} while rotating to track the \mathbf{O} on the ground plane. The singularity in the field is now at the fixation point. Note the motion parallax (differences in vector direction and length) at different distances across the surface.

one's heading; indeed, the singularity in the flow field is now at the fixation point.

Thus, to determine heading, the visual system must somehow analyze the translational and rotational components and recover the direction of self-motion. This has come to be known as the *rotation problem*. Fortunately, the retinal flow in a 3D scene contains sufficient information to solve this problem in principle. Specifically, *motion parallax between points at different depths corresponds to observer translation*, whereas *common lamellar motion across the visual field corresponds to observer rotation*.

THE PATH OF SELF-MOTION Even if the rotation problem can be solved, however, it only yields one's instantaneous

heading. A further problem is that the velocity field does not specify one's path over time—for instance, whether one is traveling on a straight or a curved path. In fact, the same flow field can be generated by a straight path together with eye rotation or by a circular path of self-motion. A particularly troublesome case appears in Figure 84.2, in which translation plus rotation about a vertical axis produces the same velocity field as a circular path on the ground plane. When presented with such flow displays, observers often report seeing a curved path of self-motion rather than a straight path plus rotation. How, then, can one determine whether one is traveling on a straight or a curved path? We will call this the *path problem*.

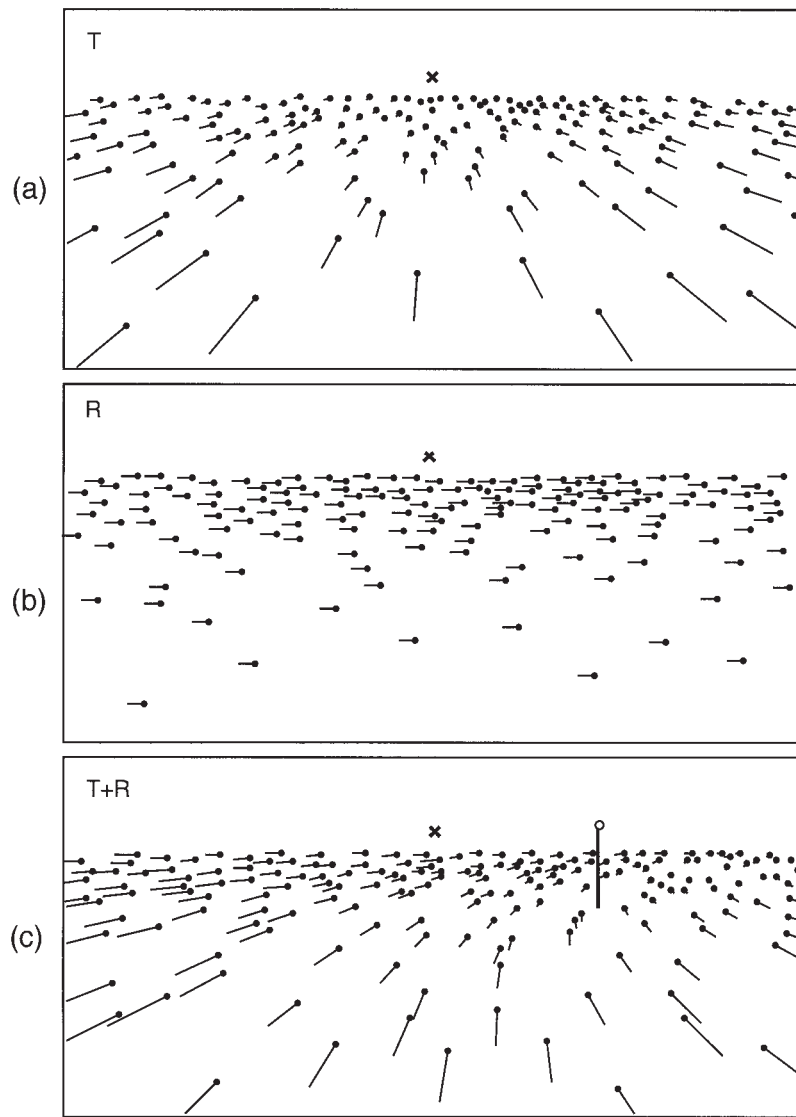

FIGURE 84.2. Retinal flow field for a ground plane with rotation about a vertical axis. *a*, *Translational component* produced by observer translation toward the **X**. *b*, *Rotational component* produced by eye rotation to the right. *c*, Flow field produced by the sum of *a* and *b* due to translating toward the **X** while rotating to track the **O** on the post, which is at eye level. An identical velocity field is generated by travel on a circular path to the right, with instantaneous heading along the tangent toward the **X**.

Before tackling these issues, let's consider the detection of optic flow patterns.

Detecting optic flow

From a mechanistic point of view, the basic question is how optic flow is detected by the visual system. It now appears that optic flow patterns are extracted in two steps, by first detecting local motion and then integrating it spatially in units sensitive to patterns of motion. This can be demonstrated psychophysically using random-dot displays in which the proportion of "signal" dots moving in a coherent flow pattern is varied relative to "noise" dots that jump to random positions on each frame. As the area of coherent motion in

the display increases, the direction of motion can be reported at a lower signal-to-noise ratio, providing evidence of spatial summation (Burr et al., 1998). Such coherence thresholds reveal summation for radial, rotary, and lamellar flow patterns over large visual angles up to 36 to 72 degrees. The data are closely predicted by an ideal integrator that pools local motion signals in units sensitive to pattern motion with large receptive fields.

FLOW-SELECTIVE UNITS IN MSTd Such findings converge with results from single-cell recordings in the dorsal region of the medial superior temporal area (MSTd) of macaque visual cortex (see Chapters 83 and 85, this volume). Saito et al. (1986) reported cells selective for expansion or con-

traction, clockwise or counterclockwise rotary flow, or directional lamellar flow, and proposed that they could be constructed by integrating input from velocity-selective cells in area MT. The MSTd cells are characterized by large receptive fields 15 to 65 degrees in diameter, distributed over the visual field to eccentricities of 50 degrees, with a higher concentration closer to the fovea (Raiguel et al., 1997). These cells exhibit stronger responses to larger stimulus patterns, consistent with spatial integration of local velocity signals (Duffy and Wurtz, 1991b; Tanaka and Saito, 1989).

About half of MSTd cells are selective for radial or rotary flow at various locations in their receptive fields, a property known as *position invariance*. Rigorous tests of position invariance ensure that a cell's response is not simply due to a coincidental match between the stimulus and a local region of the receptive field (Lagae et al., 1994). This finding is consistent with an architecture in which clusters of velocity-selective MT cells, each having a radial or rotary arrangement at different retinal loci, converge on one MSTd cell.

Such radial and rotary cells are also broadly tuned to the overall speed of motion, so that they may form a distributed representation of mean flow speed (Orban et al., 1995; Tanaka and Saito, 1989). There are also indications of sensitivity to speed gradients within the flow pattern, with some cells preferring an increasing gradient from center to periphery and others preferring a decreasing gradient (Duffy and Wurtz, 1997). However, the gradients tested were quite extreme, and MSTd cells are relatively insensitive to the fine speed gradients needed to distinguish 3D shape. Eliminating the pattern of vector directions has a far greater impact on a cell's response than eliminating the speed gradient (Tanaka et al., 1989).

MST projects to higher areas in the dorsal visual pathway, including parietal area 7a. Cells in this area are more narrowly tuned to radial, rotary, spiral, and lamellar flow patterns (Siegel and Read, 1997), indicating that the processing of optic flow continues beyond MSTd.

DECOMPOSITION OR TEMPLATES? There has been a great deal of interest in the hypothesis that specialized channels in MSTd form a basis set for the decomposition of optic flow. Koenderink and van Doorn (1975, 1981; Longuet-Higgins and Prazdny, 1980) showed that any optic flow field can be analyzed locally into lamellar motion plus three elementary components: *divergence* (div) or rate of local expansion, which together with surface slant can be used to estimate heading; *curl* or rate of local rotary flow; and *deformation* (def) or rate of shear along two orthogonal axes, which is specific to surface shape. This insight inspired a number of studies on sensitivity to radial, rotary, and lamellar flow in MSTd. However, there is often confusion between divergence and radial flow. Formally, div is a measure of the local rate of expansion, not the radial motion pattern or the FOE.

The balance of psychophysical research does not support decomposition into div, curl, def, and lamellar motion. For example, when the div is removed from an expansion pattern, resulting in radial flow with decelerating dot motion outward from the FOE, the detection thresholds for expansion in noise are unaffected (Kappers et al., 1996). Such results are contrary to a specialized divergence detector. Although the maximum of divergence can be located in visual displays (Regan and Beverly, 1982), there is no evidence that it is actually used to judge heading (Warren et al., 1988).

Similar conclusions have emerged from single-cell recordings in MSTd. When cells selective for radial or rotary flow are presented with a spiral flow pattern containing both div and curl components, the response is lower than with the equivalent radial or rotary pattern alone (Orban et al., 1992), indicating that the spiral flow is not decomposed. A majority of cells are not tuned to a single elementary component but respond to two or three individual components (Duffy and Wurtz, 1991a) or to combinations of radial and rotary flow (Graziano et al., 1994). There thus appears to be a continuum of cells selective not only for radial and rotary flow but also for intermediate spiral flow patterns.

Taken together, the evidence indicates that MSTd cells do not decompose optic flow into elementary components, but rather act as templates or filters for complex flow patterns. The advantage of a template mechanism is that, rather than simply recoding the information in the flow field, its response can signal the presence of meaningful patterns of stimulation.

Perception of translational heading

From a functional point of view, the primary question about optic flow is whether people can in fact perceive their self-motion from optic flow patterns. Cutting et al. (1992) estimated that a heading accuracy of about 1 to 3 degrees is required to guide ordinary locomotion such as running and skiing. When observers view a random-dot display of radial flow and judge whether they are heading to the left or right of a probe, they are highly accurate, with heading thresholds as low as 0.5 degree (Warren, 1976; Warren et al., 1988). Translational heading can thus be perceived from radial flow with sufficient accuracy to control locomotion.

SPATIAL INTEGRATION Heading judgments also reveal spatial integration, similar to simple coherence thresholds. In principle, a heading estimate could be obtained by triangulating just two motion vectors in a radial flow pattern. However, such a mechanism would be vulnerable to noise in local motion sensors, leading to large heading errors (Koenderink and van Doorn, 1987). Since each vector provides an estimate of the heading, pooling them allows this

redundancy in the flow pattern to reduce triangulation error. Consistent with such pooling, heading thresholds decrease as dots are added to a radial flow display, following a $1/\sqrt{N}$ rule, up to an asymptote with about 30 dots in a 40×32 degree display (Warren et al., 1988). Heading judgments are also highly robust to flow field noise created by perturbing vector directions (Warren et al., 1991a). Both of these properties are reproduced by a simple neural model of translational heading in which local motion signals are pooled in large-field radial flow templates (Hatsopoulos and Warren, 1991), consistent with the spatial integration observed in MSTd.

FLOW STRUCTURE AND SPEED GRADIENTS In line with the fact that the radial structure of flow is independent of depth, heading thresholds are similar in different 3D environments, including a ground plane, a frontal plane, and a cloud of dots. Judgments even remain accurate when speed gradients are removed by randomizing the magnitudes of local vectors, preserving their directions, but they become impossible when vector directions are randomized, preserving their magnitudes (Warren et al., 1991a). This result confirms the primary importance of the pattern of vector directions and is strikingly consistent with MSTd responses (Tanaka et al., 1989). However, heading judgments are influenced by large speed gradients. If vector magnitudes on one side of the FOE are greatly increased, perceived heading is biased toward the opposite side, and subjects report travel on a curved path (Dyre and Andersen, 1996). This is plausible because, in a homogeneous environment, the pattern of flow speeds is correlated with the path of travel. On a straight path, vectors tend to increase symmetrically from the FOE (Fig. 84.2A), whereas on a curved path, vectors on the outside of the path tend to be greater than those on the inside (Fig. 84.2C).

HEADING IN THE PRESENCE OF MOVING OBJECTS Most optic flow analyses presume a rigid scene, yet we locomote successfully in a dynamic environment with independently moving objects. A moving object can significantly alter the radial flow pattern, creating a local region of inconsistent motion. To cope with this, the visual system might segment the scene and make separate estimates of self-motion from the background flow and of object motion from the discrepant flow (Hildreth, 1992). A simpler solution would be to estimate the FOE by pooling all motion vectors, consistent with spatial integration in MSTd, although this would lead to predictable heading errors.

In fact, heading judgments exhibit just such errors when the object crosses the FOE (Warren and Saunders, 1995). If the object is moving in depth, it creates a piece of a radial flow pattern with a secondary FOE_o. This is enough to bias perceived heading *opposite* the direction of object motion by

a few degrees toward the FOE_o. Such an effect is consistent with spatial integration of all motion to locate the FOE. However, if the object is moving in the frontal plane, it creates a piece of lamellar flow, which biases perceived heading in the *same direction* as object motion (Royden and Hildreth, 1996). This effect is similar to an illusory shift in the FOE that occurs when a lamellar flow pattern is transparently superimposed on a radial flow pattern (Duffy and Wurtz, 1993) and could be a consequence of using lamellar flow to estimate observer rotation (Lappe and Duffy, 1999). On the other hand, both effects might also be explained as a result of pooling the motion parallax between the object and the background together with the local dot motions, which could be a consequence of using motion parallax to recover heading.

These results lead to the surprising conclusion that moving objects are not segmented in the course of perceiving heading, and suggest that self-motion relative to the environment may be determined by a task-specific mechanism that responds to any flow within its receptive field. MSTd cells might provide such a mechanism, for they respond selectively to a given flow pattern whether it is carried by a large field of random dots or the local boundary of a square (Geesaman and Andersen, 1996). This suggests that MSTd detects flow patterns produced by relative motion between the observer and the environment, without differentiating local object motion.

IS SELF-MOTION DETERMINED IN MSTd? Selectivity for large-field radial, rotary, and lamellar flow patterns and their combinations makes MSTd a likely candidate for extracting information about self-motion. Such global motion patterns are generated by observer translation, roll, and pitch/yaw with respect to the environment. As we have seen, there are a number of commonalities between the characteristics of MSTd cells and heading judgments: (1) large receptive fields suitable for global flow, (2) spatial integration, (3) dominance of vector directions but also (4) responses to large speed gradients, (5) speed tuning that could code the velocity of observer translation or rotation, and (6) failure to differentiate local object motion and global flow.

At first blush, the position invariance of MSTd cells appears inconsistent with this hypothesis, for heading detection by single cells implies a preferred locus for the FOE in the receptive field. However, this objection confuses response selectivity with response amplitude. Duffy and Wurtz (1995) found that 90% of expansion cells do have a preferred FOE and exhibit a graded response as the focus is shifted away from this position, which is well fit by a Gaussian tuning curve (Raiguel et al., 1997). A population of such cells is in principle sufficient for a precise distributed coding of heading direction. A second issue is that MSTd cells do not appear to form a contiguous retinotopic map of heading

direction. Nevertheless, similarly tuned cells tend to be clustered together in approximate cortical columns (Britten, 1998), which is not incompatible with distributed coding.

The most direct evidence that MSTd is involved in heading is that microstimulation in a cluster of cells biases radial flow localization judgments in the direction preferred by nearby cells in two-thirds of cases (Britten and von Wezel, 1998). The conclusion is reinforced by the finding that vestibular stimulation produced by physically translating the animal modulates the response amplitude and even the direction preference to radial flow in MSTd cells (Duffy, 1998). This strongly implies that MSTd is a site that integrates sensory stimulation about self-motion.

In humans, brain imaging studies indicate that a possible homolog of MSTd, an inferior satellite of MT/V5, is selective for radial and rotary flow patterns (Morrone et al., 2000). Using an active judgment task, Peuskens et al. (2001) found that attending to heading per se enhanced specific activity in this MT/V5 satellite, as well as in a posterior region of the dorsal intraparietal sulcus (a possible homolog of area 7a) and in dorsal premotor cortex. These results suggest that heading is detected in a pathway that is functionally similar to primate areas MSTd and 7a and directly related to motor behavior.

The rotation problem

Determining heading from radial flow during pure translation is relatively straightforward. But when the observer also makes a pursuit rotation of the eye or head, a component of lamellar flow is added, radically altering the retinal flow field (Fig. 84.2C). How, then, might the instantaneous direction of heading be determined during rotation? There are two general approaches to the rotation problem.

EXTRARETINAL THEORIES Extraretinal theories propose that internal signals about the rotational velocity of the eye and head, possibly including efferent, proprioceptive, and vestibular signals, are used to estimate the rotational component of self-motion (Banks et al., 1996; Royden et al., 1994). The rotational component can then be subtracted from the retinal flow pattern in order to recover the translational component and hence the instantaneous direction of heading. If any rotation remains in the flow pattern, it can be attributed to a curved path of self-motion. Note that the resulting heading estimate is in retinal coordinates, or an *oculocentric* frame of reference. Thus, extraretinal signals about the position of the eye and head may also be needed to transform the heading into *head-centric* and *body-centric* reference frames.

A possible mechanism for extraretinal theories is dynamic tuning of receptive fields in MSTd. During a pursuit eye movement, the preferred FOE tuning of most expansion

cells actually shifts on the retina in the direction of rotation, partially compensating for pursuit (Bradley et al., 1996). However, the mean shift is only half of what is needed to compensate fully for the eye movement. Some cells show no shift at all, but rather a modulation in the amplitude of their response, consistent with the notion of a *gain field* (Shenoy et al., 1999). On the other hand, Page and Duffy (1999) reported that a computed population vector fully compensates for pursuit rotation and might be “read out” by a higher area. Area 7a contains cells that are narrowly tuned to radial flow and show gain modulation by eye position (Read and Siegel, 1997), potentially converting an oculo-centric heading estimate into a head-centric frame.

Physiological results would thus seem to support an extraretinal approach. However, Shenoy et al. (1999) found large receptive field shifts in response to the flow pattern alone, even when the eye was stationary. This suggests that partial compensation can occur on the basis of the retinal flow itself. Moreover, these experiments only tested planar (non-3D) flow patterns, and compensation might be greater with motion parallax in the display. This leads us to the second approach.

RETINAL FLOW THEORIES Gibson argued that the optical information available in natural environments is sufficient for visual perception, and was skeptical of the need for extraretinal signals. Retinal flow theories propose that heading can be determined from the pattern of retinal flow alone (Warren and Hannon, 1990). This is theoretically possible because observer rotation simply adds a common lamellar component to the flow field, such that the differential motion due to translation remains invariant. Numerous computational models have formally shown that instantaneous heading can be recovered from the velocity field during rotation (see Hildreth and Royden, 1998; Warren, 1998, for reviews). As before, this heading estimate is in an oculo-centric frame of reference, so extraretinal position signals would seem to be necessary to convert it to head-centric and body-centric reference frames to recover one’s *absolute heading* in space. But such coordinate transformations could be bypassed by determining one’s *object-relative heading*, the direction of translation with respect to objects that are also registered in retinal coordinates. This is physiologically plausible because target position and optic flow analyses converge at least by area 7a.

There are three main classes of retinal flow theories. One class first estimates observer rotation from the lamellar flow, then subtracts the rotational component from the retinal flow pattern to recover the translational component (Perrone, 1992). In principle, the rotational component could be measured by integrating retinal velocities independently about three orthogonal axes (Koenderink, 1986). It is thus plausible that MSTd cells selective for horizontal,

vertical, and rotary flow patterns detect observer rotation; indeed, the preferred direction of pursuit eye movements in these cells is opposite the preferred direction of lamellar flow. Because the motion of more distant points is increasingly dominated by the rotational component (Fig. 84.2), depth information such as binocular disparity could also contribute to estimating the rotational component (van den Berg and Brenner, 1994).

A second class of theories determines the heading directly from motion parallax, which is also known as *relative* or *differential motion* (Longuet-Higgins and Prazdny, 1980; Rieger and Lawton, 1985). The relative motion between two points at different distances along a line of sight can be described by a difference vector. Remarkably, the set of difference vectors for a 3D scene forms a radial pattern centered on the heading. The rotation problem can thus be solved quite elegantly if there is sufficient depth structure in the environment. Moreover, relative motion and common motion could be extracted in parallel to decompose observer translation and rotation.

In theory, differential motion could be detected by an array of antagonistic center-surround units, with either circularly symmetric or bilateral center-surrounds (Royden, 1997). A majority of cells in area MT actually possesses such a bilateral opponent-motion organization, is sensitive to speed differences between center and surround, and is segregated in separate columns from classic MT velocity units (Born and Tootell, 1992; Xiao et al., 1997). Given that MT projects to MSTd, these two motion pathways could detect radial patterns of ordinary flow vectors and difference vectors in parallel, allowing the visual system to extract heading in both planar and 3D environments (Warren, 1998). Consistent with this idea, the responses of MSTd cells are enhanced by the addition of motion parallax in a radial flow display during fixation, and even more so during pursuit movements (Upadhyay et al., 2000). Thus, motion parallax signals contribute to activity in MSTd, especially during eye rotation, a finding that deserves further investigation.

A third class of theories is based on templates for the set of flow patterns produced by all possible combinations of observer translation and rotation (Lappe and Rauschecker, 1993; Perrone and Stone, 1994). The space of flow patterns is constrained by restricting rotations to pursuit of stationary points in the environment. Perrone and Stone (1998) showed that their model templates reproduce many properties of MSTd cells, including selectivity for radial, lamellar, and spiral flow, position invariance, and a preferred FOE.

PERCEIVING HEADING DURING ROTATION The psychophysical evidence on the rotation problem is mixed, and the issue remains controversial. In these experiments, displays are manipulated to dissociate retinal and extraretinal contributions. In the *actual rotation* condition, a radial flow pattern is

FIGURE 84.3. Retinal flow field for a frontal plane with rotation about a diagonal axis. The observer is translating toward the **x** while rotating to track the **O** on the plane downward and to the right. This produces a pseudo-FOE at the fixation point. Because the distance of the surface from the eye changes very little, only a little motion parallax is defined across a large display.

presented on the screen (Fig. 84.14) together with a moving fixation point that induces a pursuit eye movement; thus, extraretinal signals correspond to the rotation. In the *simulated rotation* condition, the flow pattern on the screen simulates the effect of forward translation plus a pursuit rotation (Fig. 84.1C) while the fixation point remains stationary, so extraretinal signals correspond to zero rotation. The flow pattern on the retina is thus the same in both conditions, while the extraretinal signal is manipulated. If judgments are equally accurate in the simulated and actual conditions, it implies that heading can be perceived from the retinal flow alone—even with conflicting extraretinal signals. On the other hand, if judgments are markedly less accurate in the simulated condition, it implies an extraretinal contribution.

Warren and Hannon (1988, 1990) reported that heading judgments with a random-dot ground plane (Fig. 84.1C) or 3D cloud were comparable in the two conditions, yielding heading thresholds below 1.5 degrees. On the other hand, with a frontal plane, which contains almost no motion parallax (Fig. 84.3), performance was at chance in the simulated condition but remained accurate in the actual condition. This pattern of results is consistent with retinal flow theories and confirms the importance of motion parallax. Observers even report an illusory eye rotation in the simulated condition corresponding to motion of the (stationary) fixation point away from the heading. But good performance with a frontal plane during actual eye rotation also indicates that extraretinal signals can contribute to heading judgments.

However, in these experiments the mean rotation rate over a trial was less than 1 deg/sec. At higher simulated rota-

tion rates (1 to 5 deg/sec),² heading judgments were subsequently found to be highly inaccurate (Banks et al., 1996; Royden et al., 1994). Constant errors rose to 15 degrees in the direction of simulated rotation but remained close to zero during actual eye rotation. This pattern of results is consistent with the extraretinal theory for high rotation rates. At the same time, other research supported a retinal flow theory (van den Berg, 1993; Wang and Cutting, 1999). Binocular disparity appeared to make heading judgments more reliable during simulated rotation (van den Berg and Breener, 1994), although Ehrlich et al. (1998) failed to replicate this effect.

Royden (1994) pointed out that observers frequently report a curved path of self-motion in the simulated rotation condition, and that heading errors in the direction of simulated rotation are consistent with the perception of a curved path. This might be expected from the ambiguity of the velocity field, for the same instantaneous field can be produced by a straight path plus rotation or by a circular path of self-motion with radius r (Fig. 84.2C), which are related by the ratio of translation and rotation speeds ($r = T/R$). Because extraretinal signals indicate that rotation is zero in the simulated condition, this could lead to the perception of a curved path. It is important to distinguish the concepts of *heading* and *path*, for although they are identical for a straight path, the instantaneous heading direction is tangent to a curved path. It is apparently difficult for observers to judge their instantaneous heading per se, for even when instructed to do so, they tend to report their perceived path. This leaves open the possibility that the oculocentric heading is accurately recovered during simulated rotation, but because the body-centric heading changes over time (literally drifting across the screen), subjects report a curved path.

One response to this dilemma was to try to elicit reports of instantaneous oculocentric heading by other means. When instructed to base heading judgments on the illusory motion of the fixation point, observers are more accurate than with path judgments of the same displays (van den Berg, 1996). This suggests that the visual system implicitly recovers heading during simulated rotation. When asked to judge the direction in which they are skidding while traveling on a circular path, observers' heading judgments also improve (Stone and Perrone, 1997), indicating that the instantaneous heading direction can be estimated.

Another response to the dilemma is to investigate the conditions for accurate path perception, since that is what observers tend to report.

The path problem

Observers can judge their prospective path of self-motion very accurately on a straight path, a circular path (Warren et al., 1991b), and even an elliptical path whose curvature changes with time (Kim and Turvey, 1998) from displays that simulate the view through the windshield of a turning car.³ A circular path can be parameterized by the instantaneous heading direction (\hat{T}), which is tangent to the path at the observation point, and the curvature of the path ($\kappa = 1/r$). Path curvature is equal to the rate of change in heading with respect to distance traveled ($\kappa = d\hat{T}/ds$), or with respect to time, scaled by translation speed ($\kappa = (d\hat{T}/dt)/T$). A higher-order path can be considered piecewise as a series of osculating circles, each of which is tangent to the path and defines a local path curvature.

We do not know how the visual system recovers curved paths of self-motion. The most straightforward solution is to determine the current body-centric heading and its rate of change, as just described. But contrary to this approach, path perception is quite accurate for windshield-like displays in which the body-centric heading doesn't change. This suggests a second solution: recovering the circular path directly from the flow field. A circular path on a ground plane generates a curved velocity field (Fig. 84.2C) that is stationary over time and uniquely corresponds to path curvature (for a constant eye height). The *locomotor flow line* that passes under the observer's feet specifies the oculocentric path (Lee and Lishman, 1977), and its location with respect to objects in the scene specifies the object-relative path. For higher-order paths, the flow field curvature changes over time with the path curvature. A third solution is to determine curvature from the ratio of rotation to translation speeds ($\kappa = R_p/T$), where R_p is the rotation attributed to path curvature after compensating for eye and head rotation (Ehrlich et al., 1998).

It is possible that spiral cells in MSTd code the path curvature from ground plane flow. It does not appear that extended paths are recovered by individual cells, for they respond similarly to a given flow pattern regardless of the one that precedes or follows it in a continuous sequence of stimulation (Paolini et al., 2000). Thus, single MSTd cells do not code for second-order temporal properties such as acceleration or changes in the flow pattern, but they could code the instantaneous path curvature.

RESOLVING THE PATH PROBLEM How, then, might one determine whether the path of self-motion is straight or curved from retinal flow alone? Li and Warren (2000) pro-

²A rotation rate of 1 deg/sec would be produced by fixating the ground plane 10 m ahead while walking at 1 m/sec and a 5 deg/sec rotation by fixating 4 m ahead.

³Specifically, the line of sight is along the tangent to the path, such that the instantaneous heading remains fixed on the screen.

FIGURE 84.4. Object-relative heading. *Bottom*: Sketch of retinal flow in a complex scene. The observer is heading toward **x** while rotating rightward to track **o**. *Top*: Difference vectors from motion parallax specify the instantaneous heading. The current object-relative heading is a few degrees to the left of object B. If the path is straight, the heading will remain fixed in the scene over time; if the path is curved to the right, the heading point will shift rightward with respect to object B.

posed that the visual system updates the *object-relative heading* over time. Specifically, the visual system continually extracts the instantaneous heading with respect to objects in the scene, presumably on the basis of motion parallax (Fig. 84.4). The sequence of such headings over time traces out the observer's path through the environment. For example, if the path is straight, then the heading remains fixed in the scene, whereas if the path is curved, the heading shifts relative to objects over time.

This solution to the path problem requires sufficiently dense motion parallax for an accurate heading estimate and distinct reference objects in the scene that can be tracked over time. However, most previous research used random dots, which are necessarily sparse and not easily tracked. In contrast, when displays contain dense texture-mapped scenes with distinct objects, path judgments are reasonably accurate, with mean errors below 4 degrees at simulated rotation rates up to 7 deg/sec (Cutting et al., 1997; Li and Warren, 2000). This is also the case for active steering during simulated rotation (Li and Warren, 2002). Object-relative heading thus allows the visual system to determine the path of self-motion through the environment on the basis of retinal flow, even when it is in conflict with extraretinal signals.

The mixed results for heading judgments are probably a consequence of the cue conflict for path perception in the simulated rotation condition. Extraretinal signals

indicate that eye rotation is zero; hence, the rotational component of flow must be due to a curved path. But over time, the retinal flow specifies that object-relative heading is constant, so the observer must be traveling on a straight path through the depicted environment. If the visual system makes use of both retinal and extraretinal signals, it is not surprising that the data are inconsistent. But with distinct reference objects in the display, object-relative paths tend to dominate.

ROLE OF EXTRARETINAL SIGNALS The preceding evidence indicates that both retinal flow and extraretinal signals can contribute to heading and path perception. This raises the question of how retinal and extraretinal signals are related.

Recent results suggest that an extraretinal estimate of rotation is not simply subtracted from retinal flow; rather, the two interact nonlinearly (Crowell and Andersen, 2001; van den Berg et al., 2001). When real and simulated pursuit are in the same direction, extraretinal signals exert a partial influence, but when they are in opposite directions, there is little extraretinal influence. Moreover, if the retinal flow corresponds to a 3D scene (i.e., contains motion parallax or perspective), eye rotation is determined from the common lamellar flow, providing accurate pursuit compensation. Extraretinal signals merely indicate whether or not the eye is rotating, and gate the interpretation of lamellar flow as being due to a pursuit rotation or a curved path. This is consistent with the transparent motion illusion of Duffy and Wurtz (1993), which suggests that lamellar flow is used to estimate rotation when motion parallax is present. On the other hand, if the retinal flow is planar (not 3D), the rotation rate is quantitatively estimated from extraretinal signals, but with a gain of only 50%. This is consistent with the partial compensation for eye movements observed in MSTd cells with planar flow patterns (Bradley et al., 1996).

Furthermore, it appears that extraretinal signals begin to make a contribution half a second after the onset of flow (Grigo and Lappe, 1999). With simulated rotation displays shorter than 500 msec, heading toward a large frontal plane (Fig. 84.3) is judged accurately based on minimal motion parallax, whereas with longer displays heading is perceived erroneously at the fixation point. Given that fixations normally last for 300 to 500 msec, the results imply that under ordinary conditions the visual system may rely primarily on retinal flow.

Two neural models of MSTd incorporate extraretinal influences. Beintema and van den Berg (1998) assume flow templates with Gaussian tuning for combinations of radial and lamellar flow, similar to those of Perrone and Stone (1994). The model uses an extraretinal velocity signal to modulate the gain of a subset of units tuned to the corresponding rotation rate. Lappe (1998) assumes flow templates with sigmoidal tuning and uses an extraretinal velocity signal

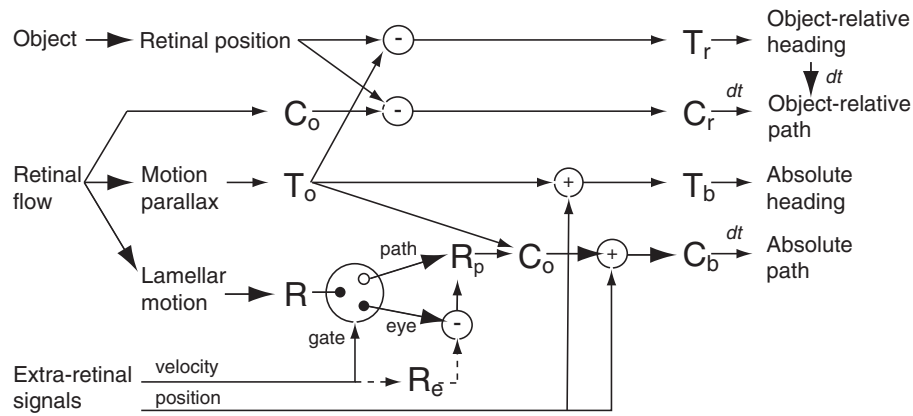

FIGURE 84.5. A heuristic summary of the flow of information in the visual system for recovering heading and path of self-motion. T , observer translation; R , total rotation; R_e , rotation attributed to eye and head pursuit; R_p , rotation attributed to path curvature; C , circular path. Subscripts o , b , and r indicate quantities in oculo-centric, body-centric, and object-relative reference frames, respectively.

to shift the tuning of individual cells so that the population response compensates fully for rotation. Given that a majority of expansion cells appear to have Gaussian-like tuning, and some evidence of gain modulation in MSTd, the first model would seem to be more plausible; on the other hand, the second model captures the observation that partial shifts in individual cells can yield full compensation in a population vector. However, both models assume that extraretinal signals provide an accurate measure of rotation rate, rather than gating the interpretation of retinal flow, and neither incorporates object-relative heading. Given the current state of knowledge, one must remain agnostic about such models, but they can help to guide further tests of MSTd.

A heuristic interpretation of the flow of information in the visual system, based on the results we have surveyed, appears in Figure 84.5. The lower part of the diagram illustrates the recovery of absolute heading and the upper part the recovery of object-relative heading. The evidence is generally consistent with the view that oculocentric translation (T_o) is determined from motion parallax and total rotation (R) from lamellar flow, either via parallel MT-MSTd pathways for differential and common motion or via compound templates in MSTd. The role of extraretinal velocity signals is largely limited to gating the total rotation R to eye and head pursuit or to path curvature (R_p), from which the instantaneous circular path (C_o) is determined. In the former case, they may provide a quantitative estimate of eye and head rotation (R_e), which is subtracted from R to estimate R_p when motion parallax is absent or fixation exceeds a half-second. To recover the absolute heading and path, extraretinal position information is needed to convert from oculocentric to body-centric frames. In contrast, objectrelative heading (T_r) is determined by merging the oculocentric heading (T_o) with an object's retinal position, bypassing the coordinate transformation. Similarly, to recover the object-relative path (C_r), the path determined from the curved flow field (C_o) is merged

with the object's position, or object-relative heading may be updated over time. Normally, the absolute and relative solutions are congruent, but during simulated rotation they are in conflict, and the object-relative solution tends to dominate.

Controlling locomotion with optic flow

We have now established that humans can perceive self-motion from optic flow under a variety of conditions and that specialized neural pathways exist to extract this information. Despite these findings, it is not a foregone conclusion that optic flow is actually used to control locomotor behavior, for other strategies are also available.

To locomote toward a stationary goal, an obvious strategy is simply to walk in the egocentric direction of the target, without using optic flow at all. For example, one could center the goal at the midline of the body and walk forward. Alternatively, optic flow from the scene could be used to steer toward a goal, using relations that are all within the visual domain. For example, one could walk so as to cancel the error between the FOE and the goal (Gibson, 1950) or between the perceived heading and the goal.

These hypotheses can be dissociated by using wedge prisms, which deflect the visual direction of the FOE from the direction of walking (Rushton et al., 1998). Thus, if participants guide walking by placing the deflecting FOE on the deflecting target, the "virtual" heading error between the FOE and the target will still be canceled, leading them to walk a straight path to the goal. But if they walk in the direction of the displaced image of the target, the virtual heading error will equal the prism deflection, and they will trace out a curved path to the goal. This is precisely what is observed with prisms in an open field, where there is minimal optic flow from fine grass texture, demonstrating that people can use egocentric direction to guide walking. On the other hand, we used a virtual reality lab to displace the FOE from

the direction of walking in a similar manner and manipulated the textured surface area in the display (Warren et al., 2001). In this setup, paths are significantly straighter and virtual heading error is reduced to near zero as optic flow and motion parallax are added to the display, consistent with an optic flow strategy. Similar improvements have also been reported with prisms as visual structure is added (Harris and Carre, 2001; Wood et al., 2000). Thus, both optic flow and egocentric direction contribute to the visual control of walking. Such redundancy provides robust locomotor control under a variety of environmental conditions.

In contrast, when walking to intercept a moving target, people rely solely on the visual direction of the target. Specifically, they walk with a direction and speed that keeps the bearing angle of the target constant, much like a sailor colliding with another boat (Fajen and Warren, 2002). This makes sense because radial flow from the whole scene is no longer informative about one's path toward a moving target.

We recently developed a dynamic theory of steering and obstacle avoidance that is based on object-relative heading with respect to goals and obstacles (Fajen et al., in press). Specifically, a goal acts like an attractor of heading, whose strength increases with its angle from the current heading and decreases with distance. In contrast, obstacles act like repellers of heading, whose strength decreases with both angle and distance. The resultant of these forces determines the current walking direction at a constant speed. The model closely fits human behavior for walking toward a goal, detouring around an obstacle, intercepting a moving target, avoiding a moving obstacle, and even predicts routes through an array of obstacles. In principle, such a model could be extended to include interactions among these basic behaviors, accounting for paths of locomotion in a complex dynamic environment.

Conclusion

We have followed optic flow through the cycle of perception and action, describing how information is generated by motion through the environment, detected to determine self-motion, and used to control behavior. Yet important questions remain unanswered. How, exactly, are translation and rotation determined from motion parallax and lamellar flow—in parallel pathways or compound templates? Can these processes account for the way moving objects bias perceived heading? How are curved paths of self-motion recovered and coded in this pathway? Precisely how do retinal and extraretinal signals interact? Are there distinct cortical representations of oculo-, head-, and body-centric heading or of object-relative heading? Is locomotion guided by perceived heading per se or by some other aspect of optic flow? And how is flow used in concert with proprioceptive and vestibular information to control locomotor behavior?

85 The Cortical Analysis of Optic Flow

CHARLES J. DUFFY

GIBSON's (1950) description of optic flow shifted visual motion studies from the perspective of a stationary observer viewing moving objects to that of a moving observer navigating past stationary objects. He emphasized that optic flow is an important cue to heading direction and the three-dimensional layout of the visual environment.

Optic flow is analyzed in the context of other self-movement cues. Proprioceptive and vestibular sensations accompany all self-movement. Kineoceptive sensation and motor signals emerge during active self-movement. These cues are always available, but people moving with their eyes open in a lighted environment are greatly guided by vision.

Visual self-movement cues include optic flow and changes in the position, size, and shape of objects. There is no absolute boundary between optic flow and object motion, but the distinction highlights their interdependence: optic flow analysis can proceed without the burden of recognizing all of the objects in the flow field, and optic flow can assist in object recognition when objects create inconsistencies in the flow field.

This review of the cortical analysis of optic flow focuses on single-neuron studies in monkeys. Relevant studies of cat and human cortex are included for comparison but are not represented comprehensively. Behavioral and psychophysical studies are treated separately in this volume (Chapter 84). Informative studies of optic flow analysis in insects and birds (e.g., Krapp and Hengstenberg, 1996; Wylie et al., 1999) are omitted because their links to cortical motion processing are beyond the scope of this chapter.

Linking dorsal association cortex and spatial vision

The visual functions of parietotemporal cortex were revealed in electrical stimulation and lesion studies (Ferrier, 1876). These findings were overshadowed by the mapping of occipital visuotopy (Holmes, 1918; Inouye, 1909). Interest in extrastriate vision was sustained by experimental evidence of visual function after striate removal (Kluver, 1936) and by clinical evidence of differential parietal and temporal involvement in spatial and object vision (Kleist, 1935).

Updated approaches revealed visual evoked electrical activity in extrastriate cortex (Doty et al., 1964) and striate projections into these areas (Cragg, 1969; Zeki, 1969). Lesion analysis put these findings in the context of dorsal extrastriate specialization for spatial perception and con-

trasted it with ventral extrastriate specialization for object identification (Ungerleider and Brody, 1977; Ungerleider and Mishkin, 1982). Lesion studies suggested that the colliculo-pulvino-parietal visual pathway (Humphrey and Weiskrantz, 1967; Schneider, 1969) supports behavioral responses to visual motion (Doty, 1973; Pasik et al., 1969). Thus, converging dorsal geniculostriate and colliculo-pulvino-parietal pathways combine to serve vision for spatial orientation (Trevathan, 1968).

The behavioral relevance of this system was seen in patients with striate lesions causing blindsight (Sanders et al., 1974) and extrastriate lesions causing spatial deficits (Botez, 1975). Posterior parietal neurons were found to combine visuosensory and visuomotor signals in a manner that suggested involvement in extrapersonal space perception (Mountcastle, 1976). These findings linked visual motion processing, visuospatial perception, and dorsal extrastriate cortex in a way that provided the theoretical foundation of efforts to understand the cortical analysis of optic flow.

Input to dorsal extrastriate areas

Converging projections from striate cortex to the posterior bank of the superior temporal sulcus (STS) are seen by anterograde fiber degeneration (Garey, 1968; Spatz et al., 1970; Zeki, 1971) and radiolabeled amino acid transport (Ungerleider and Mishkin, 1979). Combined anatomical and physiological studies identify a densely myelinated projection from striate cortex to the STS's middle temporal area (MT) with a distinct boundary at its lateral border with V4, an emphasis on movement responsiveness (Van Essen et al., 1981), and a visuotopic map of the contralateral hemifield (Maunsell and Van Essen, 1987). This projection extends from MT on the posterior bank of the STS to the floor and anterior bank of the STS, with central visual field more prominent posteriorly and peripheral vision more prominent anteriorly (Ungerleider and Desimone, 1986b).

MT is connected reciprocally to adjacent areas in the STS: dorsally to the medial superior temporal area (MST) and along the floor to the fundal superior temporal area (FST) (Desimone and Ungerleider, 1986; Kaas and Morel, 1993; Ungerleider and Desimone, 1986a). STS cortex also receives input from prestriate areas V2, V3, and V4 in the lunate sulcus (Baizer et al., 1991), projects ipsilaterally into posterior parietal cortex (Neal et al., 1988), and creates

patchy callosal connections (Van Essen et al., 1981). The STS's posterior parietal targets receive convergent somatosensory (Jones and Powell, 1970), frontal, and limbic (Mesulam et al., 1977) input. Horse-radish peroxidase (HRP) retrograde tracing and anterograde radio-amino acid tracing show reciprocal connections between the STS and the medial pulvinar thalamus. There are additional projections from pulvinar oralis, suprageniculate, and limitans thalamic nuclei to the inferior parietal lobule (IPL) (Yeterian and Pandya, 1985, 1989, 1991).

These findings support the notion of a gradient of geniculostriate and colliculopulvinar projections into dorsal extrastriate cortex. The geniculostriate projections are more prominent in the STS, whereas the colliculopulvinar projections are more prominent in posterior parietal cortex, where they are joined by a wide variety of other reciprocal connections that create a dense network of convergence (Elston and Rosa, 1997). The net effect is a highly interconnected, distributed system for visuospatial processing in this region (Felleman and Van Essen, 1991; Lewis and Van Essen, 2000).

Posterior dorsal stream motion processing

MT is the most posterior of the dorsal motion processing areas and the first motion-devoted area in that anteriorly directed stream. MT is roughly synonymous with the densely myelinated zone created by striate cortical projections to the posterior bank of the STS. Its neurons are selective for motion direction, but not object shape, with the columnar organization of direction preferences in a map of the contralateral visual field (Allman and Kaas, 1971; Dubner and Zeki, 1971; Zeki, 1974) MT has large receptive fields (~10 degrees square), with medial MT having larger peripheral receptive fields (MTp) and lateral MT having smaller foveal receptive fields (MTf) (Ungerleider and Desimone, 1986a, 1986b).

Direction, speed, and orientation tuning (Maunsell and Van Essen, 1983a) focus MT's activity on combinations of those properties (Albright et al., 1984; Mikami et al., 1986). Some MT neurons have opposite preferred directions in different parts of their receptive fields that may interact with distance cues to serve figure-ground discrimination (Allman et al., 1985; Maunsell and Van Essen, 1983b). These neurons are clustered in columns (Born and Tootell, 1992), with some showing center-surround directional organization and others showing asymmetrical arrangements (Xiao et al., 1997). Antagonistic receptive field neurons project preferentially to dorsal MST (MSTd), whereas synergistic receptive fields project preferentially to lateral MST (MSTl) and FST (Berezovskii and Born, 2000).

Anterior to MT is ventrolateral MST (MSTv or MSTl), with a mix of large and small receptive field neurons

(Komatsu and Wurtz, 1988a; Saito et al., 1986). An anterior subzone has small, peripheral receptive fields that do not include the fixation point (Tanaka et al., 1993). MSTl neurons show size- and speed-dependent direction selectivity. Small moving-dot patterns (<20 degrees in diameter) evoke one direction preference and larger patterns evoke the opposite preference. At intermediate sizes, speed modulates the responses, so opposite directions dominate at faster or slower speeds.

MSTl's size-dependent directionality is generally position invariant; size-direction relations are the same throughout the receptive field (Komatsu and Wurtz, 1988b). However, some MSTl neurons show receptive field specializations as size-dependent directional reversals requiring the occlusion of the central region. Increasing stimulus size without central occlusion suppresses all responses. Increasing size with central occlusion creates an annular stimulus that evokes reversed direction preferences (Tanaka et al., 1993). The center and the surround interact dynamically. Presenting the opposite direction in the surround enhances the center response; presenting a stationary texture in the surround causes still greater enhancement. The pronounced effect of the stationary surround distinguishes MSTl neurons from surround-sensitive neurons in MT and supports MSTl's role in object motion processing (Eifuku and Wurtz, 1998).

Object motion processing in MSTl is enhanced by sensitivity to the relative disparity of motion in the center and the surround. This is consistent with figure-ground discrimination of objects in the visual field (Eifuku and Wurtz, 1999). There are also interactions between moving objects in the receptive field, with the response to a spot moving in the preferred direction being enhanced by a second spot moving in the opposite direction and suppressed by a second spot moving in another direction. These interactions suggest an averaging of responses to paired stimuli, potentially summing signals that define an object and enhancing those responses by cues that distinguish the object from its background (Recanzone et al., 1997).

Anterior dorsal stream motion processing

Posterior parietal area 7a is at the anterior edge of the STS. The 7a neurons have very large receptive fields (>40 degrees square) (Yin and Mountcastle, 1977) that respond to moving stimuli regardless of their color, orientation, or shape (Robinson et al., 1978). These neurons are sensitive to the radial pattern of motion around the fixation point, preferring object motion either toward the fixation point or away from the fixation point. This opponent vector organization is accompanied by foveal sparing such that these neurons do not respond to stimuli at the fixation point (Motter and Mountcastle, 1981). Opponent vector neurons also possess

axial direction preferences and broadly tuned speed sensitivity, potentially enhancing their role in self-movement analysis (Motter et al., 1987; Steinmetz et al., 1987).

Neurons within the STS were first approached by the gradual encroachment of recording studies, first from the more anterior area 7a and then from the more posterior area MT. Recordings of visual tracking neurons in area 7a extended on to the anterior bank of the STS and revealed a combination of visual and pursuit responses. These neurons were activated by apparent target movement induced by the opposite direction of surround movement (the Dunker illusion) (Sakata et al., 1978). The preferred pursuit direction of these neurons was either the same as or the opposite of their preferred visual motion direction, suggesting that they receive both retinal (visual) and extraretinal (ocular proprioceptive or oculomotor corollary) input (Sakata et al., 1983).

This parietal transition zone in the STS also contains visual neurons that respond best to either object movement in the frontoparallel plane, object movement in depth (approaching or receding), or object rotation (clockwise or counterclockwise). This combination of response properties suggests that these neurons represent the complex movement of real objects in the environment (Sakata et al., 1985, 1986).

The complex direction selectivities of anterior STS neurons focused interest on MSTd. MSTd neurons were divided into three categories: 30% preferred small-object motion stimuli, 30% preferred large-field pattern motion stimuli, and the remainder were equally responsive to both (Tanaka et al., 1986). The large-field neurons were further classified by their direction selectivities: direction-selective neurons (~65%) responded best to dot patterns moving in the frontoparallel plane. Size neurons (~20%) responded best when the boundaries of an object moved to simulate symmetrical expansion or contraction. Rotation neurons (~15%) responded best when the pattern rotated clockwise or counterclockwise. The size and rotation stimuli showed position invariance, preferring the same type of movement at different locations in the receptive field such that simple local directionality did not readily explain their responses. These properties defined the DSR (direction, size, rotation) region, which is probably the same as MSTd (Saito et al., 1986).

Optic flow responses in MSTd

MSTd neuronal DSR responses were further characterized as preferring very large stimuli (circular diameters >40 degrees), with stronger responses to the movement of random-dot patterns than to small moving objects. Their direction selectivities are linked to the combination of local directionalities distributed throughout the stimuli, with less

critical contributions from the size and speed of visible elements in the pattern. These findings were the foundation of the notion that MSTd pattern motion responses were the product of an assembled pattern of MT-like local motion responses (Tanaka and Saito, 1989).

MSTd neurons were subsequently described as showing a continuum of selectivities for large (90 degrees square), planar, circular, and radial patterns of optic flow. This continuum was divided into three groups based on the statistical significance of responses to each type of optic flow: single-component neurons responded to one type, occurring as planar (10%), radial (9%), and circular (4%) neurons. Double-component neurons responded to two types with planocircular (17%) and planoradial (17%) neurons. Triple-component neurons responded to all three types as planocircularradial (29%) neurons (Duffy and Wurtz, 1991a).

These classes of neurons differed with respect to the position invariance of their optic flow selectivities, that is, their ability to maintain the same optic flow preferences when tested with small optic flow stimuli presented at different locations in the visual field. Some neurons show the same optic flow preferences throughout their receptive fields, whereas others show different optic flow preferences at different sites (Duffy and Wurtz, 1991b; Graziano et al., 1994; Lappe, 1996; Fig. 85.1). The site of greatest responsiveness to various optic flow stimuli also differed across a neuron's receptive field. One type of flow can have its greatest activation at one site, while another type of optic flow can have its greatest activation at a different site (Lagae et al., 1994).

Triple-component neurons show the least position invariance with different optic flow preferences at different locations in their receptive fields, consistent with their receptive fields being composed of local, planar directional subfields. In contrast, single-component neurons show the greatest position invariance with the same optic flow preferences at different locations in their receptive fields. Local directional subfields, or a mosaic of locally directional subfields, do not readily explain these responses. However, stronger inhibition in single-component neurons might resolve this conflict by suggesting that MSTd receptive fields are composed of partially overlapping, excitatory and inhibitory, planar directional subfields. From this perspective, stronger inhibitory subfields create the more selective single-component neurons, whereas weaker inhibitory subfields create the less selective triple-component neurons (Duffy and Wurtz, 1991b).

STS neurons were characterized by Orban et al. (1992) according to their selectivities for expansion/contraction, rotation, and deformation created by directional shear, noting that many were also responsive to planar motion. Neurons in areas MT and MST all responded to com-

FIGURE 85.1. The complex receptive field organization of an MSTd neuron. Directional responses were tested at 25 positions across the central 100 degrees square of the visual field. *A*, Color contour map of the amplitude of the strongest responses across sites showing great excitatory effects at two separate sites in the right hemifield. Insets show maps of responses to the eight different directions tested. *B*, Vector plots of net directions of responses across sites in the same neuron showing a variable pattern of rightward motion selectivity. (From Logan and Duffy, 1998.) (See color Plate 72)

binations of planar motion and optic flow. However, tests of position invariance showed that MT neurons were all position sensitive in a manner consistent with simple planar directional receptive fields, in this regard, like the triple component neurons of adjacent area MSTd (Lagae et al., 1994).

Heading selectivity in MSTd

MSTd receptive field sizes average 33 degrees square, with substantial extension into the ipsilateral hemifield and no clear relationship between receptive field size and eccentricity (Raiguel et al., 1997). These large receptive fields are well suited to the task of estimating the heading of self-movement based on the large patterns of optic flow. Evidence for heading-selective neuronal activation in MSTd was obtained by comparing responses to various optic flow stimuli. These neurons were tested with optic flow simulating nine directions of forward self-movement as outward radial motion with different foci of expansion (FOEs). MSTd neurons respond selectively to particular FOE stimuli. The mapping of heading preferences revealed three patterns: (1) preferences for peripheral FOEs in one radial segment of the visual field, (2) preferences for FOEs at or near the fixation point, and (3) preferences for FOEs around, but not at, the fixation point. These FOE preferences might detect eccentric headings, gaze-aligned headings, and subtle deviations from gaze-aligned headings, respectively (Fig. 85.2; Duffy and Wurtz, 1995).

MSTd's heading selectivity has been thought to depend on local directional subfields and to match the predictions of neural network models of MST based on MT-like small, planar-directional receptive fields. These projections provide a weighted sampling of the optic flow field arranged to implement an algorithmic solution to heading determination (Heeger and Jepson, 1990). The MST-like layer shows sigmoidal relationships between FOE location and response amplitude that might support a population representation of heading (Lappe and Rauschecker, 1993).

An alternative neural network model of MST heading detection relies on directional template matching (Perrone and Stone, 1994). In this model, MT-like direction- and speed-tuned visual field subunits create a mosaic of sensors across the visual field. A subset of these direction-speed sensors project to each MST-like neuron to impart stimulus selectivity for optic flow. This model's units showed Gaussian distributions of FOE selectivity and replicated optic flow position invariance (Perrone and Stone, 1998).

A three-layered neural network might parse observer and object motion (Zemel and Sejnowski, 1995). The model can train on optic flow to modify the weights of network connections (Zhang et al., 1993) and implement an algorithmic approach to developing optic flow-selective unit responses (Nagel, 1987). The input layer has MT-like local directional units that project to an MST-like middle layer that then projects to an output layer for heading representation. This model responds to optic flow stimuli from observer movement and to small patterns created by object motion (Zemel et al., 1998).

FIGURE 85.2. The continuum of optic flow selectivity in MSTd neurons. Icons along the top indicate the patterns of dot motion in the twelve 100 degree square optic flow stimuli used in this study. A–C, Spike density histograms of the firing rates of three neurons during the presentation of the optic flow stimuli. The vertical bar indicates the 75 spikes per second firing rate; horizontal bars indicate the 1 second stimulus duration. A, The responses of a single-

component radial neuron preferring outward radial optic flow. B, The responses of a double-component planoradial neuron preferring leftward planar and outward radial optic flow. C, The responses of a triple-component planocircularradial neuron preferring rightward planar, clockwise circular, and outward radial optic flow. (From Duffy and Wurtz, 1995.)

Another model might be derived by extending the overlapping gradient's view of MSTd's optic flow responses (Duffy and Wurtz, 1991b) to create a hierarchical processing model. Same-direction MT units covering a large part of the visual field could converge to create position-dependent triple-component neurons. Two triple-component neurons with different location and direction preferences could combine as the excitatory and inhibitory inputs to double-component planocircular or planoradial neurons with planar responses from the excitatory subfield and their radial or circular selectivity from directional inhibition. Adding another inhibitory directional input could take advantage of the orthogonality of circular and radial motion to create single-component responses.

The functional organization of MSTd

The functional organization of MSTd neuronal receptive fields has been explored by mapping direction selectivity across the central 100 degrees of the visual field. The resulting spatial-directional receptive field maps reveal several distinct subfields within each receptive field. The preferred directions of motion vary across subfields, with different subfields showing different proportions of excitatory and inhibitory responses. These subfields are differentially activated by different patterns of optic flow (Fig. 85.3; Logan and Duffy, 1998).

The columnar organization of MSTd has been examined by comparing neuronal response properties recorded along microelectrode penetration tracks. No clear visuotopic orga-

nization has been found; a clustering of similar optic flow selectivities has been observed in some penetrations but not others (Duffy and Wurtz, 1991b). Such inconsistency might reflect the different angles at which penetrations can cross MSTd along the curved path of the STS. Accounting for this curvature reveals some tendency for alternating clusters of expansion and rotation neurons across cortex (Lagae et al., 1994). Functional clustering reinforces this conclusion, with nearby neurons having more similar properties and distant neurons having dissimilar properties (Britten and van Wezel, 1998).

Radioactive isotope labeling reveals the distribution of expansion and rotation responsiveness. H^3 - and C^{14} -glucose administered during visual stimulation reveals an interdigitation of expansion-and rotation-dominated columns on the posterior bank and floor of the STS in the region of areas MT and MSTl. This interdigitation does not extend into MSTd on the anterior bank of the STS. It is not clear if the interdigitated labeling in MT and MSTl represents selective responsiveness to the patterns of optic flow or to the local planar motion components of the stimuli (Geesaman et al., 1997).

MSTd neuronal response mechanisms

Planar direction selectivity supports MSTd's responses to radial, circular, and spiral stimuli. MSTd neuronal heading specificity can be mimicked by overlapping radial or circular optic flow with planar motion stimuli. In less selective triple-component planocircularradial neurons, the underly-

FIGURE 85.3. Polar plots of directional responses of two optic flow neurons in MSTd. Arrows are scaled to the amplitude of the neuronal response to the corresponding optic flow stimulus. Responses to four planar motion stimuli are represented by the horizontal and vertical limbs, responses to inward and outward radial stimuli are represented by the oblique limbs, and responses to the clockwise and counterclockwise circular stimuli are represented by arcs. The large frames indicate the directional responses to 100 degree square

stimulus; the small frames indicate the directional responses to the set of nine 33 degree square stimuli. *A*, Responses of a position-dependent triple-component neuron that showed substantially different optic flow selectivities at different locations. *B*, Responses of a position-invariant single-component inward radial-selective neuron that showed stable optic flow selectivities at different locations. (From Duffy and Wurtz, 1991b.)

ing planar response mechanism's relationship to local motion in the pattern stimuli is obvious. In more selective single-component circular or radial neurons, the underlying planar response mechanism is obscured by inhibitory interactions (Fig. 85.4). This does not mean that MSTd encodes heading by decomposing optic flow into its planar and other components. It only shows that MSTd derives heading from the available neural mechanisms of planar directional, excitatory, and inhibitory responsiveness (Duffy and Wurtz, 1997c).

The link between planar motion and optic flow responses in MSTd is supported by the form/cue invariance of their directional selectivity. Neuronal stimulus preferences evoked by random-dot optic flow are similar to the preferences evoked by a variety of discrete visual object motion stimuli. This similarity extends to preferences for radial, circular, and spiral stimuli but not to the strength of the responses or tuning width in that spiral stimulus space (Geesaman and Andersen, 1996). These results are consistent with a fundamental role for planar motion sensitivity: spiral stimulus space reflects local planar direction around 360 degrees, and both optic flow and moving objects present planar motion.

Further characterization of object motion responses in MSTd has focused on sensitivity to the direction and the three-dimensional orientation of the rotating object. These sensitivities are position invariant across changes in the object's position in the visual field. Speed gradients in these stimuli are critical cues for deriving structure-from-motion percepts, and MSTd neuronal responses reflect sensitivity to the same stimulus parameters (Sugihara et al., 2002). These responses appear to be a consequence of MSTd's direction and speed sensitivity, and obscure the functional distinction between MSTd and MSTl with respect to the analysis of self-movement and object motion.

MSTd neuronal motion selectivity varies during prolonged stimulation. Phasic responses in the first 200 msec of stimulation are less selective than those seen thereafter, but they are not entirely nonselective, their amplitude differing substantially with different optic flow stimuli. Later, tonic responses are more selective for certain optic flow patterns, with the degree of selectivity varying across neurons and continued activity measured for up to 15 seconds of optic flow stimulation. Thus, these responses may continue to represent heading during sustained observer motion (Duffy and Wurtz, 1997b).

FIGURE 85.4. Patterns of FOF selectivity in three MSTd neurons. *A*, Arrows depict the patterns of dot motion in the 33 optic flow stimuli presented with FOFs at 10 degree intervals in the central visual field. *B–D*, Response amplitude indicated by the size of the oval at the position corresponding to that of the evoking

stimulus. *B*, A neuron that preferred down-left eccentric FOFs. *C*, A neuron that preferred central FOFs. *D*, A neuron that preferred central FOFs but not the centered FOF. (From Duffy and Wurtz, 1995.)

As with object motion responses, speed supplements direction as a primary stimulus parameter in MSTd's responses to optic flow. Speed tuning for complex optic flow patterns and planar motion most commonly show optimal responses over a range of speeds from 5 to 50 deg/sec. Slower or faster stimuli evoke successively smaller responses, with individual neurons having idiosyncratic speed-response profiles. Speed and direction tuning interact to create composite responsiveness to particular stimuli, leading to the suggestion that MSTd combines these signals to encode optic flow (Orban et al., 1995).

The notion that speed tuning might refine optic flow selectivity is supported by MSTd neuronal response sensitivity to the gradient of speeds in optic flow. Naturalistic optic flow contains speed gradients that reflect the three-dimensional layout of the visual environment, with distant features moving more slowly and nearer features more rapidly. MSTd neurons are sensitive to these speed gradients in optic

flow, so that some neurons respond best to stimuli simulating more distant features in the center of the visual field and nearer features in the periphery, as seen when moving down a corridor. Other neurons respond best to the reverse pattern, as seen when approaching an object in front of a distant background. MSTd neurons are also affected by the overlap of speed gradients that create motion parallax effects, with some neurons preferring greater simulated depth of field in optic flow stimuli (Duffy and Wurtz, 1997a).

The great majority of MSTd neurons (89%) are sensitive to binocular disparity, with 46% preferring crossed disparities (near), 38% preferring uncrossed disparities (far), and a few being tuned to a particular disparity. Almost half (40%) of the neurons reverse their preferred direction from crossed to uncrossed disparities. This does not depend on vergence angle, so that disparity relative to the plane of fixation affects responses across a range of absolute distances. This might

contribute to foreground-background discrimination as a moving observer fixates on a stationary point (Roy et al., 1992).

Together, these findings demonstrate that MSTd neurons are well suited to the analysis of optic flow during observer self-movement. Their response properties support sensitivity to the heading of self-movement, the structure of the environment, and the movement of discrete objects in the environment. Crossing the STS from MT to MSTl to MSTd, there is increasing complexity of visual motion responsiveness to both optic flow and object motion.

Temporal cortical responses to optic flow

Neuronal responses to optic flow are seen in STS cortex anterior to MSTd. About 1 cm ventroanteriorly along the STS is the superior temporal polysensory area (STP). Neurons in STP are diverse: 40% are exclusively visual, ~20% also respond to auditory stimuli, ~20% also respond to somatosensory stimuli, and ~20% respond to all three modalities. Their visual receptive fields are large, often including the entire visual field. Most are insensitive to the shape of visual stimuli, but 30%, such as neurons in inferotemporal cortex, are shape selective and prefer faces or facial features. Most are direction selective, with some preferring movement in depth and others preferring centrifugal or centripetal movement relative to the fixation point, such as opponent vector organization in posterior parietal cortex (Bruce et al., 1981).

The functional dichotomy of STP neuronal responsiveness extends to object motion responses that can be divided into two groups: those that are more selective for particular objects and those that are more selective for particular directions of movement. STP neurons that are more selective for particular objects respond only to the independent movement of those objects. The volitional movement of objects under the mechanical control of the animal's hand evokes only weak responses (Hietanen and Perrett, 1993, 1996a). The visual cues that define the object are critical to these responses, with some responding only to luminance-defined objects and other responding only to motion-defined objects (Anderson and Siegel, 1998).

STP neurons that are more selective for the direction of object motion most often prefer object motion along the cardinal axes of extrapersonal space: horizontal, vertical, and depth (Oram et al., 1993). These responses exhibit a body-independent motion discrimination such as the body-independent responses of object form neurons. That is, they respond to object movement when the animal is stationary, not when the animal is moving in a manner that might account for the apparent relative motion of the object (Hietanen and Perrett, 1996b).

The influence of relative movement on object responses suggests that these neurons might also respond to self-movement cues in optic flow. Optic flow responses are observed in 65% of STP neurons, half responding nonselectively to a variety of optic flow stimuli and half responding selectively to certain optic flow stimuli. More than half of these neurons respond to patterned optic flow but not to planar translational motion, whereas the remainder prefer planar motion. Responses to centered FOE stimuli comprise the majority of optic flow responses, although they too are accompanied mainly by translational movement responses (Anderson and Siegel, 1999).

Thus, STP neurons appear to intermix object form, object movement, and optic flow responses. The prevalence of radial expansion optic flow preferences, and the suppression of object motion responses by congruent background motion, suggest that this area may mediate the use of optic flow to detect the independent movement of animate objects seen during observer self-movement.

Parietal cortical responses to optic flow

Neuronal responses to optic flow occur in several areas in posterior parietal cortex (PPC). Neurons in the transition zone between MSTd and area 7a, in the upper-anterior bank of the STS and in the adjacent convexity cortex, have large receptive fields, often more than 90 degrees in diameter. Some respond to object movement in the frontoparallel or depth planes (Sakata et al., 1985) and others are activated object rotation, with weaker responses to planar motion or shear (the combination of two locally opposite directions). Many neurons prefer rotation in the depth plane and some respond to Ames window illusory rotation, suggesting a high-level link to object motion processing (Sakata et al., 1994).

Object motion responses in area 7a show opponent vector organization with preferences for movement toward or away from the fixation point, as well as superimposed preferences for a particular motion direction (Motter et al., 1987; Steinmetz et al., 1987). However, this radial organization of direction selectivity does not predict their responses to optic flow. Their optic flow responses can be selective for particular directions of radial or circular motion, or they can respond nonselectively to multiple directions of radial or circular motion (Siegel and Read, 1997). In addition, these neurons are sensitive to the speed of motion in optic flow, with interactions between speed tuning and optic flow selectivity, so neurons that respond to more than one type of optic flow may have different preferred speeds for those different optic flow stimuli (Phinney and Siegel, 2000).

Neurons in the floor of the intraparietal sulcus (IPS), in the ventral intraparietal area (VIP), have large visual receptive fields that respond selectively to optic flow. These

responses commonly combine radial or circular and planar motion preferences. The planar direction preferences are consistent across their receptive fields, suggesting that local planar motion preferences do not create templates favoring that neuron's preferred radial or circular stimuli (Schaafsma and Duysens, 1996).

The dorsal-medial extension of PPC includes area PEc, the caudal posterior parietal region. Neurons in this region are responsive to somatosensory stimuli and are thought to be involved in motor planning for reaching (Lacquaniti et al., 1995). They also have large visual receptive fields with robust direction selectivity. Most show simple directional responses to object motion, but some show opponent vector organization, preferring motion either inward to or outward from the fixation point. They also respond selectively to optic flow stimuli with different FOEs, with mixed object motion and optic flow responses similar to what has been observed elsewhere in the parietal lobe (Raffi et al., 2002; Squatrito et al., 2001).

In sum, optic flow responses can be elicited from a number of areas around the occipito-parieto-temporal junction. In all of these areas there is a range of preferences for optic flow stimuli simulating visual motion seen during observer self-movement. These optic flow responses are accompanied by selective responses to object motion stimuli, with both types of stimuli eliciting position invariance and speed sensitivity.

Optic flow responses in cat cortex

The dorsal association cortex of the cat includes extrastriate visual processing areas (Clare and Bishop, 1954) that receive input from the geniculo- and colliculocortical systems. The posteromedial (PMLS) and posterolateral (PLLS) regions in the lateral sulcus contain object motion direction-selective visual neurons with large binocular receptive fields that are broadly tuned for speed, with faster speeds preferred in more peripheral receptive fields. Most PLLS neurons and many PMLS neurons have receptive field locations and direction selectivities that create a preference for motion directed away from the fixation point, with fewer cells preferring motion toward the fixation point (von Grunau and Frost, 1983). Radial-selective neurons are combined with circular-selective neurons juxtaposing orthogonal directions in a potential substrate for optic flow analysis (Rauschecker et al., 1987).

Clare-Bishop neurons also respond to object motion: one-third prefer approaching stimuli, one-third prefer translational motion, and half as many prefer receding stimuli, with the remainder being nonresponsive or nonselectively responsive. These selectivities are partly attributable to size effects and partly to binocular distance cues. The posterior lateral sulcus shows more translational motion selectivity, and ante-

rior areas show more approach/recession selectivity and size effects (Toyama et al., 1990).

Anterior but not posterior lateral sulcus neurons show a centrifugal bias, as the preponderance of preferred object motion is directed away from the fixation point. In the posterior region, directional preferences are mainly orthogonal to a line from the receptive field center to the fixation point. This is consistent with a separation of radial and circular motion analysis, suggesting a large-scale organization of optic flow responses in cat lateral sulcus that has not been seen across the monkey STS (Sherk et al., 1995).

This large-scale organization may relate to differences in cortical projections, with the posterior predominance of corticotectal neurons and the anterior predominance of corticostriatal neurons. Corticotectal neurons have smaller receptive fields, slower speed preferences, centrifugal object motion, and a preference for contracting optic flow. Corticostriatal neurons have larger receptive fields, faster speed preferences, an absence of centrifugal bias, and a preference for expanding optic flow (Niida et al., 1997). Alternatively, regional differences in these responses may relate to receptive field size: posterior PMLS neurons with smaller, central receptive fields that prefer slower motion are less influenced by element size and speed gradients in optic flow. Anterior PMLS neurons with larger, peripheral receptive fields that prefer faster motion are more responsive to naturalistic element size and speed gradients (Brosseau-Lachaine et al., 2001).

The relationship between centrifugal bias and optic flow analysis was tested by raising kittens in darkness, except for timed exposure to either expanding or contracting optic flow stimuli presented either by controlled translational movement or by video simulation. Neither the direction nor the type of stimulation altered the centrifugal bias for object motion, although these animals did have more nonresponsive and nondirectional neurons. Thus, dark rearing altered the neuronal responses, but restricted exposure to certain patterns of optic flow did not change their object motion direction selectivity (Brenner and Rauschecker, 1990).

Lateral sulcus neurons prefer naturalistic optic flow stimuli as seen moving across a textured ground plane. Seventy percent of the neurons respond to optic flow, and most have stronger responses when the visual elements have distance-proportioned sizes and accelerate with simulated proximity. There is a preponderance of neurons that prefer optic flow stimuli simulating forward observer movement with mainly downward motion, compared to backward observer movement simulated with mainly upward motion (Kim et al., 1997). The optic flow selectivities of these neurons are not related to their object motion responses, with most neurons showing larger responses to the optic flow but no relationship between the preferred optic flow and object motion directions (Mulligan et al., 1997).

Radial, circular, and translational directionality differ between PMLS and PLLS. About 70% of the neurons in both areas respond to more than one type of optic flow, with an additional ~10% being unresponsive in both areas. The remaining neurons prefer one type of motion, more commonly favoring radial motion over circular or translational motion. In both areas, the nonselective neurons respond more strongly to object motion, whereas the selective neurons respond more strongly to optic flow (Li et al., 2000).

In sum, cat lateral sulcus neurons show many of the same response properties as monkey STS neurons. In cats, there may be greater regional separation of different response specializations and greater directional selectivity than in monkeys. Our understanding of optic flow analysis is still too incomplete to address the issue of whether cats and monkeys use the same neuronal processing mechanisms for optic flow analysis.

Optic flow evoked activity in human cortex

Neuroimaging has identified optic flow-responsive areas of human cerebral cortex. H_2O^{15} positron emission tomography (PET scanning) shows regional changes in cerebral blood flow (rCBF) with optic flow stimulation. Activation by random-dot motion is subtracted from that evoked by optic flow simulating observer movement across the ground plane to create a map of optic flow-selective rCBF that is matched to magnetic resonance images (MRI) used to identify cortical landmarks. Optic flow specific activation is localized to the right dorsal precuneus, right superior parietal lobule, and bilateral fusiform gyri, suggesting some right hemisphere lateralization of optic flow analysis in humans. The activated areas are roughly homologous with monkey areas V3, 7a, and TEO, respectively, but the homolog of MT/MST was not activated in this study (de Jong et al., 1994).

Complementary views of optic flow activation in humans come from combining H_2O^{15} rCBF PET imaging with blood oxygen level dependent (BOLD) functional MRI (fMRI). PET comparisons of rCBF during optic flow and stationary dot displays show multifocal optic flow specific activation in bilateral cuneus (V2, V3a), left-to-right MT/MST, bilateral dorsal IPS, bilateral dorsal premotor area, and right cerebellum. The presentation of similar stimuli during fMRI studies confirmed optic flow activation in bilateral MT/MST. Combining these data sets yielded an impression that the right MT/MST complex and the right dorsal IPS areas were most selectively responsive to optic flow (Peuskens et al., 2001).

BOLD-based fMRI has been used to distinguish between the human cortical homologs of monkey areas MT and MST. In these studies, activation of MT's purely contralateral receptive fields was compared to activation of MST's typically bilateral receptive fields. Full-field optic flow

showed activated sites selected as corresponding to human MT/MST, and also at sites in the IPS, parieto-occipital sulcus, and calcarine sulci. Contralateral hemifield stimulation activated only a more posterior segment of the MT/MST complex, with a more anterior segment activated by either contralateral or ipsilateral stimulation and considered to be homologous to monkey MSTd. Pursuit eye movements tracking a visual target also activated MT+, whereas pursuit of the imagined image of the subject's finger moving in darkness, eye movement without retinal slip, activated an anterolateral area that was considered homologous to monkey MSTl (Dukelow et al., 2001).

Neuroimaging shows the same dual roles of dorsal extrastriate cortex for optic flow and object motion analysis in humans that have been seen in single-neuron studies of monkeys. MRI shows selective activation of MT+ with intact objects versus the scrambled images of those objects. In addition, there is activation by both the movement and the shape of the objects, with synergistic interactions between movement and shape. Thus, MT+ may serve optic flow analysis and also contribute to the analysis of objects defined by movement or other cues (Kourtzi et al., 2002).

Eye position influences optic flow responses

The responses of posterior parietal visual fixation neurons are influenced by fixation position in the frontoparallel and depth planes (Sakata et al., 1980). Flashing a stationary stimulus at a constant receptive field location evokes different responses at different gaze angles. During active fixation, 61% of area 7a neurons show a substantial enhancement of visual responses at some gaze angles with no change in resting activity. In contrast, only 10% of the neurons show gaze angle effects during casual fixations between spontaneous saccades (Andersen and Mountcastle, 1983). As a result, additive models of visual gaze interactions have been rejected in favor of a multiplicative model that describes the area of preferred gaze as a gain field (Andersen and Braunstein, 1985).

Most fixation-responsive neurons (>90%) in areas 7a and MSTd show gaze angle gain fields that can be characterized as a three-dimensional function relating horizontal and vertical eye position to response amplitude. Usually, this function describes a plane, but in ~15% of the neurons this function peaks and falls off within the visual field (Squatrito and Maioli, 1996). Gaze angle interacts with visual and pursuit signals in MSTd, where 34% of pursuit neurons and 10% of visual motion neurons also show gaze angle effects (Squatrito and Maioli, 1997).

Gaze angle modulation of neuronal responses extends across cortical areas and functional response properties. Most neurons in areas MT (61%) and MST (82%) show gaze

angle effects that alter their fixation, pursuit, and visual responses without changing their direction selectivity. Gaze angle effects occur in fewer 7a (42%) and lateral intraparietal (LIP) (39%) neurons, but again, these effects alter responses to fixation, pursuit, and visual motion stimulus. In all of these areas, gaze angle response functions can be fit by a plane. In individual neurons, the same linear function could be applied to fixation, pursuit, and visual responses. This suggests that gaze angle modulates neuronal responses through a mechanism that is shared across response properties (Bremmer et al., 1997a; Bremmer et al., 1997b).

In area 7a, responses to optic flow depend on gaze angle, with more neurons (44%) showing good gaze angle fits to a linear response function than to a nonlinear function (28%). This is complicated by the observation that the function fitting the gaze angle effect often depends on the visual stimulus. This might be attributable to optic flow selectivity causing the response functions for different stimuli to extend over different ranges of response amplitude. Thus, stimulus-dependent differences in gaze angle functions might reflect nonlinear interactions with visual responses (Read and Siegel, 1997).

Pursuit eye movements and cortical motion processing

STS cortex participates in pursuit initiation and maintenance. Focal ibotenic acid lesions in MT create a retinotopic impairment of pursuit initiation in all directions, with saccade errors to moving, but not stationary, stimuli suggesting impaired motion analysis for eye movement control (Newsome et al., 1985). Foveal MT lesions cause pursuit maintenance deficits with movement toward the side of the lesion (Dursteler et al., 1987). Injections anywhere in MST cause pan-directional pursuit initiation deficits in the contralateral hemifield. Lesions in MSTl also cause directional pursuit maintenance deficits with target movement toward the side of the lesion whether the movement began in the contralateral or the ipsilateral hemifield (Dursteler and Wurtz, 1988). All of these lesion effects are temporary. The duration of MT lesion effects is proportional to the size of the lesion. When MT and most of MST is lesioned, recovery remains incomplete after 7 months, regardless of visual experience (Yamasaki and Wurtz, 1991).

Pursuit targets presented with feedback-controlled stabilization of the retinal image, or with blinking-off of the target during its movement, differentiate pursuit activation from retinal versus nonretinal input (e.g., efference copy of the movement command). Pursuit-related activity in MTf lapses during stabilization or blinking, suggesting a retinal origin. Pursuit-related activity in MSTd persists during stabilization and blinking, suggesting a nonretinal origin. Some MSTl neurons lapse and others persist. The combination of

retinal and nonretinal pursuit signals in MSTd suggests that these neurons sum retinal slip and eye velocity signals to drive pursuit (Newsome et al., 1988). Support for the retinal origin of V4 and MT pursuit responses, and for the non-retinal origin of MST pursuit responses, comes from comparisons of responses to retinal motion induced by object or ocular movement. V4 and MT neurons show the same responses to retinal motion regardless of whether it is the result of object or ocular movement, whereas MST neurons respond differently to the same retinal motion resulting from object motion or ocular movement (Erickson and Thier, 1991).

This view is supported by studies in which monkeys are trained to pursue an illusory target, the illusory intersection of incomplete lines in a regular figure. MT neurons that respond during the pursuit of a real object do not respond during pursuit of an illusory target. In contrast, some MST neurons respond during pursuit of real and illusory targets. This subset of MST pursuit-activated neurons do not stop their pursuit activity during a blinking-off of the target, seemingly identifying the subpopulation that accesses a non-retinal pursuit signal (Ilg and Thier, 1997).

MT neurons prefer the same direction during pursuit and small spot movement. MSTd neurons reverse their visual motion direction preferences with stimulus size, typically across changes in stimulus dimensions from 20×20 to 30×30 degrees. The preferred pursuit direction is the same as that preferred with small visual stimuli and the opposite of that preferred with large visual stimuli. The largest responses are evoked by slow pursuit (<20 deg/sec) across a large, patterned visual stimulus moving in the opposite direction (Komatsu and Wurtz, 1988b). This suggests that the visual responses of STS neurons that prefer small spot movement (MT and some MSTl neurons) contribute to driving pursuit, whereas the large pattern responses (MSTd and some MSTl neurons) compensate for the perceptual consequences of pursuit.

Such a mechanism may operate to differentiate visual motion from environmental movement and from saccadic eye movements. In some MST and MT neurons, saccadic eye movements evoke a reversal of the preferred direction of visual motion. Thus, the population response to saccadic visual motion sums responses to subpopulations, yielding normal and reversed direction selectivity. These two signals combine to yield no net population response. This may account for the absence of perceived visual motion during the saccades that continuously interrupt fixations (Thiele, 2002).

The contribution of retinal and nonretinal signals in the generation of MT and MST pursuit responses has been tested by cueing a monkey to choose between two alternative pursuit targets. The great majority of MT (86%) and MST (74%) neurons responded only to the visual attributes

of the stimulus, but the remaining neurons responded to the color or the direction of the target that the monkey was cued to follow. The latency to pursuit initiation is increased by the addition of the second distractor target, but MT and MST neuronal responses did not show a comparable latency shift in this task. This supported the view that MT and MST process sensory signals for pursuit target selection but do not perform that target selection (Ferrera and Lisberger, 1997).

The dynamics of pursuit target selection are linked to MT and MST neuronal responses when the initial distance between two competing targets is varied. When they are far apart, both the eye movements and the neuronal responses show initial activity reflecting winner-take-all target selection. This suggests that the separate subpopulations activated by distant targets compete through inhibitory interactions to dominate pursuit initiation, whereas subpopulations activated by nearer targets average their activity to moderate pursuit initiation (Recanzone and Wurtz, 1999). Thus, the influence of STS neuronal responses on pursuit initiation is evident only when stimulus conditions distinguish between aspects of the underlying neural organization.

Optic flow evoked ocular following

Movement of a textured visual display in the frontoparallel plane creates an optic flow pattern that evokes fast, short-latency (50 msec) eye movements (Miles et al., 1986) with characteristics that are consistent with a role in stabilizing gaze during observer movement (Schwarz et al., 1989). Ocular following may be related to short-latency vergence responses to the onset of radial optic flow (Busetini et al., 1997) that interact with the translational vestibular-ocular reflex during self-movement (Paige and Tomko, 1991). Brainstem mechanisms serving these responses (Kawano et al., 1992) may derive visual activation from STS neurons.

MST neurons show strong responses with ocular following to patterned motion stimuli, with 59% responding at least 10 msec before the eye movement. Slowing the stimulus, blurring the pattern, or lowering its spatial frequency delays both the ocular and the neuronal responses. Most (73%) of these neurons discharge during the pursuit of a small target. Blinking-off the pursuit target decreases their activity before pursuit decelerates, suggesting visual regulation of pursuit acceleration. These neurons also respond during optokinetic stimulation, so that MST's projections to the dorsolateral pontine nucleus may involve it in pursuit, ocular following, and optokinetic eye movements (Kawano et al., 1994).

The speed and size of ocular following responses are inversely proportional to viewing distance; nearer stimuli

evoke larger responses (Busetini et al., 1991; Schwarz et al., 1989). This property is shared by only some (44%) of the MST neurons that are activated by ocular following to patterned motion (Inoue et al., 1998). MST's sensitivity to binocular disparity is shared by ocular following responses. The size and speed of ocular following are greatest at slightly crossed disparities (+4 degree) in which the patterned motion stimulus is just in front of the fixation plane. Ocular following decreases more steeply for uncrossed than for crossed disparities, with parallel effects in the relationship between disparity and MST response amplitude. Furthermore, differences between the ocular following responses of individual monkeys are reflected in corresponding differences in the MST population response. Thus, there is a good correlation between disparity effects on ocular following and MST neuronal responses (Takemura et al., 2000).

As previously noted, most (~75%) MST neurons form a continuum of disparity tuning curves, with peak responses at slightly crossed disparities. The remaining neurons peak at slightly uncrossed disparities. These responses sum to relate MST's population response to the average ocular following response based on their shared disparity dependence. Population response profiles across all MST neurons are directly related to ocular following responses ($r^2 = .93$ and $.98$ in two monkeys). Excluding neurons that responded best to slightly uncrossed disparities actually worsens the population fit. Thus, it seems that all disparity-sensitive ocular following neurons contribute to the eye movement response, not just a subpopulation of neurons that individually match ocular following's disparity profile (Takemura et al., 2001).

Vestibular influences on optic flow neurons

Visual-vestibular interactions dominate perception and action during self-movement (Israel et al., 1996; Loose et al., 1996; Telford et al., 1995). These interactions may be facilitated by the anatomical proximity of dorsal extrastriate visual areas and vestibular responsive areas in somatosensory cortical area 2v (Fredrickson et al., 1966; Schwarz and Fredrickson, 1971), posterior parietal area 7a (Faugier-Grimaud and Ventre, 1989; Ventre and Faugier-Grimaud, 1988), and the nearby parietoinsular and retroinsular areas (Akbarian et al., 1994; Grusser et al., 1990; Guldin et al., 1992). These interactions are most tangible in optic flow's influence on postural stability (Asten et al., 1988), reflecting brainstem (Henn et al., 1974) and cortical mechanisms (Buttner and Buettner, 1978) and linking optic flow, postural responses, and dorsal extrastriate cortex (Duffy and Wurtz, 1996).

Half of the pursuit neurons in area 7a (51%) respond to whole-body rotation around the animal's vertical axis in darkness. Most (36%) prefer the same direction of pursuit

and body rotation, with the remainder (15%) preferring opposite directions, possibly reflecting the directionality of convergent pursuit and vestibular inputs (Kawano et al., 1984). Areas 7a and MST also respond to vestibular signals about body tilt. Neurons with direction selectivity for the rotation of a visual object are inhibited by tilting the animal's body in the opposite direction. The tilt responses occur in complete darkness but are stronger when the animal is in a light. Such visual-vestibular interactions might distinguish between visual rotation from object motion or from body movement (Sakata et al., 1994).

MSTl neurons show similar preferred directions for pursuit, visual motion, and body rotation in darkness, although the body rotation responses are smaller (Thier and Erickson, 1992). Similarly, STP neurons respond to the looming of a moving visual object viewed by a stationary monkey, but not to the forward translational movement of the animal toward the stationary object (Hietanen and Perrett, 1996a). Together, these findings suggest that dorsal extrastriate areas integrate visual motion, body movement, and eye movement signals to distinguish between retinal motion from object versus observer movement.

Visual-vestibular interactions in MSTd neurons combine signals from optic flow and translation whole-body movement. Most neurons (70%) respond to optic flow stimuli simulating translational movement in the ground plane, and 48% show significant direction selectivity. Half of those neurons (24%) also show significant direction selectivity during translational movement in darkness. When optic flow is presented during the same direction of translational movement, the responses simply reflect optic flow's directionality. When optic flow is combined with the opposite direction of translational movement, there are many more significant interaction effects. This suggests that MSTd accesses visual and vestibular signals about translational self-movement to represent heading direction (Fig. 85.5; Duffy, 1998).

Optic flow responses during pursuit

Eye movements interact with optic flow analysis in several ways: as noted above, pursuit drives optic flow neurons, and optic flow evokes pursuit-like ocular following. In addition, pursuit complicates heading estimation by altering the retinal image of optic flow (Longuet-Higgins and Prazdny, 1980). Nevertheless, people can derive heading from the visual array during pursuit (Royden et al., 1992; Stone and Perrone, 1997; Warren and Hannon, 1990). This observation caused many to abandon the notion that the FOE is an important heading cue during self-movement and motivated much of the recent work on optic flow.

MSTd neurons show different FOE preferences for optic flow presented during fixation and pursuit. This reflects changes in the retinal image of the optic flow field caused

by eye rotation as well as direct responses to pursuit. About 27% of the neurons maintain similar FOE preferences during fixation and pursuit along the neuron's preferred pursuit axis. This effect is not seen when the retinal effects of pursuit are simulated in the optic flow display while the monkey remains fixated. This suggests that some MSTd neurons have pursuit responses that compensate for the effects of pursuit on the retinal image of optic flow. Alternatively, pairs of neurons with opposite pursuit-induced changes might combine to create pursuit-invariant FOE responses (Bradley et al., 1996).

Similar changes in the retinal image of optic flow can result from head rotation. MSTd neuronal responses to optic flow show different FOE preferences during fixation, pursuit, and head rotation. The changes induced by eye and head rotation are less than would be predicted by accounting for the impact of these movements on the retinal image of the optic flow. Some MSTd neurons seem to use pursuit and vestibular signals to maintain heading selectivity during eye or head rotation in either the preferred or antipreferred pursuit direction. Other neurons might form functional pairs to combine signals that could provide a veridical representation of heading and possibly support the responses of the pursuit-rotation invariant neurons (Shenoy et al., 1999).

Heading selectivity should be invariant with all pursuit directions. Three criteria for pursuit-invariant neurons are heading selectivity during fixation, stable responses to the fixation-preferred heading during pursuit, and no other heading becoming the preferred heading during pursuit (Fig. 85.6). Only 2 of 146 MSTd neurons satisfied all three criteria for eight pursuit directions, and both had purely inhibitory responses. The failure of individual neurons to maintain pursuit-invariant heading selectivity can be contrasted with the robust pursuit invariance of the population responses. MSTd population responses derived by vector summation (Georgopoulos et al., 1986) reliably indicate heading in optic flow during fixation and pursuit. This suggests that a population representation of heading in MSTd that might correspond to the behavioral capacity to interpret optic flow during fixation and pursuit (Fig. 85.7; Page and Duffy, 1999).

Heading estimation during pursuit is complicated by the presence of visible elements at various distances along the observer's line of sight (Longuet-Higgins and Prazdny, 1980). Nevertheless, human heading estimation improves with the addition of multiple depth planes in optic flow (Royden et al., 1992; Stone and Perrone, 1997; Warren and Hannon, 1990). MSTd neurons are sensitive to the presence of speed-defined depth planes in optic flow. These stimuli are created by dividing the moving flow elements into three groups with faster, moderate, and slower speeds simulating closer, intermediate, and farther distances, respectively, as a

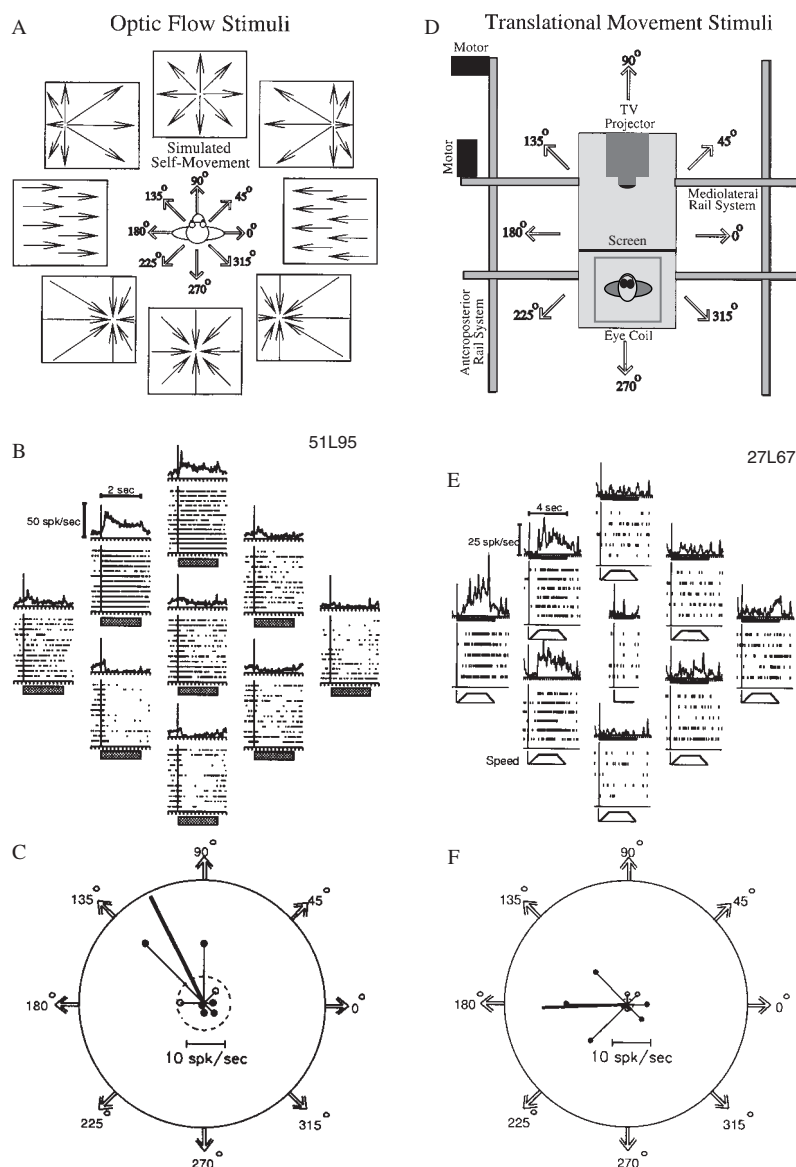

FIGURE 85.5. Responses of MSTd neurons to optic flow simulations of the self-movement scene (*left*) and to whole-body translational self-movement in darkness (*right*). *A*, Optic flow stimuli simulating movement in the ground plane. *B*, Spike density histograms and raster displays of optic flow responses. *C*, Polar plot

of responses showing a preference for leftward movement. *D*, Translational movement stimuli created by two-axis sled. *E*, Spike density histograms and raster displays of movement responses. *F*, Polar plots of responses showing a preference for leftward movement. (Modified from Duffy, 1998.)

motion parallax depth cue. Most neurons (70%) show stronger heading selectivity with multiple depth planes, with many (54%) showing a preference for a particular speed-defined depth plane. This suggests a solution to the creation of multiple FOEs during pursuit across multiple depth planes. MSTd neurons might use their speed sensitivity, possibly in conjunction with disparity sensitivity, to respond to only one of several depth planes in the stimulus. Thus, they might solve the depth planes problem by ignoring all but one depth plane, possibly with enhanced responses from the motion parallax cue (Upadhyay et al., 2000).

Interactions between pursuit effects and translational

vestibular responses alter MSTd neuronal heading selectivity for the direction of movement in the ground plane. Individual neurons show varying responses to optic flow, pursuit, and translational movement, with the vector addition of these response directionalities accounting for a large number of the responses to combined visual, pursuit, and movement stimuli. These interactions show prominent nonadditivities that cause each neuron's responses to combined stimuli to reflect idiosyncratically the contributions of optic flow, pursuit, and vestibular signals. Population vector summation again yields reliable heading responses whether the monkey maintains neutral gaze or pursues an earth-stationary

FIGURE 85.6. Responses of MSTd neurons to eight eccentric and the centered FOE outward radial stimuli during fixation and pursuit. *A*, Circles scaled to amplitude of fixation responses to the nine stimuli showing a preference for FOE no. 7. Polar limbs scaled to amplitude of responses during right-down pursuit show a centered FOE preference. *B*, *F* values from two-way analysis of variance of pursuit effects in 146 MSTd neurons showing that most had substantial changes in FOE preferences during pursuit (filled bars represent significant effects, $p < .05$). (From Page and Duffy, 1999.)

target. This supports the view that MSTd serves heading estimation by population encoding (Fig. 85.8; Page and Duffy, 2003).

Optic flow analysis, perception, and behavior

Motion perception is linked to activity in STS cortex (Pasternak and Merigan, 1994). MT and MST neuronal responses to their preferred and antipreferred motion directions are related to the monkey's motion coherence discrimination thresholds for those stimuli. The monkey's motion discrimination responses to near-threshold stimuli

FIGURE 85.7. MSTd population responses to optic flow during fixation and pursuit. *A*, Net vectors of population responses to eccentric FOE stimuli during fixation (*bold lines*) and pursuit (*fine lines*; pursuit direction indicated by the *adjacent arrow*). *B*, Results of statistical comparisons between population responses during fixation and pursuit showing few significant differences. *C*, Direction of population net vector plotted against simulated heading (*left*) and pursuit direction (*right*) showing good agreement between the population response and the simulated heading. (From Page and Duffy, 1999.)

are correlated with neuronal response amplitudes on a trial-by-trial basis. Furthermore, both behavioral and neuronal responses show similar effects of varying motion parameters (Britten et al., 1992; Celebrini and Newsome, 1994). Monkeys trained in two-alternative forced-choice tasks make direction discriminations even when the stimulus is below the monkey's contrast detection threshold. In such cases, MST and STP neurons (but not MT neurons) show greater

FIGURE 85.8. Interactions between optic flow, vestibular responses, and pursuit responses in MSTd neurons. *A*, Two oculomotor conditions are compared during eight directions of movement in light: gaze fixed straight ahead and landmark pursuit of

an earth-stationary target. *B*, Visual stimuli (*above*) and neuronal responses (*below*) showing strong responses with gaze fixed. Responses with landmark pursuit show very different directional preferences. (Modified from Page and Duffy, 2001.)

activity when the monkey chooses that neuron's preferred direction (Thiele and Hoffmann, 1996). These findings suggest a correspondence between neuronal activity in STS cortex and perceptual decisions about the direction of planar visual motion.

Microstimulation in MSTd alters the animal's ability to identify preferred versus antipreferred optic flow stimuli. Stimulation at a site where neurons prefer FOEs on one side promote the animal's responding to indicate the presence of the FOE on that side. Microstimulation interacts with pursuit effects, favoring behavioral responses indicating FOEs in the direction of the pursuit. This might reflect interference with mechanisms that compensate for pursuit effects on the retinal image of optic flow. These effects are not consistent across all sites in MSTd, but robust effects at some sites support the existence of links between neural activity in MSTd and optic flow perception (Britten and van Wezel, 1998).

MSTd neuronal activity has been linked to the illusory perception of optic flow. When a radial pattern of optic flow is superimposed on a uniform pattern of planar translational movement, the FOE appears to be displaced in the direction of the planar movement (Duffy and Wurtz, 1993). Some MSTd neurons show similar effects of overlapping radial and planar stimuli with responses that shift to match those evoked by radial stimuli with shifted FOEs (Duffy and Wurtz, 1997c). This behavior is mimicked by neurons

in a computational model of MSTd optic flow analysis, with that correspondence including the spectrum of neurons with and without the illusion-like shift of FOE tuning. This supports the notion that MSTd neuronal population encoding is linked to optic flow perception (Lappe and Duffy, 1998).

A link between optic flow analysis and the neural control of behavior is suggested by optic flow responses in motor cortex. In area 7a, 63% of the neurons respond to optic flow, with 38% responding to only one of eight stimuli. In motor cortex arm representation, only 21% of the neurons respond to optic flow but 74% are selective for only one of the eight stimuli. The large receptive fields of 7a neurons contrast with the absence of discernible receptive fields in motor cortical neurons. Motor cortical responses to optic flow might guide the interceptive targeting of arm movements to approaching objects and adjust arm movements to the kinematics of self-movement (Merchant et al., 2001).

Optic flow from natural observer movement presents a sequence of motion patterns that reflect heading changes. MSTd neurons respond to continuously changing optic flow patterns by transitioning their responses from those evoked by the preceding pattern to those evoked by the subsequent pattern (Duffy and Wurtz, 1997b). These transitions are not simple linear interpolations between responses. Rather, all MSTd neurons show nonlinear changes in activity during transitions between some stimuli. In most cases, those

changes constitute a response to the transition itself, with either linear, peaked, or stepwise response profiles. These effects are not attributable to the temporal context created by a sequence of optic flow stimuli. Rather, they reflect unique responses to particular motion patterns seen during the transition between other patterns (Paolini et al., 2000).

Stimulus sequence effects are more evident in MSTd neuronal responses to whole-body translational movement on clockwise (CW) and counterclockwise (CC) circular paths around a room while the animal views a wall-mounted light array. Heading selectivity is seen in 35% of the neurons as a preference for the same heading during CW and CC movement. Another 45% of the neurons show significant heading selectivity on only the CW or the CC path, and 20% of the neurons reverse their heading preference on the CC and CW paths (Fig. 85.9). The latter group responds at the same place in the room, regardless of the path to that place. A combination of heading sequence effects and location-specific activity contributes to these path-dependent heading responses and path-independent place responses. Thus, MSTd might contribute to spatial orientation by integrating self-movement cues over time (Froehler and Duffy, 2002). This could be achieved through interactions between MSTd and hippocampal place neurons for mapping extrapersonal space (McNaughton et al., 1994; O'Keefe and Nadel, 1978).

Behavioral influences on optic flow analysis

Behavior influences neural activity throughout extrastriate visual cortex, with evidence of spatial and nonspatial effects of attention and working memory that alter the amplitude and timing of neuronal discharges (Connor et al., 1997; Desimone, 1998; Fries et al., 2001). In humans, fMRI reveals attentional enhancement of visual responses (Kastner et al., 1998) and resting activity (Kastner et al., 1999), more so in extrastriate than striate areas. Spatial attention activates striate and extrastriate areas, with a correspondence between the spatial scale of the task and the retinotopic scale of cortical activation (Sasaki et al., 2001; Somers et al., 1999).

Spatial and featural attention influence fMRI-recorded activation in human STS cortex. The spatial allocation of attention enhances fMRI-measured activation by spot stimuli at corresponding sites in prestriate more than striate retinotopic maps. No retinotopic map is apparent in MT/MST using such stimuli, but greater activation is seen in the hemisphere that is contralateral to the attended location (Tootell et al., 1998). When subjects view visual motion during a direction or speed discrimination task, activation of MT+ is substantially greater than when they view the same stimuli passively or during a contrast or color discrimination task. When subjects direct attention to a centrally placed sta-

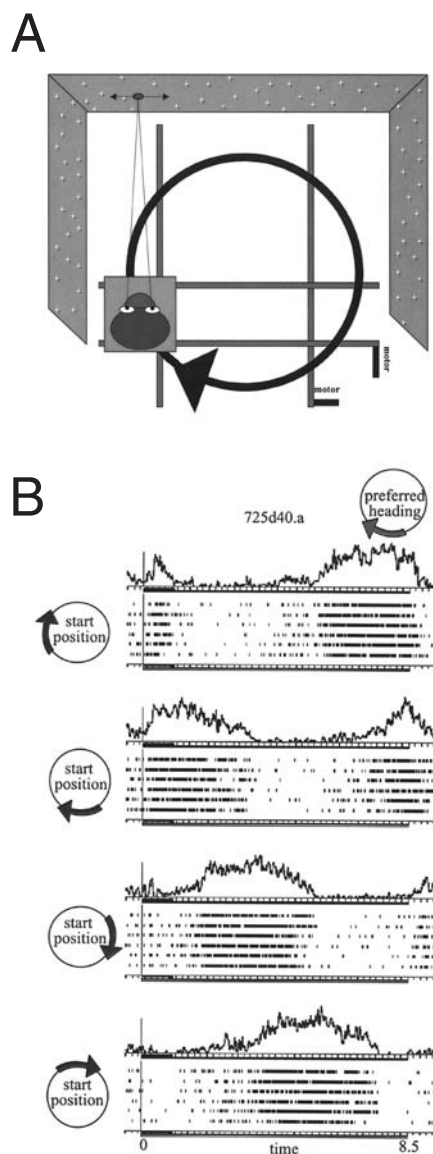

FIGURE 85.9. Responses of an MSTd neuron to movement on a circular path through the room. *A*, Sled movement was clockwise, (illustrated) or counterclockwise, with the monkey maintaining neutral gaze and head position toward the far wall (*top*). *B*, Responses of an MSTd neuron showing leftward movement selectivity that is phase-shifted across different starting positions of sled movement and is stronger during clockwise than counterclockwise movement. (Modified from Froehler and Duffy, 2000.)

tionary target rather than to the surrounding pattern of visual motion, MT+ activation is decreased (Beauchamp et al., 1997; Huk and Heeger, 2000). Even if an array of stationary dots fully overlaps the array of radial motion, MT+ activation is greater when the subject attends to the movement (O'Craven et al., 1997). Attention to tactile stimulation also decreases MT+ activation during the presentation of rotational patterns of visual motion (Haug et al., 1998).

Thus, the detailed characteristics of ongoing behavior can change the pattern of cortical activation that is created by optic flow stimuli.

Task demands influence single-neuron activity in areas MT and MST. These neurons are more responsive to spot movement in their receptive fields when attention is directed within their receptive fields, even when other nonattended stimuli are moving in the receptive field (Treue and Maunsell, 1996). Subtle changes in the task can alter the magnitude of spatial attentional effects on MT neuronal responses to moving stimuli. The spatial separation of moving stimuli and the timing of the monkey's discrimination responses play major roles in these effects (Seidemann and Newsome, 1999). Similarly, the impact of featural attention relies on task demands, with magnitude but not tuning effects on directional responses (Treue and Martinez Trujillo, 1999). Thus, spatial and featural attention can change STS neuronal responses to movement stimuli in a manner that depends on the detailed characteristics of the tasks.

Spatial attention alters the responses of area 7a neurons in a spatial match-to-sample task. The cue stimulus alters the resting activity of the neurons until the presentation of the next stimulus. Cue stimuli presented in the neuron's receptive field suppress responses to stimuli subsequently presented at that site (Constantinidis and Steinmetz, 1996; Steinmetz et al., 1994). Suppression at the cued location is not altered by presentation of the cue along with other distractor stimuli or by presentation of nonmatch stimuli prior to presentation of the match stimulus. This suggests that 7a neurons participate in the reorienting of spatial attention, preventing the entrapment of spatial attention at a cued location (Constantinidis and Steinmetz, 2001a, 2001b).

MSTd neuronal responses to optic flow are affected by spatial working memory and attention. The effects of spatial working memory are seen in a memory-guided saccade task in which optic flow is presented as a distractor between the spatial cue and the saccade. Both cue position and cue proximity effects occur: in some neurons, the absolute position of the cue enhances the optic flow responses. In other neurons, the distance from the cue to the FOE determines the cue's influence on the optic flow responses. The nonspatial effects of attention are seen when optic flow is alternately presented as the cue in an FOE-guided saccade task and as a distractor in a shape-guided saccade task (Fig. 85.10). The optic flow responses differ between the two tasks, mainly with greater response amplitude and narrower FOE tuning during trials in which optic flow guides the subsequent saccade (Dubin and Duffy, 2001). Thus, it appears that optic flow responses in MSTd are affected by both spatial working memory and attentional aspects of the task.

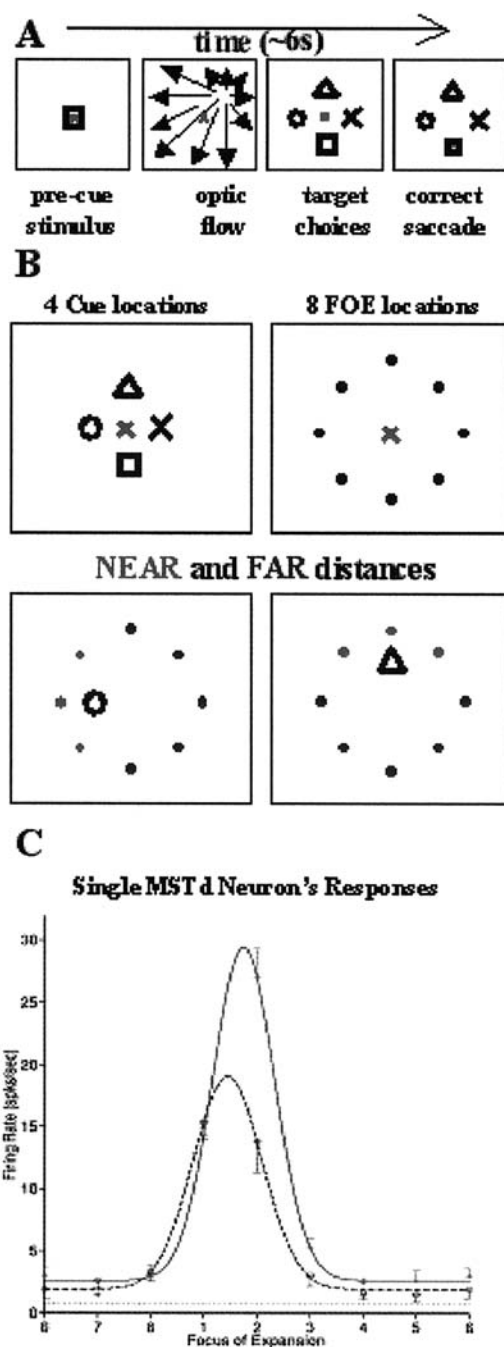

FIGURE 85.10. Spatial working memory effects on MSTd neuronal responses to optic flow. *A*, Stimulus paradigm in which a shape cue is first presented, followed by an optic flow stimulus and then by a target array that guides the monkey's response. *B*, Four shape cue locations and optic flow FOE locations presented in this study. *C*, Responses of an MST neuron to the FOE stimuli when the shape cue implied a location near (red) versus far (blue) from the FOE. Endogenous cueing of spatial working memory modifies the optic flow responses. (After Dubin and Duffy, 2001.) (See color Plate 73)

Conclusions

Optic flow analysis occurs in a distributed temporoparietal system that integrates a variety of sensory and motor signals about self-movement. Visual direction and speed are the most critical stimulus parameters contributing to optic flow-selective responses.

In the STS, area MT contains an array of local motion detectors that are modulated by motion in the surrounding segments of the visual field. Adjacent area MST supports the successive refinement of these signals across neurons to create optic flow-selective responses that are integrated with vestibular signals about self-movement. Posterior parietal and frontal motor cortices show optic flow responses that represent a heading signal that is seemingly extracted from its origins in receptive field-dependent visual mechanisms.

Oculomotor control mechanisms are intimately linked with optic flow analysis. The patterned motion of optic flow contributes to pursuit initiation and maintenance. Conversely, pursuit signals influence the neuronal population encoding of heading estimation to compensate for eye movement effects on the retinal image of optic flow. These mechanisms derive self-movement signals that are suitable to the task of guiding navigation through the visual environment. Such tasks influence optic flow analysis, potentially adapting to spatial and nonspatial aspects of ongoing behavior.

The cortical analysis of optic flow provides a model of multisensory integration and its inseparability from reciprocal interactions with behavior. Optic flow processing supports adaptation to the demands of complex environments and to the opportunities of a rich behavioral repertoire.

Acknowledgments

This chapter is dedicated to Dr. Katherine P. Duffy, whose support and tireless efforts to rewardingly occupy our sons facilitated the completion of this manuscript. This work was supported by grants from the National Eye Institute (EY10287) and the National Institute on Aging (AG17596). I am grateful to Drs. William K. Page, Marc J. Dubin, Michael T. Froehler, and David J. Logan for their comments and contributions to the work. I am grateful for the assistance of Jennifer Postle and Sherry Estes.

86 The Perceptual Organization of Depth

ROLAND FLEMING AND BARTON L. ANDERSON

THE GOAL OF DEPTH perception is to identify the spatial layout of the objects and surfaces that constitute our surroundings. One important observation about the world around us that influences the way we see depth is that physical matter is not distributed randomly, with arbitrary depths at every location. On the contrary, the environment is generally well organized: the world consists mainly of tightly bound objects in a discernible layout. This order results from countless forces and processes (such as gravity and biological growth) which tend to organize matter into objects and place those objects in certain spatial relations. The central thesis of this chapter is that our perception of depth mirrors this organization. We argue that because the world consists of objects and surfaces, our perception of depth should likewise be represented in terms of the functionally valuable units of the environment, namely, surfaces and objects. As we shall see, this has profound consequences for the processing of depth information. In particular, there is more to depth perception than simply measuring the distance from the observer of every location in the visual field. Rather, the perception of depth is the *active organization* of depth estimates into meaningful bodies. Depth constrains the formation of perceptual units, and, reciprocally, the figural relations between depth measurements allow the visual system to parse its representation of depth into ecologically valuable structures.

There are many sources of information about depth from “pictorial” perspective to motion parallax. An exhaustive review of all these sources of information is beyond the scope of this chapter (although see Bruce et al., 1996; Palmer, 1999, for introductory reviews). Instead, we discuss three key domains in which the visual system “organizes” our perception of depth into meaningful units to emphasize the intimate relationship between depth processing and perceptual unit formation.

In the first section, we discuss how the visual system infers the layout of surfaces from local measurements of depth. We will argue that local estimates of depth are ambiguous but that the geometry of occlusion critically constrains the legal interpretations. Occlusion occurs when one opaque object partly obscures the view of a more distant object, as happens frequently under normal viewing conditions. Occlusion is important because it occurs at object boundaries, and therefore the depth discontinuities introduced by occlusion

provide ideal locations for the segmentation of depth into objects. Moreover, as we will show in the first section, the geometry of occlusion causes relatively near and relatively far depths to play different roles in the inference of surface structure.

In the second section we discuss the visual representation of environmental structures that are hidden from view. If the visual system is to organize depth into meaningful bodies, it must represent whole objects, not only those fragments that happen to be visible. In order to do this, the visual system must interpolate across gaps in the image to complete its representation of form. We argue that by considering the particular environmental conditions under which structures become invisible (specifically occlusion and camouflage), we can make predictions about the mechanisms underlying visual completion. We also discuss how visual completion influences the representation of depth.

Finally, we discuss what happens when the scene contains transparent surfaces, and thus multiple depths are visible along a single line of sight. We argue that this introduces a second segmentation problem in the perceptual organization of depth. The visual system not only needs to segment “perpendicular” to the image plane, such that neighboring locations are assigned to different objects; with transparency, the visual system also has to segment depth “parallel” to the image plane by separating a single image intensity into multiple depths, a process known as *scission* (Koffka, 1935). We discuss the conditions under which the visual system performs scission and how the ordering of the surfaces in depth is resolved.

We argue that the ambiguity of local depth measurements, the representation of missing structure, and the depiction of multiple depth planes are three of the major problems faced by a visual system if it is to organize depth into surfaces and objects. Through systematic explanations of example stimuli, we discuss some of the ways in which the visual system overcomes these problems.

Interpreting local depth measurements: the contrast depth asymmetry principle

In this section we discuss how occlusion constrains the interpretation of local depth estimates. Specifically, we show that

occlusion enforces a crucial asymmetry between relatively near and relatively distant structures that can have profound implications for the representation of surface layout. Although the principles are discussed in terms of binocular disparity, the fundamental logic relates to the geometry of occlusion and therefore applies to any local estimate of depth.

BINOCULAR STEREOPSIS AND THE CORRESPONDENCE PROBLEM
 Binocular stereopsis is the most thoroughly studied source of information about depth. Binocular depth perception relies on the fact that the two eyes receive slightly different views of the same scene. Because of the horizontal parallax between the two views, a given feature in the world often projects to two slightly different locations on the two retinas (Fig. 86.1). These small differences in retinal location, or binocular *disparities*, vary systematically with distance in depth from the point of convergence and can thus be used to triangulate depth. For a thorough treatment of stereopsis, see Howard and Rogers (1995) and Chapter 87.

In order to determine the disparity of a feature in the world, the visual system must localize that feature in the two retinal images. Once it has identified matching image features, the difference in retinal location is the binocular disparity, which can then be scaled to estimate depth. The visual system must not measure the disparity between features that do not belong together; otherwise, it will derive spurious depth estimates (Fig. 86.1). Because of this, the accuracy of the matching process is critical to binocular depth perception. The problem of identifying matching features in the two eyes' views (i.e., features that originate from a common source in the world) is known as the *correspondence problem*.

If the features that the visual system localizes in the two images are very simple, such as raw intensity values (or *pixels*), then in principle there could be many distracting features that do not in reality share a common origin in the world. Under these conditions the correspondence problem would be difficult, as the visual system would have to identify the one true match from among a large number of false targets.

However, there is considerable debate about what types of image features the visual system matches to determine disparity (Jones and Malik, 1992; Julesz 1960, 1971; Marr and Poggio, 1976, 1979; Pollard et al., 1985; Prazdny, 1985; Sperling, 1970). Psychophysically, at least, it now seems unlikely that the visual system matches raw luminances. Rather, the visual system seems to match local *contrast signals*, that is, localizable variations in intensity, such as luminance edges (Anderson and Nakayama, 1994; Smallman and McKee, 1995). This seems an almost inevitable consequence of early visual processing, which

FIGURE 86.1. *a*, The two eyes converge by angle α on a point P . Therefore, by definition, P projects to the foveae of both eyes (P'). The Vieth-Müller circle is one of the geometrical horopters, that is, it traces a locus of points in space that project to equivalent retinal locations in the two eyes and thus carry no interocular disparity. Point Q is closer to the observer than P (as it falls inside the horopter). Therefore, it projects to different locations on the two retinas (Q). The difference in the locations of Q is the binocular disparity, which can be scaled by the vergence angle, α , to derive depth. *b*, When the visual field contains many points, there is a potential ambiguity concerning which image features correspond in the two eyes. Correct matches yield correct depth estimates, such as d_A . *c*, By contrast, false matches yield erroneous depth estimates. Here, the image of point A has been incorrectly matched with the image of point B , leading to an incorrect depth estimate, d^* .

maximizes sensitivity to contrasts rather than to absolute luminances (Cornsweet, 1970; Hartline, 1940; Ratliff, 1965; Wallach, 1948). By the time binocular information converges in V1, the visual field appears to be represented in terms of local measurements of oriented contrast energy (De Valois and DeValois, 1988; Hubel and Wiesel, 1962), and thus it is likely that these are the features from which disparity is computed.

If this is true, then the image features that carry disparity information are local contrasts such as luminance edges.

However, this poses a problem for the visual system, for in order to capture the functional units of the environment, the visual representation of depth should be tied to *surfaces and objects*, not to local image features. There is therefore a potential discrepancy between the image features that *carry* disparity information (i.e., local contrasts) and the perceptual structures to which depth is *assigned* (i.e., regions) in the ultimate representation of environmental layout. This discrepancy plays a critical role in the theoretical discussion that follows (see Anderson, in press).

A local image feature, such as an edge, has only one true match in the other eye's image. Therefore, the edge carries only one disparity. However, depth is ultimately assigned to the *two regions* that meet to form the edge. This results in a problem: in order to represent surface structure, the visual system must assign depth to *both sides* of an edge, even though the edge carries only one disparity (Fig. 86.2). How does the visual system infer the depths of two regions from every local disparity signal? We will show that the geometry of occlusion imposes an inviolable constraint on the interpretation of local disparity-carrying features. To anticipate, we show that the simple fact that near surfaces can occlude more distant ones, but not vice versa, has pro-

FIGURE 86.2. *a*, The image of a square occluding a diamond. A receptive field of limited extent (the ellipse) captures only local information about the scene, here a vertical luminance edge. This local information is ambiguous, as many different scenes could have resulted in the same image feature. *b*, If disparity is calculated by matching local contrasts, then the edge carries only a single disparity. However, in this case, the light and dark sides of the edge result from two distinct objects, and therefore different depths have to be assigned to the two sides of the edge.

FIGURE 86.3. Asymmetries in depth interpolation. *a*, When the left stereopair is cross-fused, the diamonds appear to float independently in front of the Kanizsa triangle, as schematized in *b*. When the disparity of the diamonds is inverted (by cross-fusing the right stereopair), the diamonds drag their background with them, creating the percept of a triangular hole, even though only the disparity of the diamonds has changed (*c*). This asymmetrical change in surface structure can be explained by the contrast depth asymmetry principle (see text). (Adapted from Takeichi et al., 1992.)

found consequences for the assignment of depth to whole regions.

ASYMMETRIES IN DEPTH: A DEMONSTRATION By way of motivation for the theoretical discussion that follows, consider Figure 86.3, which is based on a figure developed by Takeichi et al. (1992). The figure consists of a Kanizsa illusory triangle and three diamonds. When disparity places the diamonds closer to the observer than the triangle and induces (by cross-fusing the stereopair on the left of Fig. 86.3), the diamonds appear to float independently in front of the background, and the Kanizsa triangle tends to be seen as a figure in front of the circular inducers; this percept is schematized in Figure 86.3*B*. The disparities in the display can be inverted simply by swapping the left and right eyes' views, as can be seen by cross-fusing the stereopair on the right side of Figure 86.3. In this case, what was previously distant becomes near and vice versa, such that the diamonds are placed *behind* the plane of the inducers. In both versions of the display, the triangle itself carries no disparity relative to the circular inducers; only the disparity of the diamonds changes from near to far. This simple inversion leads to a change in surface representation that is more

FIGURE 86.4. A contour which carries a depth signal (e.g., disparity) is inherently ambiguous. Two main classes of world states could have given rise to the contour: the contour could have originated from a single continuous surface (e.g., a reflectance edge or cast shadow), or it could have originated from an occlusion event. In the occlusion case, the border ownership of the contour (i.e., which side is the occluder) is ambiguous. Nonetheless, in all configurations, both sides of the contour are constrained to be at least as far as the depth signal carried by the contour. This introduces a fundamental asymmetry in the role of near and far contours in determining surface structure (see text for details). (Adapted from Anderson, in press; see also Anderson et al., 2002.)

complex than a simple reversal in the depth ordering of the perceptual units (as schematized in Fig. 86.3B). When the diamonds recede, they drag their background back with them, such that the triangle appears as a *hole* through which the observer can see a white surface; the three black diamonds lie embedded in the more distant white surface. This recession of the background has a secondary effect of increasing the strength of the illusory contour (the border of the triangle).

The important observations with regard to the theory are the following. First, when the diamonds are in front, they are freely floating and separate, while when they recede, they drag the background with them. Second, when the diamonds are forward, the Kanizsa triangle tends to be seen as a figure (rather than ground), but when the diamonds are more distant, the triangle is seen as a hole. And yet all that changed in the display was the disparity of the diamonds. Why does this simple reversal in depth lead to an asymmetric change in the surface representation? Why does the disparity of the diamonds influence the appearance of the triangle? These are the asymmetries of depth to which the following discussion pertains.

FROM FEATURES TO SURFACES: INTERPRETATION OF LOCAL DISPARITY SIGNALS Let us assume that the visual system has located a luminance edge and derived a disparity, d_0 , from that edge. What possible surface configurations are consistent with the local disparity measurement? Broadly, the legal interpretations fall into two classes, as shown in

Figure 86.4. The first class consists of surface events in which both sides of the edge meet at the depth of the edge, d_0 . There are many surface events for which this is the case: reflectance edges, cast shadows, and creases in the surface, to name just three. When the feature originates from a continuous manifold, as in these cases, interpretation is simple, as both sides of the edge are assigned the same depth, d_0 .

The second class of interpretations occurs when the edge corresponds to an object boundary and therefore represents a depth discontinuity (Fig. 86.4). In this case, one side of the edge lies at the depth of the occluding object, and the other side of the edge lies at the depth of the background. Therefore, the visual system must assign *different* depths to the two sides of the edge. How can the visual system assign two depths, when it is given only one disparity, d_0 ? The answer is that it only assigns a unique depth to the occluding side. The critical insight is the following: the depth measurement acquired at an occluding edge *only specifies the depth of the occluding surface*. The visual system assigns depth d_0 to the occluding surface. All that it knows about the other side is that it must be *more distant* than the occluding surface. If the more distant surface is untextured, then it could be at any depth behind the occluder and the local image data would remain the same. By contrast, if the depth of the occluding surface varies, the disparity carried by the object boundary must also change, because the occluding surface “owns” the contour (Koffka, 1935; Nakayama et al., 1989) and is therefore responsible for the disparity associated with the edge.

Although the visual system cannot uniquely derive the depth of the occluded side (i.e., the background) from the local disparity computation, there is one critical piece of information that it does have: the occluded side is *more distant* than the occluder. There is no way for an occluding object to be more distant than the background that it occludes. If the background is brought closer than the object, then the background *becomes the occluding surface* and carries the edge with it. In this way, occlusion introduces a fundamental asymmetry into the interpretation of disparity-carrying edges: the occluded side of the edge can be at any distance greater than d_0 , but neither side can be nearer than d_0 .

We can summarize the possible depth assignments (from the occlusion and nonocclusion classes just described) in the form of a constraint on the interpretation of local disparity-carrying contrasts, termed the *contrast depth asymmetry principle* (Anderson, in press; see also Anderson et al., 2002):

Both sides of an edge must be situated at a depth that is *greater than* or *equal to* the depth carried by that edge.

Although this geometric fact is simple in form, it can have pronounced effects on the global interpretation of images when the constraint applies to all edges simultaneously. We will now run through an example to show how the principle can explain the asymmetric changes in perceived surface structure that occur when near and far disparities are inverted.

APPLICATION OF THE CONTRAST DEPTH ASYMMETRY PRINCIPLE In order to demonstrate the explanatory power of the contrast depth asymmetry principle (hereafter CDAP), we will now use it to account for the demonstration in Figure 86.3. Recall that when the diamonds carry near disparity, they float freely in front of the background, and the illusory triangle tends to be seen as figure. When the disparity is reversed, however, the diamonds drag the background back with them, and the triangle appears as a hole. This asymmetry in surface layout is depicted in Figure 86.3B.

Let us first consider the case in which the diamonds appear to float in front. The visual system has to interpret the disparity signals carried by the edges of the diamonds. The CDAP requires both sides of the diamonds' edges (i.e., the black inside and the white outside of the diamonds) to be at least as distant as the edges. Now consider the "pacman" inducers, which are more distant than the diamonds. The constraint requires both sides of these edges to be at least as distant as their edges. This means that all of the black interior of the inducers must be at least this distant and, more importantly, *all of the white background* must be at least this distant, which is farther than the disparity of the diamonds. If all of the white background is farther than the diamonds, then the edges of the diamonds must be *occluding* edges, and the black interior of the diamonds must be an occluding surface. This explains why the diamonds are seen as independent occluders, floating in front of the large white background and black inducers: the edges of the "pacman" inducers drag the white background back, leaving the diamonds floating in front.

Now consider the case in which the diamonds are more distant than the inducers. Again, the CDAP requires both the inside and the outside of the diamonds to be at least as far back as their disparity dictates. This means that both the diamonds *and their white background* are dragged back to the more distant disparity. Now consider the "pacman" inducers, which carry a relatively near disparity. Because the white background behind the diamonds has been dragged back with the diamonds, the inducers and their white background must be occluding surfaces. This means that the background immediately surrounding the diamonds must be visible through a hole in the occluding surface. The edges of this hole are the illusory contours of the Kanizsa figure. Note again: the fact that both sides of every edge have to be

at least as far as the edge leads to asymmetrical surface structures when disparities are inverted.

This is just one example that shows how the CDAP can account for asymmetrical effects of relatively near and relatively far disparities on perceived surface layout. Because the CDAP is derived from the geometry of occlusion, it can account for a very large number of displays and can be used to generate surprising new displays (Anderson, 1999, Anderson, in press).

Occlusion and camouflage: hallucinating the invisible

The central thesis of this chapter is that the visual system does not merely record depth at each location in the visual field; rather, it actively organizes its depth measurements into functionally valuable units. In the previous section, we discussed how occlusion plays a key role in this organization. In this section, we discuss how the visual system handles what is arguably the hardest problem posed by occlusion: the visual representation of structures that are hidden and are therefore completely invisible. If seeing depth is about representing the actual layout of objects in the environment, then all portions of the objects must be represented, even those that are hidden from view: hidden portions do not disappear from the environment just because they do not appear in the image. Therefore, the visual system has to go beyond local image data to construct representations of hidden structures. We will now discuss how the environmental conditions of occlusion and camouflage predict properties of the construction process.

MODAL AND AMODAL COMPLETION We will consider two major ways in which parts of the scene can become invisible. The first is simple occlusion, in which an opaque object obscures part of a more distant object. When this happens, the occluded structures of the more distant object have no corresponding features in the image, and thus the visual system must somehow "reconstruct" the missing data. The second way that viewing conditions can lead to invisible structures is through camouflage. In camouflage it is the nearer, *occluding* surface that is rendered invisible because it happens to match the color of its background. Because the boundaries of the camouflaged object do not project any contrast, they have no corresponding features in the image, and thus the nearer object is effectively invisible. Under these circumstances, the visual system must actively "hallucinate" the invisible structures. In both cases, the visual system interpolates missing data, a process known as *visual completion*. This process is important to depth perception because it is one of the means by which the visual system organizes its depth measurements into meaningful bodies. We argue that depth perception and unit

FIGURE 86.5. *a*, Modal completion. Most observers report seeing a vivid white triangle in front of three discs and a black triangular outline. The contours of the white triangle are subjectively distinct, resembling real contours, even though there is no corresponding image contrast, and hence the triangle is illusory. *b*, Amodal completion. Most observers report seeing a single continuous black shape, part of which is hidden from view by the gray occluder, even though the parts that are hidden from view are, by definition, invisible. *c*, A self-splitting object. Even though the shape is uniformly black, it tends to be seen as two forms, one in front of the other. Which form tends to complete modally, and which amodally, depends in part on the distance that must be spanned by the completion (Petter's law).

formation are intimately intertwined, for depth constrains the perceptual units that are formed, and perceptual organization influences the interpretation of local depth measurements.

The phenomenal quality of completed structures differs, depending on whether it is near (camouflaged) or far (occluded) structures that are interpolated. In the case of camouflage, the interpolation leads to a distinct impression of a contour or surface across the region of missing data. This is referred to as *modal completion* (Michotte et al., 1964/1991) because the experience is of the same phenomenal modality as ordinary visual experience. An illusory contour, for example, is crisp and subjectively similar to a real contour, as can be seen in Figure 86.5A. In contrast, the sense of completion experienced with occluded structures is less distinct. The black form in Figure 86.5B tends to be seen as a single object, part of which is hidden, rather than as two distinct objects, whose boundaries coincide with the boundary of the gray occluder. There is a compelling sense that the two visible portions of the black form belong to the same object and that that object continues in the space behind the occluder. However, this impression, although visual in origin, is not of the same phenomenal mode as normal and modal contours and is therefore referred to as

amodal completion (Michotte et al., 1964/1991). In general, the regions of the image which are visible, and lead to visual completion, are referred to as *inducers*.

THE IDENTITY HYPOTHESIS There is a vast literature on visual completion; a thorough discussion of all the issues is beyond the scope of this chapter. One important issue that is discussed in greater detail in Chapter 75 is whether visual completion occurs relatively early or late in the putative processing hierarchy. However, the perceptual organization of depth has a direct bearing on another current debate, specifically the extent to which modal and amodal completion are the consequences of a single process. This issue is intimately bound to depth perception because it determines the extent to which depth processing and perceptual organization are independent.

The debate runs roughly as follows. On the one hand, a strong claim has been made that a single mechanism is responsible for both modal and amodal completion. According to this account, perceptual organization (including visual completion) produces perceptual units, and an independent process places those units in depth. The theory states that psychological differences between modal and amodal completion result from the final depth ordering of the completed forms (Kellman and Shipley, 1991; Kellman et al., 1998; Shipley and Kellman, 1992) rather than a difference between the completion processes themselves. This is known as the *identity hypothesis*. On the other hand, the two processes could be largely independent, subject to different constraints and subserved by distinct neural mechanisms. A strong form of this *dual mechanism* hypothesis would be that the two processes are fundamentally different in nature—for example, that modal completion is largely data driven, while amodal completion is essentially *cognitive*. To anticipate, although we do not subscribe to the strongest form of the dual mechanism hypothesis, we will provide evidence that modal and amodal completion follow different constraints and argue that they are subserved by distinct neural processes. Central to the arguments that we present are the geometric and photometric conditions under which occlusion and camouflage actually occur in the environment.

The principal evidence for the identity hypothesis has been that subjects perform similarly with modally and amodally completed figures in a variety of tasks. In one task, Shipley and Kellman (1992) varied the spatial alignment of the inducing elements in both modally and amodally completed squares. Such misalignment is known to weaken the sense of completion, as the completed boundary is forced to undergo an inflection. Subjects were asked to rate the subjective strength of visual completion as a function of the degree of misalignment for modal and amodal versions of the display. Shipley and Kellman (1992) found that ratings

declined at the same rate as a function of misalignment for both modal and amodal figures. This has been interpreted as evidence that a single mechanism is responsible for both forms of completion.

Using a more rigorous method, Ringach and Shapley (1996) performed a shape discrimination task with modal and amodal versions of a Kanizsa figure. By rotating the inducing elements, the vertical contours of the completed square can be made to bow out (creating a “Fat” Kanizsa) or curve in (creating a “Thin” Kanizsa). Subjects were asked to discriminate between Fat and Thin versions of the display while the angle through which the inducers were rotated was varied. Ringach and Shapley found that discrimination performance as a function of rotation was nearly identical for modal and amodal versions of the display, a finding which is consistent with the identity hypothesis.

One problem with this type of evidence is that it relies on negative results, that is, a failure to detect a difference, which could be due to the method rather than to a fundamental property of the system being studied. If positive evidence could be provided that modal and amodal completion are subject to different constraints, or result in different perceptual units, then the identity hypothesis would no longer be tenable.

There are two major reasons for believing that modal and amodal completion should be subject to different constraints, both of which are related to the environmental conditions under which occlusion and camouflage occur. First, occlusion occurs over greater distances across images because it only requires that one object be in front of another. Camouflage, on the other hand, requires a perfect match in color between the near surface and its background, and thus occurs less frequently in general. This difference is reflected in a constraint on the image distances over which modal and amodal completion occur, which was first documented by Petter (1956). Petter used a class of stimuli now known as *spontaneously splitting objects* (SSOs), which consist of a single homogeneously colored shape, such as the one shown in Figure 86.5C, that tends to be interpreted as two independent shapes, one behind the other. Which object is seen in front tends to oscillate with prolonged viewing. However, which shape is seen in front first, and which tends to be seen in front for a greater proportion of the time, can be predicted rather well from the lengths of the contours that must be interpolated. Petter’s rule states that longer contours tend to be completed amodally, while shorter contours tend to be completed modally. Thus, which figure is seen in front can be predicted from the length of the contours that must be completed. If the two types of completion are subject to different constraints on the distances over which they occur, this opens the possibility that they are subserved by different mechanisms.

A second reason for believing that modal and amodal completion are subject to different constraints relates to the color conditions that are required for occlusion and camouflage to occur. Again, occlusion can happen between objects of any color. The reflectance of the near object is unrelated to the fact that it hides the more distant one from view. This suggests that amodal completion should not be sensitive to the luminance relations between the image regions involved. Camouflage, by contrast, requires a perfect match in luminance between the near and far surfaces. This implies that modal completion *should* be sensitive to the luminance relations between the image regions involved.

Recent experimental work has shown that this luminance sensitivity can lead to large differences between modal and amodal displays (Anderson et al., 2002). Anderson et al. created displays consisting of two vertically separated circles filled with light and dark stripes, as shown in Figure 86.6. The binocular disparity of the circles was kept constant, but the disparity of the light-dark contours inside the circles was altered to place the stripes behind or in front of the circular boundaries. When the stripes were further than the circles, the top and bottom stripes tended to complete amodally to form a single continuous dark and light surface, which appeared to be visible through two circular holes, as schematized in Figure 86.6D. This percept occurred irrespective of the luminance of the region surrounding the circles.

By contrast, when the disparity placed the contours *in front* of the circles, the dark and light stripes separated into different depth planes. The way in which the stripes separated from one another depended on the luminance of the surround. When the surround was the same color as the light stripes, the light stripes appeared to float in front and completed modally across the gap between the two circles. In this condition, the dark stripes completed amodally underneath the light stripes to form complete circles. This led to an impression of light vertical stripes in front of dark circles, as schematized in Figure 86.6E. However, when the surround was the same luminance as the dark stripes, the percept inverted, such that the dark stripes appeared to float in front of light discs. This demonstrates a fundamental dependence on luminance that was not present in the amodal version of the display. Furthermore, if the surround was an intermediate gray, then the display was not consistent with camouflage, as neither the light nor the dark stripes perfectly matched the luminance of the background. Under these conditions, there was no modal completion across the gap, and the percept was difficult to interpret. This demonstrates that modal completion is sensitive to luminance relations, while amodal completion is not.

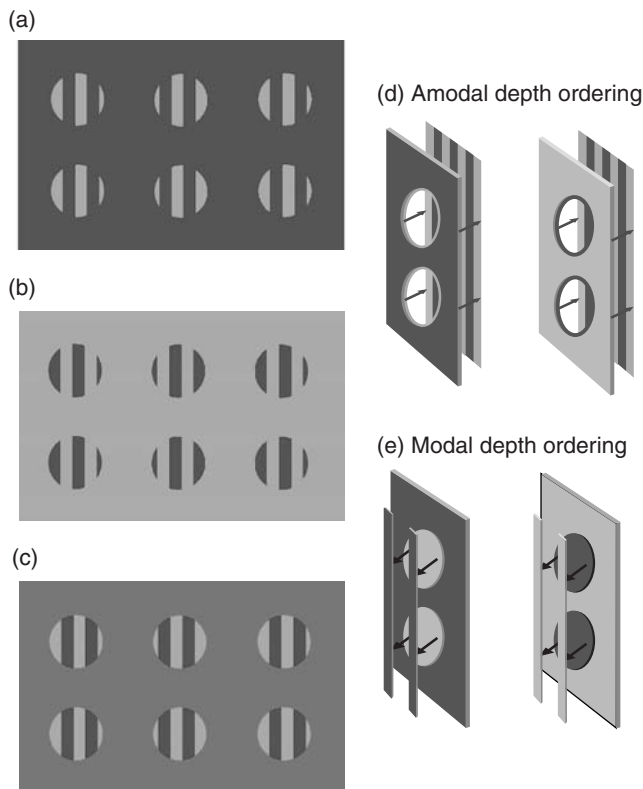

FIGURE 86.6. Demonstration of dependence of modal completion on surround luminance. When the left stereopairs of *a*, *b*, and *c* are cross-fused, the stripes tend to complete amodally between the gaps between the circular hole, creating the impression of a single striped surface (like wallpaper) viewed through two apertures, as depicted in *d*. This occurs irrespective of the luminance of the surround. However, when the right stereopairs are cross-fused, thus inverting the disparity, only two stripes appear to complete modally, and which stripes complete depends critically on the surround luminance, as depicted in *e*. When the surround is dark, as in *a*, the dark stripes complete modally; when the surround is light, as in *b*, the light stripes complete modally; and when the surround is intermediate, no completion is visible. This demonstrates that modal completion is luminance dependent, while amodal completion is not. (Adapted from Anderson et al., 2002.)

Anderson et al. showed that this luminance sensitivity could affect performance on basic visual tasks such as vernier acuity. The stripes in the top and bottom circles can be horizontally offset (i.e., misaligned slightly) without destroying the sense of completion. Subjects were asked to report in which of two displays the contours were slightly misaligned. Both modal and amodal completion facilitate performance in this task. However, in the amodal case, performance was unaffected by the luminance of the surround, while in the modal case, performance was much worse when the luminance of the surround was an intermediate gray (the condition in which the stripes do not complete across the gap). Thus, modal and amodal com-

pletion are subject to different constraints, both on the distance over which they occur and on the luminance conditions that are required to induce them. This positive evidence for a difference between modal and amodal completion uses essentially the same types of task as the negative evidence that had previously been used to support the identity hypothesis.

VISUAL COMPLETION AND THE PERCEPTUAL ORGANIZATION OF DEPTH The geometric and photometric differences between modal and amodal completion are derived directly from the environmental conditions of occlusion and camouflage. Because occlusion and camouflage occur under different circumstances, they have different consequences for the organization of depth into meaningful bodies. In fact, the differences can be exploited to generate stimuli in which modal and amodal completion lead to different shapes. This is important, as it shows that unit formation is intimately bound to the placement of structures in depth.

The greater “promiscuity” of amodal completion is the key in the generation of these displays. Figure 86.7 is a recently developed stereoscopic variant of the Kanizsa configuration in which the inducing elements are rotated outward (Anderson et al., 2002). When the straight segments (the “mouths” of the “pacmen”) are placed in front of the circular portions of the inducers, the impression is of five independent illusory fragments that float in front of five black discs on a white background. However, when the two eyes’ views are interchanged, and thus the straight contours are placed *behind* the circular segments, the impression is rather dramatically altered. With the disparity inverted, the impression is of a single amodally completed, irregularly shaped, black figure on a white background, which is visible through five holes in a white surface (these percepts are schematized in Figs. 86.7*B* and 86.7*C*). Thus, the former case consists of a total of 11 surfaces (5 fragments + 5 discs + white background), while the latter case consists of 3 (1 white surface with 5 holes + 1 black shape + white background). Clearly, the placement in depth has a considerable effect on what perceptual units are formed.

Anderson et al. also provided evidence that differences between modal and amodal interpolation can lead to differences in the very shapes of completed contours themselves. When the left-hand stereopair in Figure 86.8*A* is uncross fused, the resulting percept consists of six circular discs that are partly occluded by a jagged white surface on the right-hand side, as schematized in Figure 86.8*B*. However, when the disparities are inverted (by uncross-fusing the right pair of Fig. 86.8*A*), the modal completion across the regions between the four black blobs tends to take the form of a

FIGURE 86.7. *a*, Relative depth alters perceptual organization. When the left stereopair is cross-fused, the figure tends to appear as five discs occluded by five distinct image fragments, as depicted in *b*; the transparency in *b* is included only so that both depth planes can be depicted simultaneously. When the depth ordering is reversed by cross-fusing the right stereopair, a single irregular black “star” appears to lie on a continuous white background, which is visible through five holes in a continuous overlying layer (*c*). In this depth ordering the black shape tends to appear as figure. (Adapted from Anderson et al., 2002.)

continuous wavy contour that runs down the center of the display. This percept is schematized in Figure 86.8C. The importance of this demonstration is that it shows that modal and amodal completion can not only result in different surface structures, but even in differently shaped contours. It is difficult to see what the concept of a single completion mechanism serves to explain if the two processes can result in different completed forms.

Ultimately, the identity hypothesis is a claim about mechanism and can therefore be assessed physiologically. There is a considerable body of evidence for extrastriatal units that are sensitive to illusory but not to amodally completed contours (see Chapter 76 for a review). A critical additional piece of evidence was provided recently by Sugita (1999), who found cells in V1 that respond to amodal completion across their receptive fields but not to modal completion. Cells responded weakly when presented with two unconnected edges; holes and occluding surfaces on their own; and stimuli in which two unconnected edges were separated by a hole. However, when the cells were presented with two edge fragments separated by an occluder (a

FIGURE 86.8. The serrated-edge illusion. When the left stereopair in *a* is uncross-fused, the resulting percept consists of six circular disks that are partly occluded by a jagged white surface on the right, as depicted in *b*. When the right stereopair is uncross-fused, the modal completion of these four black blobs tends to take the form of a single wavy contour that runs vertically down the center of the display, as depicted in *c*. Although other percepts are possible, this is an existence proof that depth inversion alone can alter the shape of modally and amodally completed contours. (Adapted from Anderson et al., 2002.)

stimulus that leads to amodal completion of the edge), the cells responded vigorously. This shows that at the earliest stages of cortical processing, there is a double dissociation between the representations of modal and amodal structures, a conclusion which supports the dual mechanism hypothesis.

Transparency, scission, and the representation of multiple depth planes

Transparency poses a particularly interesting problem in the perceptual organization of depth. With transparency, one object is visible *through* another, and thus two distinct depths lie along the same line of sight (Fig. 86.9). If the visual system is to represent depth in terms of the actual surfaces of the environment, it has to depict *two distinct depths* at a single location in the visual field. The process of projection compresses

FIGURE 86.9. Perceptual transparency. The figure in *a* tends to be seen as a light gray transparent surface in front of a bipartite background, as depicted in *b*, and thus two distinct surfaces are visible along the same line of sight. Transparency is seen only when certain relations hold between the various regions of the display. In *c* the central region is higher in contrast than its surround and thus is not seen as transparent. In *d*, the polarity of the contrasts is reversed, and again transparency is not seen. In *e*, the contour of the underlying layer is not continuous inside and outside the central region, eliminating the percept of transparency. In *f*, the contour of the overlying layer is not continuous, which also reduces the percept of transparency.

the light arriving from the transparent surface and the light arriving from the more distant surface into a single image intensity on the retina. In order to represent both surfaces, the visual system has to separate a single luminance value into multiple contributions, a process known as *scission* (Koffka, 1935). We argue that scission is a type of perceptual segmentation, as it parses the representation of depth into distinct surfaces. However, rather than segmenting *neighboring* locations into distinct objects, scission separates depth into layers, or planes, and thus operates “parallel” to the image plane.

Scission poses the visual system with two principal problems. The first is to identify when a single luminance results

from two distinct depths. The second is to assign surfaces properties correctly at the two depths. By studying when and how we see transparency, we can learn how the visual system scissions depth into layers.

Much of the seminal work on perceptual transparency was conducted by Metelli (1970, 1974a, 1974b; see also Metelli et al., 1985), who provided a quantitative analysis of the color mixing that occurs when one surface is visible through another. When a background is visible through a transparent sheet, only certain geometrical and luminance relations can hold between the various regions of the display (Fig. 86.9). From these relations Metelli derived constraints that determine whether a region will look transparent or not, and how opaque it will appear if it does look transparent. This is important, as it determines the conditions under which the visual system scissions a single image intensity into multiple layers, and thus how the visual system stratifies its representation of depth.

Broadly, the conditions required for perceptual scission fall into two classes. The first are the photometric conditions for transparency, which detail the relations between the light intensities of neighboring regions that are necessary for scission. The second set of conditions for perceptual scission are geometrical, or figural. Depth separates into layers only when these relations hold between the various regions of the display.

PHOTOMETRIC CONDITIONS FOR SCISSION Consider the display shown in Figure 86.9A, which tends to be seen as a bipartite background that is visible through a transparent filter. The vivid separation of the central region into two depths occurs only when certain luminance relations hold. Metelli derived two constraints on the photometric conditions required for perceptual scission.

The intuition behind the first constraint, which we refer to as the *magnitude constraint*, is that a transparent medium cannot increase the contrast of the structures visible through it. The consequence of this constraint is that the central diamond must be lower or equal in contrast than its surround in order to appear transparent, as shown in Figure 86.9A. This constraint is important, as it restricts the conditions under which scission occurs: a region can scission only if its contrast is less than or equal to the contrast of its flanking regions. As can be seen in Figure 86.9C, infringement of this constraint with respect to the central diamond prevents the central region from undergoing scission. However, in this display, the constraint is satisfied for the region *surrounding* the diamond; thus, the display can be seen as a bipartite display viewed through a transparent filter with a diamond-shaped hole in the center.

The intuition behind the second luminance constraint, which we refer to as the *polarity constraint*, is that a transparent medium cannot alter the contrast polarity of the

FIGURE 86.10. The polarity constraint means that transparency manifests itself in distinctive local ordinal relations in luminance. The only difference between the three figures is the luminance of the region of overlap. In *a*, the region is dark and the image is bistable, as either square can be seen in front. When this occurs, a line that passes progressively from brighter to darker regions creates a **Z** shape. In *b*, the overlap is intermediate, such that the line that joins regions of decreasing brightness is **C**-shaped. When this happens, exactly one of the surfaces appears transparent. In *c*, the overlap is light, creating a crisscross pattern. In this case, neither square appears transparent, as the polarity constraint is infringed for both squares. (Adapted from Beck and Ivry, 1988.)

structures visible through it. Put another way, if a dark-light edge passes underneath a transparent medium, the dark side will remain darker than the light side, no matter what the *absolute* luminances are. As can be seen in Figure 86.9D, infringement of this constraint prevents perceptual scission, demonstrating that the visual system respects this optical outcome of transparency. This constraint is particularly important in determining the depth ordering in transparent displays.

The polarity constraint enforces certain restrictions on the ordinal relationships between the luminances of neighboring regions. This means that, in principle, we can classify the locations where neighboring regions meet to determine whether scission is or is not possible in each region. This provides the visual system with a *local* signature of transparency. Beck and Ivry (1988) noted that if one draws a series of lines running progressively from the brightest to the darkest regions, there are three possible shapes that result, as shown in Figure 86.10. The only difference between the three figures is the luminance of the region of overlap between the two squares. In the first instance (Fig. 86.10A), the image is bistable, as either square can be seen as a transparent overlay. In these circumstances, the lines linking regions of

increasing luminance form a **Z** configuration. When the lines form a **C** shape (Fig. 86.10B), only one of the squares is seen as transparent, and when the lines crisscross (Fig. 86.10C), the polarity constraint is infringed for all regions and neither square scissions. Adelson and Anandan (1990) provided a similar taxonomy based on the number of polarity reversals. A number of lightness illusions demonstrate that scission can be predicted from the class of X-junctions in the display and that these X-junctions can have powerful effects on many qualities of our experience (see, e.g., Adelson, 1993, 1999).

The magnitude and polarity constraints can be unified as a single rule that describes a powerful local cue to scission. Anderson (1997) phrased the rule as follows: “When two aligned contours undergo a discontinuous change in contrast magnitude, but preserve contrast polarity, the lower-contrast region is decomposed into two causal layers.” There are two valuable consequences of this rule. The first is that it unifies the two Metelli constraints. The second is that it provides a *local* signature of transparency that can be applied to any meeting of contours. This includes those T-junctions that are in fact degenerate X-junctions, that is, those in which two neighboring regions happen to have exactly the same luminance. Anderson also demonstrated that a number of traditional lightness phenomena, including White’s effect and its variants, and neon color spreading, can be accounted for as cases of scission rather than as the consequence of traditional “contrast” or “assimilation” processes.

Having identified that a location contains two surfaces, the visual system has to partition the luminance at that location between the two depths. How much of the light is due to reflectance of the underlying surface, and how much is due to the properties of the overlying layer? The opacity of the overlying layer determines how the luminance is divided between the two depths. Metelli’s model makes explicit predictions about the perceived opacity and lightness of the transparent layer. The equations predict that two surfaces with identical transmittance should look equally opaque irrespective of their lightness. However, Metelli himself noted that dark filters tend to look more transparent than light filters with the same transmittance. Why does the visual system confuse lightness and transmittance in partitioning luminance between two depths?

In a series of matching experiments, Singh and Anderson (2002) recently resolved this issue. Subjects adjusted the opacity of one filter until it matched the perceived opacity of another filter with a different lightness. Singh and Anderson found that perceived transmittance is predicted almost perfectly by the ratio of *Michelson contrasts* inside and outside the transparent region, even though

such a measure is actually inconsistent with the optics of transparency. As discussed above, there is a general consensus that the early visual processing tends to optimize sensitivity to contrast rather than absolute luminance. Hence, in assigning transmittance, the visual system appears to use the readily available contrast measurements, even though they are not strictly accurate measurements of opacity.

FIGURAL CONDITIONS FOR SCISSION In addition to the luminance conditions, certain geometrical relations must hold between the various regions of the display in order for depth stratification to occur (Kanizsa, 1995/1979; Metelli, 1974a). These figural conditions fall into two broad classes. The first class requires good continuation of the *underlying* layer. Specifically, the contours that are in plain view should be continuous with the contours viewed through the region of presumed transparency. As can be seen in Figure 86.9E, infringement of this condition interrupts the percept of transparency. The second figural condition requires good continuation of the *transparent* layer. Figure 86.9F shows that infringement of this condition weakens or eliminates the percept of transparency.

There are conditions in which the figural cues to transparency are so strong that they can override the luminance cues. Beck and Ivry (1988) showed subjects displays like the one shown in Figure 86.10C, in which the region of overlap between the two figures is the wrong contrast polarity for either figure to be seen as transparent. Despite this, naive subjects did occasionally report seeing such figures as transparent, demonstrating that the sense of figural overlap is a central aspect of the percept of transparency. Certainly most observers are willing to agree that the region of overlap in Figure 86.10C appears to belong to two *figures* simultaneously, an impression that can be enhanced with stereo and relative motion. However, it should be noted that the gray of the overlap region does not appear to scission into two distinct sources, at least not in the same way as the overlap of a normal transparency display does (as in Figs. 86.10A and 86.10B). This leads to the possibility of two distinct neural processes in the perception of transparency. One is driven by relatively local cues and leads to phenomenal color scission. The other is driven by more global geometrical relations and leads to stratification in depth. Under normal conditions of transparency, the two processes operate in concert to produce the full impression of transparency. However, using carefully designed cue-conflict stimuli, such as those used by Beck and Ivry, these two factors in the representation of transparent surfaces can be distinguished. An open question, however, is how these processes are instantiated neurally. All we can conclude is that the representation of depth is much more

sophisticated than a mere two-dimensional map of depth values.

SCISSION AND THE PERCEPTUAL ORGANIZATION OF DEPTH Scission can have pronounced effects on perceptual organization. For example, Stoner et al. (1990) demonstrated that perceived transparency can alter the integration of motion signals into coherent moving objects. When a plaid is drifted at constant velocity across the visual field, it is typically seen as a single coherent pattern that moves at the velocity of the intersections between the two component gratings. However, with prolonged viewing, the plaid appears to separate into two component gratings that slide across each other, each of which appears to move in the direction perpendicular to its orientation. When the plaid is coherent, it appears to occupy a single depth plane, but when it separates into its components, the gratings tend to appear at different depths.

Stoner et al. varied the intensity of the intersections of the plaids and measured the proportion of time for which the plaid was seen as coherent. They found that when the color of the intersection was consistent with one grating being seen through the other (i.e., when the junctions were consistent with transparency), the proportion of the time for which the plaid appeared to separate into gratings was greatly increased. By contrast, when the color of the intersections infringed the polarity constraint, such that neither grating could be seen as transparent, the pattern tended to be seen as a coherent plaid rather than undergoing scission into distinct layers. This demonstrates that scission has important consequences for the representation of visual structure. When an image region scissions, the effects can spread to regions distant from the local cues to scission.

Scission acts as a nexus between depth and other visual attributes. Scission of depth can cause regions to change in apparent lightness; conversely, changes in luminance can cause changes in depth stratification. Figure 86.11 demonstrates this close relationship between luminance, scission, and the perceptual organization of depth. Three circular patches of a random texture were placed on a uniform background. Critical to the demonstration is that disparity is introduced between the circular boundaries and the texture inside the circles. When the disparity places the texture behind the circular boundaries, the circles appear as holes through which the texture is visible. The texture tends to appear as a single plane with continuously stochastically varying lightness. However, when the disparity places the texture in front of the circular boundaries, the percept changes considerably. The texture separates into two distinct layers: a near layer made up of clouds with spatially varying transmittance and a far layer that is visible through the

FIGURE 86.11. Scission and the perceptual organization of depth. The top and bottom figures are identical apart from the brightness of the surround. When the right stereopair is cross-fused, the figure appears as a single textured plane that is visible through three circular holes. This is seen irrespective of the luminance of the surround. However, when the disparity is reversed (by cross-fusing the left stereopair), the texture appears to separate into two depth planes. The near layer contains near clouds that vary spatially in thickness or opacity. Through these clouds can be seen three more distant discs, which appear more or less uniform in lightness. For this depth ordering, the structure completely reverses with a change in the luminance. In the top case, the dark portions of the texture form the clouds; in the bottom case, the light portions of the texture form the clouds. Scission makes these percepts possible by allowing the visual system to separate the intermediate grays into two distinct contributions. (Adapted from Anderson, 1999.)

clouds, which consists of uniform discs on a uniform background (see Anderson, 1999; Anderson, in press).

Another interesting property of this display is that the lightness and spatial structure of the clouds and discs reverse completely when the luminance of the surround varies. In Figure 86.11, the top and bottom displays are identical except for the lightness of the surround. When the surround is dark, the texture scissions into dark, smoke-like clouds in front of white discs. However, when the surround is white, it is the light portions of the texture that move forward, floating like mist in front of dark discs. One final observation about the display is that when the texture carries near disparity, and thus undergoes scission, the clouds that float in front tends to complete modally across the gaps in between the discs. This is in part due to the fact that the conditions for camouflage are satisfied, as discussed in the second section.

When the depth is reversed in the display, two asymmetries occur. The first is *geometrical* in that it alters the structure of the depths in the scene. In the near case the texture scissions into two layers, while in the far case the texture

appears relatively uniform in depth by comparison. The second asymmetry that occurs with depth inversion is *photometric* in that it is driven by the luminance of the surround and determines the lightness of the cloud and discs. When the texture is distant, the percept changes very little with changes to the luminance of the surround; by contrast, when the texture is near, the luminance of the surround critically determines how the scission occurs, as well as the lightness of the cloud and discs. In what follows, we will use the CDAP discussed in the first section and the concept of scission to explain these asymmetries. For a more thorough discussion, see Anderson (in press).

Let us first consider the case in which the texture carries far disparity relative to the circular boundaries. Because the texture is continuously varying in luminance, it carries localizable disparity signals at almost every location. Put another way, if disparity is carried by *contrast*, as argued in the first section, then patterns that are richly structured bear the densest distribution of disparities. Recall that the CDAP requires both sides of every contrast to be at least as distant as the disparity carried by the contrast. This means that when the texture is given far disparity (or, more precisely, when the *contrasts of the texture* are given far disparity), both the light and dark matter in the texture recede to this depth. In turn, the depth placement of the texture uniquely determines the border ownership of the boundaries of the discs, which carry relatively near disparity. If the *insides* of the discs (i.e., the texture) carry far disparity, then the *outsides* (i.e., the region surrounding the discs) must be at the depth carried by the circular boundary. Thus, the circles are seen as holes in the surrounding surface; it is through these holes that the texture is visible.

The situation is more complex when the depth is reversed, that is, when the contrasts of the texture are nearer than the contrast of the circular boundaries. Crucial to the following argument is that it is *contrasts* that carry disparity, while it is the light and dark regions that make up the contrasts to which depth is assigned. First, let us consider the circular boundary between the surround and the texture. When the surround is light, it is the dark portions of the texture (inside the circles) that contrast with the surround. Thus, the disparity of the circular boundary is carried by the contrast between the light matter of the surround and the dark portion of the textured disc. The CDAP requires both of these regions to be at least as distant as the disparity carried by the boundary. This means that the light surround is dragged back to this depth, and the dark matter of the texture is also dragged back to this depth. Now consider the contrasts between the dark and light portions within the texture. These contrasts carry relatively near disparity. But the contrast between the dark matter and the surround has already constrained the dark matter to be at least as distant

as the circular boundary. This means that it must be the *light matter of the texture* that is responsible for the near disparity of the texture, that is, the light matter is a near surface that partly obscures the dark matter. This explains why the texture splits into two depths: the dark matter is dragged back by forming a contrast that carries far disparity (i.e., the boundary of the disc) and the light matter floats in front, as its boundaries with the dark matter carry near disparity.

The final logical step in the explanation involves scission. The texture does not consist of only two luminances, but of a continuous range of luminances from light to dark. How can we explain the appearance of the intermediate luminances in the texture? Scission makes it possible to separate the intermediate luminances into two distinct components: dark “stuff” and light “stuff,” which have been compressed into a single luminance by the process of projection onto the retina. These two components lie in different depth planes. Put another way, scission allows the visual system to interpret the gray regions as *dark matter viewed through light matter*. The critical insight is that it is the dark stuff in the texture that forms the contrast with the surround. Therefore, all of the dark stuff belongs to the more distant depth, including the dark stuff within the grays. All of the remaining lightness in the grays belongs to the transparent clouds that float in front of the discs. In this way, the intermediate luminances are interpreted as varying degrees of transmittance of the overlying layer. The lighter the gray, the thicker the cloud; the darker the gray, the sparser. This explains why the disc appears as a uniform dark disc: all of the dark is “sucked out” of intermediate regions and is dragged back to form the disc. The “leftover” lightness is attributed to the transparent clouds.

The whole argument reverses when we change the surround from light to dark. When the surround is dark, it is the light portions of the texture that contrast with the surround, and therefore, it is the light portions of the texture that are dragged back. The near disparity of the texture must therefore be due to the dark regions, and thus dark clouds are seen to float in front of white discs. Again, as it is the *whiteness* of the texture that is dragged back, all of the whiteness in the intermediate luminances is attributed to the more distant discs. The remaining darkness in the grays is attributed to the dark clouds that float in front. In this way, changing the luminance of the surround changes which contrasts carry the disparities and thus which regions are dragged back by virtue of the CDAP. Scission enables the visual system to separate luminances into multiple contributions and thus segment the intermediate grays into two distinct depth planes.

This demonstration and others like it are important, as they show how multiple processes interface to determine our

percepts of depth and material quality. It is through the CDAP and scission that the visual system interprets local variations in luminance as meaningful surfaces located in depth. Depth stratification complements traditional segmentation as an important process through which the visual system organizes its representation of depth into ecologically valid structures.

Conclusions

It is common to think that depth perception involves little more than determining the depth at each location in the visual field. We have argued, to the contrary, that the visual system mirrors the structural organization of the environment by tying its representation of depth to surfaces and objects. Thus, depth perception is an active process of perceptual organization, as well as a passive process of acquiring depth estimates. We have argued that luminance, disparity, and contrast are some of the basic image features that carry local information about depth, while scission, visual completion, and the CDAP are some of the means by which depth is organized into surfaces.

In the first section, we introduced the CDAP and argued that

1. Disparity is carried by local contrasts (e.g., luminance edges) but depth is assigned to the regions that meet to form the contrasts.
2. Occlusion introduces a critical constraint on the interpretation of local disparity signals, the CDAP. This constraint requires that both sides of a contrast are at the depth specified by the contrast, or one side could be a more distant occluded surface. In the latter case, the disparity determines the depth of the *occluding* side.
3. The CDAP imposes a fundamental asymmetry between near and far structures. When simultaneously applied to all edges in a display, the CDAP can explain a number of asymmetrical changes in perceived surface layout that occur with simple inversion of the disparity field.

In the second section, we discussed how the visual system deals with structures that are invisible because they are hidden by occlusion or camouflaged against their background. We argued that

1. The visual system has to actively complete the missing data if it is to segment depth accurately into objects.
2. Consideration of the environmental conditions of occlusion and camouflage predicts (a) that modal completion is sensitive to luminance, while amodal completion is

not, and (b) that modal completion tends to occur over shorter distances than amodal completion.

3. As predicted from the environmental differences, distinct mechanisms are responsible for the two types of completion. The differences can be used to generate displays in which the completed forms differ when the disparity field is inverted.

Finally, in the third section, we discussed how scission allows the visual system to represent two depths along the same line of sight and thus organize depth into layer. We argued that

1. Certain luminance and figural relations must obtain in order for a region to undergo scission.

2. Scission can have pronounced effects on perceptual organization in regions distant from the local signatures of transparency.

87 Stereopsis

CLIFTON M. SCHOR

STEREOPSIS IS ONE of our primary senses of spatial layout. Slightly different viewpoints of the two eyes produce binocular retinal image disparities that are used to perceive *relative depth* between objects as well as *surface slant* (orientation) and percepts of *object volume*. Stereopsis also provides information about forms hidden by texture camouflage (such as branches in tree foliage) and direction of object motion in depth relative to the head. Stereopsis is an extremely acute mechanism with one of the lowest visual thresholds—less than the width of a single retinal photoreceptor—which makes it one of the hyperacuities (Westheimer, 1979b).

Visual directions

Stereopsis is stimulated by horizontal disparity that results from the slightly different perspective views of the two eyes. Each eye views slightly more of the temporal than the nasal visual field and also sees more of the ipsilateral than the contralateral side of a binocularly viewed object. When viewed with one eye at a time, the retinal images of the three-dimensional (3D) scene have slightly different locations relative to the fovea of each eye, and they are seen in slightly different directions relative to the line of sight (oculocentric directions). However, each eye perceives the targets in a common direction relative to the head (egocentric direction). The perceived egocentric direction of an object is equal to the average of its oculocentric directions in the two eyes combined with the average of right and left eye positions (conjugate eye position). Movements of the eyes in opposite directions (convergence) have no influence on perceived egocentric direction. Thus, when the two eyes fixate on near objects that lie to the left or right of the midline (straight ahead) in asymmetrical convergence, only the conjugate component of the two eyes' positions (produced by movements of the two eyes in the same direction) contributes to perceived direction. Ewald Hering summarized these facets of egocentric direction as five rules of visual direction, and Howard (1982) has restated them. The laws are mainly concerned with targets imaged on corresponding retinal regions (i.e., stimulation of corresponding retinal points in the two eyes results in percepts in identical visual directions).

How are oculocentric visual directions of the two eyes combined in a common visual space, sometimes referred to as the *cyclopean eye*? When the target lies near the plane of fixation, its egocentric direction is based upon the similar

retinal image locations of the two eyes. When the target is slightly nearer to or farther from the plane of fixation, its monocular images are formed at different horizontal eccentricities from the foveas; however, its averaged direction is seen as single (allelotopia). The range of disparities that produce singleness is referred to as *Panum's fusional area* (Schor and Tyler, 1981). The consequence of averaging monocular visual directions of disparate targets is that binocular visual directions are perceived correctly from a reference point midway between the eyes (cyclopean eye). Binocular visual directions can be judged accurately only for targets with averaged visual directions. When targets are positioned far in front of or behind the plane of fixation, their retinal image disparity becomes large and the disparate targets appear diplopic (i.e., they are perceived in two separate directions). The directions of monocular components of the diplopic pair are perceived inaccurately as though each of the images had an invisible paired image formed on a corresponding retinal point in the other eye. There are ambiguous circumstances in which a target in the peripheral region of a binocular field is seen by only one eye because of partial occlusion of the other eye by the nose. The monocular target could lie at a range of viewing distances. However, its direction is judged as though it was located in the plane of fixation such that if it were seen binocularly, its images would be formed on corresponding retinal points.

Several violations of Hering's rules for visual direction have been observed in both abnormal and normal binocular vision. A common binocular abnormality is strabismus (an eye turn or deviation of one eye from the intended binocular fixation point). In violation of Hering's rules, people who have a constant turn of one eye (unilateral strabismus) can have constant diplopia, and they use the position of their preferred fixation eye to judge visual direction, regardless of whether they fixate a target with their preferred or deviating eye. People who have an alternating strabismus (either eye is used for fixation, but only one at a time) use the position of the fixating eye to judge the direction of objects (Mann et al., 1979). People with both types of strabismus use the position of only one eye to judge direction, whereas people with normal binocular eye alignment use the average position of the two eyes to judge direction with either eye alone.

Two exceptions in normal binocular vision involve monocular images, and a third exception involves judgment

of direction of binocular-disparate targets. Hering's rules predict that if a target is fixated with one eye while the other is covered, the target will appear to move in the temporalward direction (toward the ear nearest the open eye) if the eyes accommodate (focus on a near target), even if the monocular position of the open eye remains stationary. The perceived temporalward movement results from the nasalward movement of the covered eye caused by the cross-coupling between accommodation and convergence (Müller, 1843). When the open eye focuses on a near target, the covered eye automatically converges (i.e., turns nasalward) (cross-coupling). Hering's rules predict that the average horizontal position of the two eyes determines the egocentric direction of the foveated target. The first exception occurs when the apparently temporalward motion is greater during accommodation on a near target when one eye is occluded compared to when the other eye is occluded. This asymmetry between the eyes resembles the biased perception of egocentric direction in constant-unilateral strabismus, and it may be related to an extreme form of eye dominance.

The second exception to Hering's rules occurs when the retinal image of a target that is seen monocularly is imaged near a disparate target seen by both eyes (binocular view). Monocular views occur naturally in the peripheral visual field when one eye's view is occluded by the nose. The direction of the monocular target is judged as though it was positioned at the same depth as any nearby disparate binocular target rather than at the plane of fixation. The visual system assumes that there is an occluded counterpart of the monocular target in the contralateral eye that has the same disparity as the nearby binocular target, even though the image is seen only by one eye (Erkelens and van Ee, 1997).

The third exception to Hering's rules is demonstrated by the biased visual direction of a fused disparate target when its monocular image components have unequal contrast (Banks et al., 1997). Greater weight is given to the retinal locus of the image that has the higher contrast. The average location of the two disparate retinal sites is biased toward the monocular direction of the higher-contrast image. These are minor violations that occur mainly for targets lying nearer to or farther from the plane of fixation or distance of convergence. Since visual directions of off-horopter targets are mislocalized, even when Hering's rules of visual direction are obeyed, the violations have only minor consequences.

Binocular correspondence (the horopter)

We perceive space with two eyes as though they were merged into a single cyclopean eye located midway between them. This merger of the two ocular images is made possible by a sensory linkage between the two eyes that is based upon the anatomical combination of homologous regions of the two

retinas in the primary visual cortex. Unique pairs of retinal regions in the two eyes (corresponding points) must receive images of the same object so that these objects can be perceived as single, that is, in a common visual direction, and at the same depth as the point of fixation. This is made possible by the binocular overlap of the two eyes' visual fields. Hering defined binocular correspondence operationally as retinal locations in the two eyes which, when stimulated by real points in space, resulted in a percept in identical visual directions. For a fixed angle of convergence, optical projections into space, from corresponding retinal points located along the equator and midline of the each eye, intersect. In other cases, such as oblique eccentric (tertiary) locations on the retina, corresponding points have visual directions that do not intersect in real space. The horopter is the locus of object points in space whose images can be formed on corresponding retinal points. The horopter serves as a reference throughout the visual field for the same disparity as at the fixation point (zero disparity). To appreciate the shape of the horopter, consider a theoretical case in which corresponding points are defined as homologous locations on the two retinas (i.e., corresponding points are equidistant from and in the same direction relative to their respective foveas). Consider binocular combinations of points imaged on the horizontal retinal meridians or equators that pass through the foveas. The egocentric visual directions of corresponding points located on the retinal equator intersect in space at real points that define the longitudinal horopter. This theoretical horopter is a circle whose points will be imaged at equal eccentricities from the two foveas on corresponding points except for the small arc of the circle that lies between the two eyes (Ogle, 1962) (Fig. 87.1). While the theoretical horopter is always a circle, its radius of curvature increases with viewing distance. This means that its curvature decreases as viewing distance increases. At the limit, the theoretical horopter is a straight line at infinity that is parallel to the face and the interocular axis (frontoparallel). Thus, a surface representing zero disparity has many different shapes, depending on the viewing distance. The consequence of this spatial variation in horopter curvature is that the spatial pattern of horizontal disparities is insufficient information to specify depth magnitude or even depth ordering or surface shape and curvature. Additional information about target distance and direction relative to the head is needed to interpret surface shape and orientation (Garding et al., 1995).

Binocular matching (the correspondence problem)

Alignment of the two retinal images depends on eye position and the optical center of the eye (nodal point). The two separate components of eye position are the direction of gaze relative to the head (version) and the distance of gaze

Theoretical Longitudinal Horopter

FIGURE 87.1. The theoretical horopter. The theoretical horopter or Vieth-Müller circle passes through the entrance pupils of the two eyes and the point of fixation (F). All points on this circle (e.g., $T1$ and $T2$) subtend equal angles at the entrance pupils of the two eyes ($\alpha_L = \alpha_R$). The Vieth-Müller circle represents the geometric locus of targets that subtend zero retinal image disparity.

where the two visual axes intersect (vergence). If both version and vergence eye position are known, the 3D scene can be reconstructed geometrically by projecting images from the retina through the nodal points of the two eyes, and the target lies at the points of intersection. However, the success of this exercise relies upon selecting image points that correspond to the same target in space. In complex natural scenes, there are many textured patterns that have similar shapes that lie in different locations, and potential binocular matches are possible between a given feature in one eye and several features in the other eye. This problem is exacerbated by camouflage surface texture such as tree foliage, where there is little spatial uniqueness of any particular texture element in the pattern. For example, false matches can occur when viewing a vertically oriented repetitive pattern (Fig. 87.2). The vertical bars in wallpaper patterns can appear to float out of the depth plane of the wall (the wallpaper illusion). The visual system utilizes several inferential shortcuts to limit the possible matches in natural textured patterns to a manageable number.

Disparities of the two retinal images could be analyzed in various ways. In a local analysis, individually perceived forms could be compared to estimate their binocular disparity. In this local analysis, form perception would precede depth perception (Helmholtz, 1909). In a global analysis, luminance properties of the scene, such as texture and other token elements, could be analyzed to code a disparity map from which depth was estimated. The resulting depth map would contribute to the perception of form. In this analysis, depth perception would precede form perception. In the

FIGURE 87.2. The wallpaper illusion. A repetitive pattern of vertical bars or an equally spaced horizontal row of dots can be matched in the two eyes to form one of many different depth planes.

local analysis, it is clear which monocular image components are to be matched binocularly because of their uniqueness. The global analysis is much more difficult since many similarly textured elements must be matched, and the correct pairs of images to match are not obvious. The matching problem is constrained by restricting matches to certain features of texture elements (types of primitives or tokens) and by prioritizing certain matching solutions over others. In addition, there is an interaction between the local and global analyses that simplifies the process. Local features are often visible within textured fields. For example, there are clumps of leaves in foliage patterns or target edges that are clearly visible prior to sensing depth. Vergence eye movements can align these unique monocularly visible patterns onto or near corresponding retinal points and reduce the overall range of disparity subtended by the textured object (Marr and Poggio, 1976). Once this has been done, the global system can begin to match tokens based upon certain attributes such as luminance spatial frequency and orientation.

Several serial processing models have been proposed to optimize solutions to the matching problem. These serial models utilize the spatial filters that operate at the early stages of visual processing. Center-surround receptive fields and simple and complex cells in the visual cortex have optimal sensitivity to limited ranges of luminance periodicity that can be described in terms of spatial frequency. The tuning or sensitivity profiles of these cells have been modeled with various mathematical functions (difference of two Gaussians, Gabor patches, Kauche functions, etc.), all of which have bandpass characteristics. They are sensitive to a limited range of spatial frequencies that is referred to as a *channel*, and there is some overlap in the sensitivity range of adjacent channels. These channels are also sensitive or tuned to limited ranges of different orientations. Thus, they encode both the size and orientation of contours in space. These filters serve to

FIGURE 87.3. The center row in the middle panel has the same absolute disparity as the figure shown in the bottom panel, and the flanking rows in the middle panel have the same disparity as the rows shown in the upper panel. When the center panel is fused by crossing the eyes to merge the vertical lines on the left and right,

the depth ordering of the center panel is reversed from its counterparts in the upper and lower panels. This stereogram demonstrates that the minimum relative disparity has a higher priority than the minimum absolute disparity in the binocular matching process.

decompose a complex image into discrete ranges of its spatial frequency components. In the Pollard Mayhew and Frisby (PMF) model (Frisby and Mayhew, 1980), three channels tuned to different ranges of spatial frequency filter different spatial scale components of the image. Horizontal disparities are calculated between the contours having similar orientations and matched contrast polarities within each spatial scale. In addition, priority is given to similar matching solutions across several spatial scales. Most of these models employ both mutual facilitation and inhibition between disparity detectors; however, several stereo phenomena suggest a lesser role for inhibition. For example, we are able to see depth in transparent planes, such as views of a stream bed through a textured water surface, or views of a distant scene through a spotted window or intervening plant foliage. In addition, as the separation between two surfaces increases, their depth can be averaged, that is, seen as filled in, or they can be seen as two separate surfaces lying in different depth planes (Stevenson et al., 1989). Inhibition between dissimilar disparity detectors would obstruct these percepts.

Computational models of stereopsis employ a number of algorithms that constrain stereo matches to produce the smallest disparity offset from the plane of fixation (nearest neighbor match) or to minimize the disparity differences

between nearby features. In some natural scenes, such as a slanted textured plane, the nearest neighbor match and the minimum disparity difference match are in conflict when disparities in regions away from the point of fixation exceed one cycle of the texture spacing. In Figure 87.3, the center stimulus in the middle panel is surrounded by upper and lower flanking stimuli with the same disparity amplitude but the opposite depth sign. The flank and center are shown in isolation in the top and bottom panels, respectively. These patterns have multiple depth matches, as described above in the wallpaper illusion. The minimum depth difference (relative disparity) between the flank and center is smaller than the difference between the absolute disparities of the overall stimulus. When the top panel is fused by crossing the eyes (cross-fused), the flank appears nearer than the fixation lines. When the bottom panel is cross-fused, the center appears farther than the fixation lines. When the center panel is cross-fused, both the center and flanks appear either nearer to or farther from the fixation lines, and their depth ordering is reversed compared to the top and bottom panels. Figure 87.3 demonstrates a priority of minimum relative depth over minimum absolute disparity matching solutions.

Except for the edges, most textured areas of the plane have potential matching ambiguity, and their depth solution

will depend on the area, spatial separation, and disparity of adjacent textured regions. Binocular matches minimize the relative disparity between adjacent regions of the surface so that the textured surface is perceived as planar rather than fragmented (smoothness or continuity constraint) (Papathomas and Julesz, 1989; Zhang et al., 2001). The limited range of spatial interactions promotes matches that reduce abrupt changes in disparity while allowing large gradual increases in the disparity of slanted surfaces.

Disparity coded from edges and contrast information (second-order stereopsis)

Binocular matching is most difficult with repetitive textures that are presented in large fields located either in front of or behind the plane of fixation. A coarse-to-fine strategy reduces this matching ambiguity by first seeking matches of edge information (Mitchison and McKee, 1987). Edges or overall target shape can be described as a contrast variation of surface texture. Contrast variations are coded by a nonlinear or second-order process that is equivalent to rectifying the neural representation of the retinal image (Wilson et al., 1991b). Contrast-defined edges (contrast envelope) can be used to make coarse matches in stereo tasks involving large disparities that are near the upper disparity limits for stereopsis (Hess and Wilcox, 1994). These studies show that the upper disparity limit for stereopsis (maximum disparity that stimulated stereo depth) is not limited by first-order or luminance information such as the spatial frequency of a textured surface. Instead, the upper disparity limit for stereopsis increases with the size of the contrast envelope that contains the textured pattern (Hess and Wilcox, 1994). These results could be attributed to the disparity of edges coded by a nonlinear extraction of the contrast envelope (Wilcox and Hess, 1995).

Transient and sustained stereopsis

Second-order contrast cues stimulate both sustained and transient stereopsis. Sustained stereopsis is stimulated by small disparities (within the singleness range) that are presented for long durations. Transient stereopsis creates a brief (transient) impression of depth, and it is stimulated by briefly presented images (Kumar and Glaser, 1994) whose disparity can range from small values within the sensory fusion range (0.5 degree) to highly diplopic values (>8 degrees). Both sustained and transient stereopsis can be stimulated by first-order (luminance) and second-order (contrast) forms of spatial information. Transient stereopsis relies more heavily on second-order information than does sustained stereopsis. The transient system is more broadly tuned than the sustained system to differences between the texture (carrier) properties of the stimulus presented to the two eyes (i.e.,

spatial frequency, orientation, contrast, and contrast polarity) (Edwards et al., 1999; Schor et al., 1998).

Vivid stereoscopic depth can be perceived with brief stimuli, even when the detailed structure of the two retinal images differs markedly. Contrast envelope size (Schor et al., 2001) and, to a greater extent, temporal synchrony of the two eyes' stimuli (Cogan et al., 1995) are the primary means for selecting matched binocular inputs for transient stereopsis. Second-order stimuli work well in concert with first-order stimuli to assist the computation of binocular matches in a coarse-to-fine strategy. Second-order information from the contrast-defined edges provides coarse information to guide matches of small disparities in the luminance-defined texture by the fine system (Wilcox and Hess, 1997). This is not a function reserved exclusively for second-order stimuli because coarse first-order luminance information also guides disparity matches (Wilson et al., 1991a). This coarse-to-fine strategy utilizing contrast and luminance information is effective because spatial information represented by contrast and luminance is usually highly correlated in images formed in natural environments.

Stereo acuity

Stereopsis is the sense of relative depth between two or more features. It is stimulated by differences between absolute disparities subtended by these features (Westheimer, 1979a). Absolute disparity of an object quantifies its retinal disparity relative to the horopter. It is the difference in the locations of its retinal images in the two eyes from corresponding retinal points. Stereopsis is stimulated by differences between several absolute disparities, that is, relative disparity. Relative disparity describes the disparity difference between features. Relative disparity thresholds for stereopsis are lowest when targets are imaged on or near the horopter. Stereo sensitivity to relative disparity varies dramatically with the distance of these targets from the horopter or plane of fixation (Fig. 87.4). The average disparity of targets from the fixation plane is described as their *depth pedestal*. Stereo-depth discrimination thresholds, measured as a function of the depth pedestal, describe a depth discrimination threshold function that is summarized by a Weber fraction (stereo threshold/depth pedestal). The Weber fraction for stereopsis indicates that the noise or variability of the absolute disparities subtended by the targets is less than 5% over a range of disparity pedestals up to 0.5 degree (Badcock and Schor, 1985). Judgments of depth beyond this range of pedestals are clouded by the appearance of diplopia.

Spatial pooling and uncertainty

Stereo sensitivity can either be enhanced or reduced by nearby targets. The threshold for detecting depth corruga-

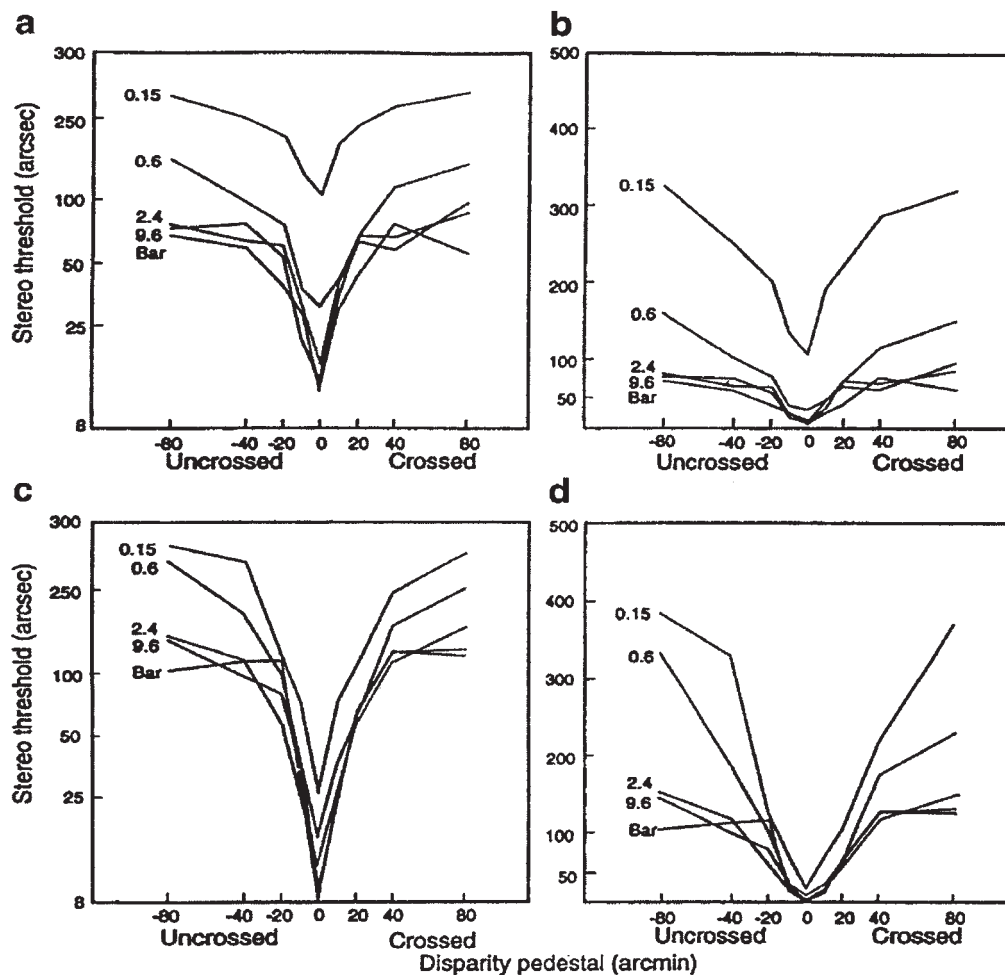

FIGURE 87.4. Threshold for depth discrimination between a test stimulus and a comparison stimulus as a function of the disparity offset (pedestal) of the comparison stimulus. Each curve shows the results using bandpass-filtered bar stimuli whose center spatial frequencies range from 0.15 to 9.6 c/deg. Stereo depth is most sensitive for targets located on the horopter, and threshold increases exponentially with disparity pedestal.

tions of a surface such as the folds in a hanging curtain decreases with depth-modulation frequency (reciprocal of spacing between the folds), up to 0.3 c/deg where the threshold is lowest (Tyler, 1975). At depth-modulation frequencies lower than 0.3 c/deg, the threshold for stereopsis is elevated and appears to be limited by a disparity gradient (i.e., a minimal rate of change in the depth/degree of target separation). At depth-modulation frequencies higher than 0.3 c/deg, the stereo threshold is elevated as a result of depth averaging of adjacent targets. Similar effects are seen with separations between point stimuli for depth (Westheimer, 1986; Westheimer and McKee, 1979).

When a few isolated targets are viewed foveally, changes in the binocular disparity of one target produce suprathreshold depth changes or depth biases in other targets when their separation is less than 4 arc min. This depth attraction illustrates a pooling of disparity signals (Parker and Yang, 1989).

When targets are separated by more than 4 to 6 arc min, the depth bias is in the opposite direction and features appear to repel one another in depth. Attraction and repulsion also occur with cyclopean targets (i.e., targets that can only be revealed by stereo depth, such as clumps of tree foliage) (Stevenson et al., 1991), showing that they are not based simply on positional effects at the monocular level. The enhancement of depth differences by repulsion might be considered a depth-contrast phenomenon that is analogous to Mach bands in the luminance domain (enhanced perceived contrast of edges) that are thought to result from lateral inhibitory interactions. Depth distortions that are analogous to Mach bands have been demonstrated with horizontal disparity variations between vertically displaced contours (Lunn and Morgan, 1996), demonstrating analogous spatial interactions in the horizontal disparity domain and the luminance contrast domain.

FIGURE 87.5. Position and phase encoding of disparity: two possible schemes of disparity encoding are shown. *Position coding:* a, Solid curves show the receptive field profile of left and right eye inputs to a binocular cell. The abscissa for each curve gives retinal position, and the ordinate gives the cell's sensitivity to luminance. b, The disparity tuning of the binocular cell that is sensitive to posi-

tional disparity. *Disparity coding:* c, Solid curves show the receptive field profile of left and right eye inputs to a binocular cell. The abscissa for each curve gives retinal phase, and the ordinate gives the cell's sensitivity to luminance. d, The disparity tuning of the binocular cell that is sensitive to phase disparity.

Frame of reference

Typically, stereo acuity is measured while looking straight ahead with respect to a flat (frontoparallel) frame of reference rather than the curved horopter. The frontoparallel frame of reference is an implicit or familiar frame of reference. Its pattern of disparities is usually symmetrical with respect to the gaze normal direction and the horopter. However, the frontoparallel plane is somewhat arbitrary since it contains disparities that do not lie on the zero-disparity surface of the horopter. A slanted plane can also be used as an arbitrary explicit frame of reference to make relative depth judgments. Indeed, depth discrimination off the plane of fixation is improved when the targets are presented within a reference surface of dots that have the same mean disparity as the pedestal (Andrews et al., 2001). However, with a frontoparallel reference plane, stereo thresholds increase with the distance in depth (disparity pedestal) of targets from the plane of fixation (Badcock and Schor, 1985). These observations suggest that the frame of reference for relative depth judgments is most effective when it is well defined by visual stimuli.

Disparity processing by early spatial filters

Stereo acuity depends upon spatial scale (range of spatial frequencies). The dependence of stereopsis on luminance spatial frequency suggests that disparity is processed early in the visual system by linear channels that are tuned to discrete bands of spatial frequency. When tested with a limited

range of spatial frequencies (narrowband luminance stimulus) (1.75 octaves) such as those produced by a difference of two Gaussians, the stereo threshold becomes lower as spatial frequencies increase up to 2.5 c/deg (Schor et al., 1984a; Smallman and MacLeod, 1994). When expressed as a phase disparity, stereo threshold is constant over this range of spatial frequencies. At spatial frequencies higher than 2.5 c/deg, stereo threshold has a constant position disparity. The constant position disparity at high spatial frequencies contradicts theories of disparity sensitivity based upon phase sensitivity within spatial channels. In addition to phase sensitivity, there may be other factors that limit disparity resolution, such as position sensitivity. Given the presence of both a phase and a position limit, the threshold is set by the limit that is higher. For low spatial frequencies, the constant phase limit would be higher than the position limit, and the converse would be true for high spatial frequencies. The higher limit would determine the threshold.

Disparity coding metrics (phase vs. position)

Physiologically, binocular receptive fields have two fundamental organizational properties (Fig. 87.5). The receptive fields that represent binocular disparity can be offset from a point of zero retinal correspondence (position disparity). They can also have zero positional disparity combined with a quadrature organization in which there is a 90 degree phase shift of the areas of excitation and inhibition in one eye's receptive field compared to the other (phase disparity) (DeAngelis et al., 1995). The position limit at high spatial

frequencies could result from positional jitter in all binocular receptive field sizes. Jitter would have a large influence on the disparity sensitivity of small receptive fields but only a minor influence on the sensitivity of large receptive fields. The same jitter is large relative to the phase coding ability of small (high-frequency) receptive fields. Jitter is responsible for the breakdown of the size-disparity correlation. At high spatial frequencies, stereo threshold is limited by positional uncertainty that causes the threshold to remain constant above 2.5 c/deg. For further discussion of neural mechanisms underlying stereopsis, see Chapter 48.

Other models of stereopsis assume that disparity processing is based solely upon positional information in spatial channels tuned to frequencies above 2.5 c/deg (Kontsevich and Tyler, 1994). In this model, elevated stereo thresholds at low spatial frequencies (below 2.5 c/deg) result from reduced effective contrast of low spatial frequencies passed by the lowest binocular spatial frequency channel that is tuned to 2.5 c/deg. The bandpass stereo tuning characteristics observed with interocular differences in low spatial frequencies (<2.5 c/deg) (Schor et al., 1984b) could result from the differences in effective contrast of these stimuli and interocular inhibition (Kontsevich and Tyler, 1994; Stevenson and Cormack, 2000).

Stereo-depth scaling (mapping from retinal angles to linear depth intervals)

Stereoscopic depth is stimulated by two-dimensional (2D) retinal disparities that can be described in angular units. Some information is lost from the 3D object when it is mapped optically to a 2D retinal image. A given 3D object maps to a specific 2D retinal image pattern; however, a given 2D retinal image pattern maps to many possible 3D scenes (the inverse mapping problem) (Pizlo, 2001). Horizontal retinal image disparity is insufficient to reconstruct a 3D space percept. The same horizontal retinal image disparity can correspond to 1 cm at an arm length and to 1 m at a remote 10 m viewing distance. Despite this growth of the linear depth interval with viewing distance for a fixed angular disparity, we perceive stereo depth veridically. A tennis ball appears to have the same thickness or volume at all viewing distances (depth constancy). Additional information is needed to map the disparity of two retinal images into absolute depth in head-centric (egocentric) space coordinates. In addition to retinal image disparity, stereo-depth perception depends upon the distance and direction (azimuth) of targets relative to the head. Three independent variables involved in mapping stereo depth into head-centric coordinates are retinal image disparity, viewing distance, and the separation in space of the two viewpoints (i.e., the baseline or interpupillary distance). In stereopsis, the relationship

FIGURE 87.6. A top-down view of several slanted surfaces in different locations. Surfaces *A* and *B* are gaze normal. They subtend similar horizontal retinal image disparities, yet they have very different slant angles with respect to the head. Surfaces *A* and *C* both have the same head-centric frontoparallel orientation, but they subtend very different horizontal disparity patterns.

between the linear depth interval between two objects and their retinal image disparity pattern is approximated by the following expression:

$$\Delta d = \eta \times d^2 / 2a \quad (1)$$

where η is retinal image disparity in radians, d is viewing distance, $2a$ is the interpupillary distance, and Δd is the linear depth interval between two targets. The terms $2a$, d , and Δd are all expressed in the same units (e.g., meters). The formula implies that in order to perceive depth in units of absolute distance (e.g., meters), the visual system utilizes information about the interpupillary distance and the viewing distance. The equation illustrates that for a fixed retinal image disparity, the corresponding linear depth interval increases with the square of viewing distance and that information about viewing distance is used to scale the horizontal disparity into a linear depth interval.

Stereo-slant scaling

Disparity cues for surface shape and orientation also depend on target location relative to the head (distance and azimuth). For example, a surface that is parallel to the face has a similar horizontal retinal image disparity pattern when viewed straight ahead to a gaze normal surface that is tilted toward the right eye when viewed in rightward gaze (compare surfaces *A* and *B* in Fig. 87.6). Information about target distance and direction that is needed to discriminate between these two slant stimuli can be obtained from extraretinal and retinal cues. Extraretinal cues include infor-

FIGURE 87.7. Slant (S) = $-\tan^{-1}(1/\mu \ln \text{HSR} - \tan \theta)$.

mation about version and horizontal vergence eye position. Surface orientation or slant can be estimated with a combination of horizontal disparity and eye position cues. Retinal image disparity for horizontal slant about a vertical axis can be described by the ratio of horizontal size of the two retinal images (left/right horizontal image size = HSR) (Ogle, 1962; Rogers and Bradshaw, 1995). For a single surface, the relationship between slant angle and combined cues of horizontal retinal image disparity (HSR), horizontal gaze angle (azimuth) (ϕ), and convergence angle (μ) is given by (Backus et al., 1999) (Fig. 87.7)

$$\text{Slant } (S) = -\tan^{-1}(1/\mu \ln \text{HSR} - \tan \phi) \quad (2)$$

Apart from extraretinal eye position signals, vertical disparity cues can also be used to estimate target azimuth when computing slant. Vertical disparities occur naturally with targets in tertiary directions from the point of fixation (Garding et al., 1995; Gillam and Lawergren, 1983; Liu et al., 1994) (Fig. 87.8). Vertical disparity can be described as the vertical size ratio of the two retinal images (left/right vertical image size = VSR) (Rogers and Bradshaw, 1995). The relationship between slant angle and combined cues of horizontal and vertical retinal disparity and convergence angle is given by (Backus et al., 1999)

$$\text{Slant } (S) = -\tan^{-1}(1/\mu \ln \text{HSR}/\text{VSR}) \quad (3)$$

This is a gaze normal description. Adding the azimuth (ϕ) yields slant relative to the head. The use of vertical disparity for slant perception is demonstrated by the tilt of an apparent frontoparallel plane that is induced by a vertical magnifier before one eye (i.e., the induced effect) (Ogle, 1962). The effect is opposite to the tilt produced by placing a horizontal magnifier before the same eye (the geometric effect). If both a horizontal and a vertical magnifier are placed before one eye in the form of an overall magnifier,

FIGURE 87.8. Vertical disparities occur naturally when targets are placed in tertiary positions while the eyes are aimed in another direction of gaze. Here the target is closer to the left than the right eye, and its image is larger in the left eye. Vertical disparity increases with target azimuth, elevation, and proximity to the observer.

no tilt of the plane occurs. In eccentric gaze, optical geometry causes the proximity of a target to one eye to produce an overall magnification of the image in the nearer eye. This could be sufficient to allow observers to make accurate frontoparallel settings in eccentric gaze. Together, vertical and horizontal magnification provide sufficient information to distinguish between a tilted plane that is viewed straight ahead and a frontoparallel plane viewed in eccentric gaze.

Simultaneous versus sequential stereopsis

One of the primary functions of the visual system is to provide a spatial sense of our surrounding environment. Tasks such as reaching or grasping involve motor interactions between ourselves and objects about us, and they require knowledge about the location and orientation of objects relative to ourselves in head-centric coordinates. Stereopsis is one of our primary senses of spatial layout. Stereopsis is most sensitive to relative disparity between two or more adjacent targets that can be imaged simultaneously within the high-resolution region of the central retina (Westheimer, 1979a, 1979b). Stereo-depth differences are more difficult to estimate when targets are imaged in the periphery, such as when comparing the depths of widely separated targets and only one target can be imaged on the fovea at a time. Under these conditions, stereoscopic depth discrimination is less sensitive than when both targets can be imaged on the fovea (McKee et al., 1990; Schor and Badcock, 1985). Perceiving the depth differences between several targets in different directions requires either that some of the objects be viewed peripherally at the same time (*simultaneous stereopsis*) or that the targets

be viewed sequentially with high-velocity gaze shifts (saccades), at different times, with successive saccadic-foveal fixations (*sequential stereopsis*).

With large target separations, simultaneous stereopsis is impaired by elevated thresholds for disparity discrimination in the retinal periphery. Similar effects are found for stereo-depth discrimination between targets that are presented sequentially in different directions (Enright, 1991; McKee et al., 1990). One target disparity is imaged briefly (150 msec) on the fovea, and when it is extinguished, another target disparity is imaged briefly on an eccentric retinal location while gaze remains fixed in one direction. The task is to compare differences in depth between sequential views of the two targets that are presented one at a time. Simultaneous and sequential stereopsis have identical thresholds when tested with large target separations (>2 degrees) during steady fixation (Enright, 1991; McKee et al., 1990). Thresholds increase proportionately with target eccentricity (Berry, 1948; McKee et al., 1990). Retinal position uncertainty is believed to increase with retinal eccentricity (Levi et al., 1984), and this source of noise is thought to account for the increase of stereo threshold with target separation (McKee et al., 1990).

Thresholds of both simultaneous and sequential stereopsis at 1.5 degrees of target separation are equal (approximately 0.5 to 1.0 arcmin) (Enright, 1991). Simultaneous stereopsis continues to improve at smaller separations down to a lower limit of a few seconds of arc; however, sequential stereopsis does not improve at separations of less than 2 degrees (McKee et al., 1990). With small target separations, the sequential stereo threshold is three to four times higher than for a single simultaneous view of the same target (Enright, 1991; Kumar and Glaser, 1994; McKee et al., 1990; Westheimer, 1979a). Eye position uncertainty, in the form of unregistered vergence fluctuations, is believed to account for the elevated threshold for sequential stereopsis (without eye movements) (McKee et al., 1990). Vergence noise would not impair simultaneous stereopsis because vergence jitter is common to binocular images seen simultaneously, and it is canceled in a presumed differencing process (Westheimer, 1979a).

Sensorimotor interactions

Saccadic gaze shifts in sequential stereopsis improve depth discrimination between widely spaced targets by imaging them near the fovea and horopter, where disparity resolution is most acute. Stereo sensitivity to depth differences between widely separated targets (>5 degrees) can be improved by as much as 50% with sequential gaze shifts that image the two targets sequentially onto the fovea compared to the same test without gaze shifts (Enright, 1991; Ogle, 1956; Wright, 1951). This improvement is thought to be due primarily to

the reduction of retinal position uncertainty when targets are imaged on the fovea (McKee et al., 1990).

Depth comparisons between targets in different locations are represented in head-centric coordinates, and stereo-depth perception depends upon target location relative to the head as well as horizontal retinal image disparity. In particular, vergence information is essential for estimating target distance from the head when vertical disparity information is sparse or absent (Brenner and van Damme, 1998; Wright, 1951). In the extreme case, vergence aligns the eyes precisely during fixation so that absolute retinal image disparity is reduced to zero. Yet depth differences between the sequentially fixated targets that subtend zero disparity can still be discriminated because efferent signals that align the eyes can be used to estimate target distance from the head (Brenner and van Damme 1998). Stereo threshold is limited by the uncertainty with which eye position is sensed (Backus et al., 1999), by the duration or dwell time of each fixation, and by time delays between sequential views (Kumar and Glaser, 1994) that are related to the dynamics of saccadic eye movements (Bahill et al., 1975). Even small to moderate saccades take 25 to 50 msec (Bahill et al., 1975), and this introduces an inter-stimulus interval (ISI) during which information about the first target depth may be lost or corrupted. The ISI could be extended beyond the duration of the saccade by saccadic suppression (reduced visual sensitivity during saccades) that occurs while changes in visual direction are updated to correspond to abrupt changes in eye position (Matin, 1986).

The minimum dwell time for fixating in a given direction of gaze is approximately the latency for a saccadic eye movement, or about 200 msec. The simultaneous stereo threshold is elevated by over fivefold when target duration is reduced from 1 second to about 7.5 msec (Harwerth and Rawlings, 1977). Thresholds for sequential stereopsis are reduced as the number of alternate saccadic fixations increases up to four to eight saccades (two to four cycles of alternate fixation) (Enright, 1991). Sequential stereo thresholds also become lower during the first four to six cycles of alternating sequential target presentations to the fovea without saccadic eye movements (Kumar and Glaser, 1994). Repeated fixations allow averaging to reduce the uncertainty of retinal disparity cues and target location sensed with eye position cues. In addition, the memory of sequential views could be refreshed by repeated gaze shifts (Hayhoe et al., 1998). Thresholds become elevated as stimulus onset asynchrony (SOA) increases (Kumar and Glaser, 1994). Increasing stimulus duration of sequential stimuli elevates the stereo threshold by lengthening the time between the onsets of the two stimuli (i.e., increase of SOA) (Kumar and Glaser, 1994). The improvement of sequential stereopsis appears to depend on the number of times the stimulus appears and the SOA, rather than the total presentation time. It is more

important to have short than long time intervals between sequential stereo stimuli.

Temporal masking

Temporal masking (Alpern, 1953) also elevates thresholds for sequential stereopsis (Butler and Westheimer, 1978; Tyler and Foley, 1974). Saccadic gaze shifts produce time delays between successively fixated targets. The transient onset of the second stimulus could mask the appearance of the first stimulus (backward masking) or vice versa, especially when the two stimuli are large textured surfaces (Kahneman, 1968). Backward masking has been shown to influence sensitivity to apparent motion with random-dot patterns (Braddick, 1973). An example of backward masking in stereopsis was reported by Butler and Westheimer (1978). They observed that the stereo threshold was elevated by adjacent contours presented 100 msec after the onset of the stereo test stimulus. The spatiotemporal masking is greatest when the mask and stereo stimulus have the same disparity. Masking is reduced by half when the disparity of the mask differs from that of the stimulus by only 15 sec arc.

Calibration errors

The magnitude of perceived depth difference between two targets may differ in simultaneous and sequential stereopsis. Calibration errors for retinal and extraretinal cues for stereo depth could have different emphasis or weights in these two forms of stereopsis. Retinal and extraretinal cues for stereo depth, including horizontal disparity, retinal eccentricity, and eye position signals, often have calibration errors that could produce perceived depth and slant biases (i.e., constant errors). Biases in horizontal disparity are related to uniform and nonuniform magnification effects for perceived direction, as described by Ogle (1962), that cause planar surfaces to appear curved and slanted. Biases in perceived visual direction are described by Ogle (1962) as partition errors. Perceived directions, stimulated by equal physical horizontal retinal eccentricities from the fovea (nasal vs. temporal), appear to have unequal perceived magnitudes (unequal oculocentric directions) in the nasal and temporal halves of the visual field (Kundt and Munsterberg asymmetries). These errors in perceived eccentricity of targets imaged on the two hemiretinas could cause directional biases of head-centric depth and slant estimates based on retinal eccentricity and gaze azimuth (θ) (see equation 2). Eye movement signal biases are related to minor muscle paresis or weakness within the oculomotor system that can cause over- or underestimation errors of sensed eye position that vary with direction of gaze. When foveal and peripheral targets are viewed simultaneously without eye movements, retinal position and disparity biases contribute to constant errors of depth and slant

estimates. When separated targets are fixated foveally with sequential gaze shifts, eye position biases will also contribute to constant head-centric errors of depth and slant estimates. Thus, the perceived depth difference between two widely spaced targets might appear different, depending on whether they were fixated sequentially with the fovea or viewed simultaneously at two different retinal locations.

Conclusions

Space perception is based on several sources of information that are estimated by the visual system. The perception of direction, distance, surface shape and orientation, and object volume can be obtained from monocular sources of information including motion parallax, texture gradients, perspective cues, and stimulus overlap (partial occlusion), and from the binocular source of retinal image disparity (stereopsis). The subject of stereopsis has been used to investigate spatial resolution limits of the visual system, to learn how 3D spatial information is represented in the brain, and to understand how perceptual systems reduce information content to a manageable level and also reduce information ambiguity of stimuli by employing ecological inferences as well as computational strategies.

Disparity by itself is an ambiguous depth cue since it is in retinal coordinates. To yield a depth percept, it must be mapped into head-centric coordinates using information about direction and distance to interpret relative depth magnitude and to reference depth in head-centric coordinates. Currently, a concentrated effort is being made to determine how this mapping occurs and the sensory and motor sources of information that are used to obtain information about distance and direction. Ultimately, these investigations will lead to an understanding of how we build up a 3D perceptual representation of space with sequential views such that our percept of space extends beyond any momentary field of view.

88 Binocular Rivalry

RANDOLPH BLAKE

WE VIEW THE WORLD through two laterally separated eyes, and yet we experience a single, stable visual world. The brain, in other words, manages to blend, or fuse, the two monocular images in a way that belies any hint of their dual origins, and it does so in a way that extracts stereoscopic information about the three-dimensional (3D) layout of objects in the environment. Several other chapters in this volume (Chapters 48, 49, and 87) cover material on binocular single vision and stereopsis.

The neural operations responsible for binocular single vision and stereopsis, however, are labile in the sense that they can be disrupted when dissimilar monocular stimuli are imaged on corresponding retinal locations. Under these conditions, the eyes transmit contradictory information to the brain. Faced with this contradiction, the brain lapses into an unstable state characterized by alternating periods of monocular dominance that persist as long as the eyes receive discordant stimuli—the phenomenon termed *binocular rivalry*. This chapter introduces the phenomenon, describes major characteristics of rivalry including conditions under which it does and does not occur, summarizes what is known about the neural bases of rivalry, and concludes with a section on the role of rivalry in normal vision. Because the literature on rivalry is so large, a comprehensive review is beyond the scope of this chapter. Interested readers are referred to any of several recent reviews of this literature (Blake, 2001; Fox, 1991; Howard and Rogers, 1995). For a very thorough, up-to-date bibliography on rivalry, take a look at Dr. Robert O'Shea's reference list on the World Wide Web at http://psy.otago.ac.nz/r_oshea/br_bibliography.html. Finally, readers are invited to visit the author's web page, which provides demonstrations of binocular rivalry and some of its major characteristics: <http://www.psy.vanderbilt.edu/faculty/blake/rivalry/BR.html>.

Binocular rivalry's characteristics

EXPERIENCING RIVALRY You can experience rivalry for yourself using each of the three pairs of pictures in Figure 88.1. You will need to follow the instructions in the caption to achieve the conditions for rivalry, and when you do, you will notice several of rivalry's hallmark characteristics. First, note that your visual experience is highly dynamic, with one figure dominating perception for several seconds, only to become phenomenally suppressed in favor of the competing

figure. Sometimes you may see bits and pieces of both figures, creating an impression of a dynamic patchwork. But often you'll see only one figure or the other for several seconds at a time, and neither figure will stay exclusively visible indefinitely (unless you have a strongly dominant eye). Note, too, that you cannot hold one eye's view dominant at will, even when one of the competing figures is a potentially interesting picture such as a female face; the alternations in dominance and suppression evidently are obligatory and may stem from neural adaptation of the currently dominant image (Lehky, 1988; Matsuoka, 1984; Mueller, 1990). You can, however, rescue one eye's figure from suppression prematurely by introducing an abrupt "transient" in the suppressed figure. In the laboratory, this can be accomplished by abruptly incrementing the contrast of a suppressed target (Blake et al., 1990; Wilson et al., 2001) or by introducing motion into a previously stationary, suppressed target (Walker and Powell, 1979). To demonstrate how these transient events can disrupt suppression, view rivalry between a pair of the rival figures in Figure 88.1. When one of the targets becomes suppressed, simply flick your finger in front of that figure; this maneuver will immediately restore the figure to dominance. If you were to repeatedly break suppression of that figure in this way—artificially forcing it to remain dominant—you would also find that it would stay dominant for shorter and shorter periods of time (Blake et al., 1990).

When considering binocular rivalry, it is important not to confuse it with Troxler's effect, the spontaneous fading of a visual figure that can occur when maintaining strict visual fixation. Troxler's effect does not require discordant stimulation to the two eyes, and it occurs readily in peripheral parts of the visual field and can be observed in central vision with targets of a few degrees in visual angle or larger. Troxler's effect is usually attributed to local retinal adaptation, whereas rivalry almost certainly arises from central neural events. It is important to distinguish Troxler's effect from rivalry suppression when studying the disappearance of rival targets viewed in the periphery (Levelt, 1965).

WHAT TRIGGERS RIVALRY Binocular rivalry can be instigated by differences between left- and right-eye views along almost any stimulus dimension, including contour orientation (Wade, 1974), spatial frequency (Fahle, 1982), and motion velocity (Breese, 1899; van de Grind et al., 2001).

FIGURE 88.1. Provided here are three pairs of rival targets, each of which illustrates the alternations in dominance and suppression characterizing binocular rivalry. To achieve dichoptic stimulation (i.e., presentation of each figure to separate eyes), you must view these pairs either by crossing your eyes or by diverging your eyes, so that the fovea of each eye is seeing one image or the other. (Readers unable to “free-fuse” the targets may see anaglyphic examples of rivalry presented on the author’s web page: <http://www.psy.vanderbilt.edu/faculty/blake/rivalry/BR.html>.) While viewing the upper pair of rival targets—faces of two differ-

ent people—see if you can hold one face perceptually dominant indefinitely. Most people viewing rival targets find this to be impossible. The middle pair of rival targets were used by Wilson et al. (2001) to study *dominance waves* experienced as one portion of a previously suppressed figure emerges into dominance, quickly spreading to encompass the rest of the figure. To see these waves, fixate the central “bull’s-eye” portion of the figure and see what happens as the radial grating assumes dominance. The bottom pair of rival targets are computer-generated images created by David Bloom and used here with permission of the artist. (See color plate 74.)

FIGURE 88.2. When one views binocularly a scene in which one object partially occludes another nearby object, one eye will see portions of the occluded object that are invisible to the other eye. This viewing situation—illustrated schematically in the upper part of this figure—creates a local region where dissimilar images stimulate corresponding retinal areas, conditions normally sufficient for binocular rivalry. When this condition is simulated in the laboratory, the incidence of rivalry is reduced (Shimojo and Nakayama, 1990). The pair of half-images in the lower part of the figure may be used to compare binocular rivalry for a “valid” binocular con-

figuration and an “invalid” binocular configuration. If you combine the two half-images by crossing your eyes, use the middle and left-hand figures; if you combine the two half-images by uncrossing your eyes, use the middle and right-hand figures. When the two half-images are appropriately fused, the gray squares will stand out in depth from the textured background, and the partially occluded striped object will be valid in the upper part of the figure and invalid in the lower part. Compare how frequently the striped region disappears in the upper versus the lower field.

There are several conditions, however, in which dissimilar stimulation to corresponding areas of the two eyes does *not* seem to trigger rivalry. One of these is when the two eyes view rapidly flickering rival targets (O’Shea and Blake, 1986; O’Shea and Crassini, 1984), and another is when the two rival targets are very low in contrast, near their threshold for visibility (Liu et al., 1992). In both instances, people describe seeing the binocular superimposition of the two dissimilar targets. It has been noted that these two stimulus conditions—rapid flicker and low contrast—both favor activation of the magnocellular pathway (see Chapter 30), which could mean that rivalry is more tightly coupled to neural activity in the parvocellular pathway (Carlson and He, 2000; Ramachandran, 1991).

Another interesting situation where dissimilar monocular stimulation does not yield rivalry has to do with the geome-

try of 3D space (Shimojo and Nakayama, 1990). Consider the two monocular images produced when you view a 3D scene in which one object (a gray rectangle in this example) partially occludes another (a striped rectangle), as illustrated by the drawing in the top part of Figure 88.2. In this situation, your right eye would be seeing parts of the occluded object that are invisible to your left eye. This means, in other words, that a region of the right eye’s image will contain a pattern of optical stimulation that is different from the optical stimulation falling on the corresponding region of the left eye’s image. (By the way, this geometrical consequence of looking at the world from two different perspectives was realized and discussed by Leonardo da Vinci.) Despite this conflicting stimulation to corresponding retinal areas, observers report that vision is relatively more stable when viewing pairs of images that mimic this situation, implying

FIGURE 88.3. Two stamps that are nearly identical in form but different in color. Free-fuse these two rival stamps and note the appearance of color. (See color plate 75.)

that the brain “understands” that the “conflict” is attributable to the 3D layout of objects in the world (Nakayama and Shimojo, 1990). Interestingly, when the images going to the two eyes are exchanged, observers experience more instances of binocular rivalry within this region of conflict. (Readers may experience the dependence of rivalry on scene interpretation using the pair of stereo images in the bottom part of Fig. 88.2.) These observations imply that the brain knows which eye is receiving which figure, which in turn determines whether one experiences stable fusion or unstable rivalry (see also Blake and Boothroyd, 1985).

Finally, there is some evidence that different “colors” viewed by the left and right eyes do not necessarily rival each other in the same way that different forms do. This can be seen in Figure 88.3, which presents a version of one of the stimulus conditions studied by Creed (1935) in his widely cited (and sometimes misinterpreted) study of binocular fusion and binocular rivalry. Note that the two stamps are identical in form except for the numerals and words signifying the stamps’ value; the colors, however, are distinctly different. When these two images are viewed in binocular combination, however, the color differences do not alternate in dominance; instead, people describe seeing a “washed-out” brown. Whatever the perceived color, it is clear—to put it in Creed’s words—that “we are not dealing with the common type of binocular rivalry in which the form that prevails brings with it the colour of its own object” (p. 383). Using these stamps, you might also try to compare the color of the numeral 1, when it is dominant, with the numeral 2, when it is dominant. Here, too, there is no sense that color changes over time, even though the form does. Again, to quote Creed, “Successive rivalry of forms is therefore not necessarily accompanied by successive rivalry of the corresponding colours” (p. 384).

TEMPORAL AND SPATIAL DYNAMICS The alternations in dominance and suppression during rivalry are not periodic, like the oscillations of a metronome; instead, successive durations of visibility are independent, random events that

collectively conform to a gamma distribution (Fig. 88.4). In other words, one cannot predict exactly how long a given duration of dominance will last (Fox and Herrmann, 1967; Lehky, 1995; Levelt, 1965). However, it is possible to influence the overall predominance of one figure over another, where *predominance* is defined as the total percentage of time that a given figure is dominant during an extended viewing period. Thus, for example, a high-contrast rival figure will tend to predominate over a low-contrast one (Mueller and Blake, 1989), and this increased predominance comes about mostly because the durations of suppression of a high-contrast figure are shorter, on average, than those of a low-contrast figure. It is as if a “stronger” stimulus manages to overcome suppression more quickly than does a “weaker” one (Blake, 1989; Fox and Rasche, 1969). When you stop and think about it, this also means that rivalry alternations should be faster, on average, between a pair of high-contrast rival targets than between a pair of low-contrast rival targets; this is, in fact, the case (Levelt, 1965). Besides contrast, other stimulus variables that “strengthen” a rival target and thereby enhance its predominance include spatial frequency (Fahle, 1982), motion velocity (Blake et al., 1998; Breese, 1899), and luminance (Levelt, 1965).

A rival figure embedded in a larger meaningful context also tends to predominate over one viewed in isolation, but in this case increased predominance arises from a lengthening of the durations of dominance, not an abbreviation of suppression durations (Sobel and Blake, 2001). This dissociation between the effect of a rival figure’s context and the effect of the strength of the figure itself suggests that rivalry dynamics have multiple determinants (Blake, 2001). There are also reports in the literature that meaningful or familiar rival targets predominate in rivalry over less meaningful or unfamiliar ones (for a review of this literature, see Walker, 1978; for an alternative interpretation of the role of meaning in rivalry, see Blake, 1988). It would be informative to replicate these results and, moreover, to learn whether increases in predominance with meaning, if reliably demonstrable, come about through lengthened dominance durations. To the extent that meaning influences other aspects of visual perception (Raftopoulos, 2001), it would not be surprising to find that meaning influences dominance periods of rivalry, for the dominance phases of rivalry appear to be functionally equivalent to normal monocular vision (Fox, 1991).

The potency of global context to influence the temporal dynamics of rivalry could reflect the involvement of higher-level visual processes in rivalry. Is there other evidence for the involvement of such processes? There are several published studies pointing to a role for attention in the control of rivalry dynamics. Several decades ago, Lack (1978) showed that observers could be trained to prolong one eye’s view during rivalry without resorting to tricks such as moving

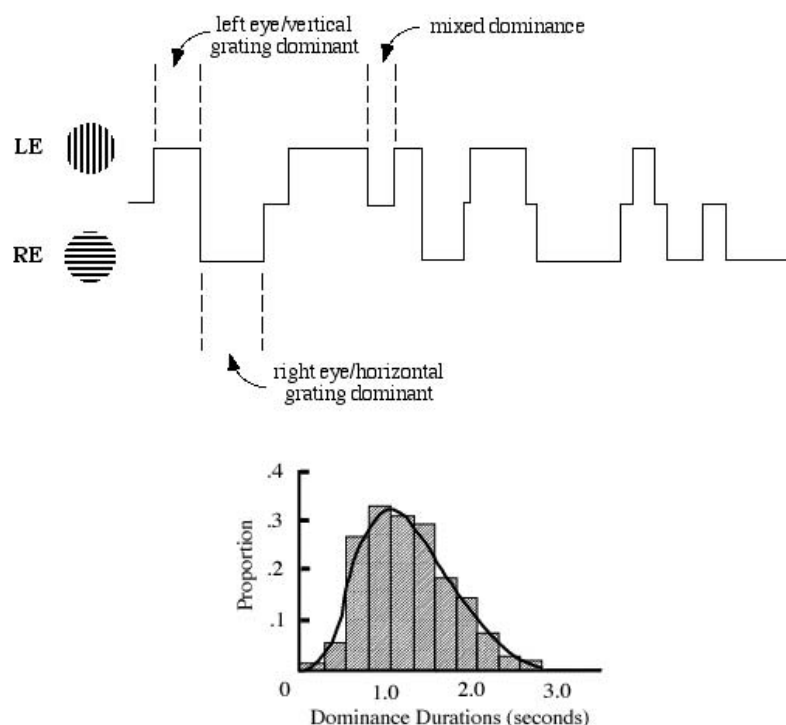

FIGURE 88.4. When an observer presses buttons to indicate successive periods of dominance of two rival targets, those successive durations are randomly distributed, independent variables (Levelt, 1965). The upper diagram shows a representative time line of successive periods of exclusive dominance of a vertical rival grating (viewed by the left eye in this case) and periods of exclusive dominance of a horizontal rival grating (viewed by the right eye). Intermixed among periods of exclusive dominance are occasional periods of “mixed” dominance during which portions of both rival

gratings are visible in a patchwork mosaic pattern. The incidence of mixed dominance tends to be greater with rival targets larger in angular subtense (Meenes, 1930). When dominance durations measured during extended tracking periods are plotted as a frequency histogram (lower portion of the figure), that distribution is well fit by a gamma distribution (solid line in the histogram). In general, the gamma distribution provides a close fit to rivalry alternation data when parameters are adjusted for individual differences (Fox and Herrmann, 1967; Logothetis, 1998).

the eyes in a manner that would favor that view. Instead, Lack’s observers purportedly directed attention to the favored target and thereby prolonged its visibility. It should be noted that rivalry alternations were not abolished under these conditions; despite focused attention, spontaneous reversals in dominance still occurred, albeit less frequently. More recently, Ooi and He (1999) showed that directing attention to a region of the visual field where a rivalry target is currently suppressed boosts the potency of visual motion at that region of the field to break suppression of that target.

What happens when one views multiple rival patterns distributed throughout the visual field? Take a look at the rival display presented in Figure 88.5, a pair of arrays of black and white Gaussian (i.e., blurred) blobs, with each white blob in one array pitted against a black blob in the other array. View the two arrays dichoptically using the free-fusion technique, hold your gaze steadily on the small fixation cross, and concentrate on the pattern of dominance throughout the visual field. Note how often all the black blobs or all the white blobs are simultaneously dominant. When observers actually track these periods of simultaneous dominance, the total incidence turns out to be greater than what would be

predicted if the individual blobs were rivaling independently on their own (Logothetis, 1998). There is a tendency, in other words, for dominance periods of coherent patterns to become perceptually entrained.

This tendency is even more pronounced in the color rival patterns shown in Figure 88.6, a variation of the display created by Diaz-Caneja (1928; see Alais et al., 2000). Here the addition of color further encourages grouping according to coherence, as you can confirm by comparing the rivalry associated with the gray-scale version and the color version.

In both Figures 88.5 and 88.6, periods of coherent dominance can be achieved only by very specific combinations of left-eye and right-eye components that are dominant simultaneously. This means, then, that one eye alone cannot be responsible entirely for dominance at any given moment. Instead, dominance may consist of a patchwork of visible features (Blake et al., 1992; Meenes, 1930), in this case collated from left- and right-eye views. Interocular grouping during rivalry has been nicely documented by Kovács et al. (1997), and it has been studied by others as well (Alais and Blake, 1999; Dörrenhaus, 1975).

FIGURE 88.5. Rival display consisting of spatially distributed rival targets. Each eye's view consists of an array of blurred circles (Gaussian blobs) differing in contrast polarity between left- and

right-eye views. Free-fuse these two targets and note how often all blobs of a given contrast polarity are simultaneously dominant. (This display is a version of one described by Logothetis, 1998.)

One other intriguing characteristic of rivalry deserves mention, one having to do with the appearance of rival figures during transitions from suppression to dominance. Looking again at rivalry produced by the rival pair in the second row of Figure 88.1, pay particular attention to the emerging appearance of the rings as they assume dominance. You will probably notice that dominance originates

within a restricted region of a ring and spreads from there to encompass the entire figure. These “waves” of dominance are typical of rivalry produced by all sorts of rival figures; they imply the existence of neural “cooperativity” wherein interconnections among neighboring ensembles of neurons promote the spread of activation over spatially extended regions of cortical tissue. Wilson et al. (2001) estimated the

FIGURE 88.6. Two versions of the well-known display of Diaz-Caneja (1928). Upon viewing the gray-scale version (upper pair of rival targets), observers often see a complete bulls-eye pattern or a complete pattern of vertical lines. This implies that portions of

each eye's target are simultaneously dominant, presumably promoted by the spatial grouping that produces a coherent figure. This tendency toward grouping is even stronger in the color version of this figure shown at the bottom. (See color plate 76.)

speed with which dominance waves travel around the circumference of circular rival targets like those pictured in the second row of Figure 88.1, coming up with an average wave speed of about 4 degrees of visual angle per second. This estimated wave speed was even faster when the contours forming the rival target were collinear (i.e., the target was a concentric grating), presumably because waves of dominance travel more effectively along collinear contours. Wave speed (expressed in units of visual degrees per second) was also faster for larger rival targets whose contours were imaged in more peripheral regions of the retina. Expressed in units of cortical tissue (not degrees of visual angle), however, wave speed remained constant with retinal eccentricity, implying that these waves are being generated in a visual area whose magnification factor matches that for visual area V1 (i.e., the exaggerated neural representation of the fovea in the visual cortex).

With these spatial and temporal characteristics of binocular rivalry in mind, we turn next to a consideration of the source of interest in rivalry. Why have vision scientists been fascinated with this phenomenon for almost two centuries, and why in recent years have neuroscientists become intrigued with rivalry?

Binocular rivalry and visual awareness

Binocular rivalry was first systematically described by Sir Charles Wheatstone in his famous monograph on binocular stereopsis (Wheatstone, 1838). But it was Hermann von Helmholtz (1866/1925) and William James (1891) who brought rivalry to the forefront of psychology by treating it as a paradigm case for the study of attention. The noted British neurophysiologist Sir Charles Sherrington (1906) also exploited rivalry to make the case that the brain analyzed left- and right-eye views independently and merged the two views only after each had been fully elaborated. Expressed in contemporary terms, binocular rivalry was construed as a high-level cognitive activity involving competition between conflicting object descriptions. This conceptualization was maintained throughout much of the twentieth century (Walker, 1978), and it led to some unusual ideas about rivalry's practical applications. For example, some psychologists thought that rivalry might provide a revealing indirect tool for assessing intelligence (Crain, 1961), personality (Kohn, 1960), and a tendency to perceive violence (Toch and Schulte, 1961). Those psychometric applications never really caught on, although recent work by Pettigrew (2001) suggests that the issue is not dead.

What has caught on during the past decade or so is the idea that rivalry may provide a powerful tool for studying the neural concomitants of visual awareness (Blake, 1997; Crick and Koch, 1998; Logothetis, 1998). After all, a complex suprathreshold rival pattern can disappear from

visual awareness for seconds at a time, even though that pattern remains imaged on the eye; from a perceptual standpoint, a suppressed pattern temporarily ceases to exist. It should be possible, then, to find fluctuations in neural activity correlated with the intermittent appearance and disappearance of that pattern. And while the search for those neural events has not produced unambiguous answers, the initial results, summarized in the next paragraph, are tantalizing.

Brain imaging studies have discovered modulations in hemodynamic responses and, by inference, neural activity in visual areas of the brain that are tightly correlated with fluctuations in dominance and suppression during rivalry. These response modulations are observed in brain areas as early as primary visual cortex (Lee and Blake, 2002; Polansky et al., 2000; Tong and Engel, 2001), and they are even more pronounced in higher cortical areas in the temporal lobe (Tong et al., 1998) and in the parietal lobe (Lumer et al., 1998). Visual evoked potential measurements (Brown and Norcia, 1997) and neuromagnetic responses (Srinivasan et al., 1999) corroborate the involvement of occipital lobe regions in rivalry but do not pinpoint exactly where in the occipital lobe neural activity is varying with perception. Single-unit studies have recorded action potentials from neurons in awake monkeys trained to report rivalry alternations, and here the evidence points to an increasingly tight coupling between neural firing rate and perception as one moves from primary visual areas to higher cortical regions in the temporal lobe (Leopold and Logothetis, 1996; Logothetis and Schall, 1989; Sheinberg and Logothetis, 1997). Besides neural firing rate, temporal patterns of neural activity also may be correlated with dominance and suppression states during rivalry (Fries et al., 1997), a possibility that could tie rivalry to the larger issue of the role of synchronized neural discharges in perceptual grouping (Engel et al., 1999).

Although admittedly more indirect, perceptual data can also be used to draw inferences about the neural operations mediating binocular rivalry. Reiterating a point made earlier, a normally visible monocular stimulus is temporarily erased from sight during rivalry. To what extent does that stimulus remain visually effective despite its absence from phenomenal awareness? Answers to this question can shed light on the neural locus of rivalry relative to other visual processes (Blake, 1995). If suppression blocks input to a neural processing stage responsible for a given aspect of vision, that blockage should be reflected in visual perception. To illustrate this strategy in operation, consider the well-known motion aftereffect (MAE), that is, the illusory perception that a stationary object is moving produced by prolonged exposure, or adaptation, to real motion (see Chapter 83 for more on the MAE). It has been found that the MAE can be generated even when the adaptation motion itself is suppressed from awareness for a substantial portion of the adaptation

phase owing to binocular rivalry (Lehmkuhle and Fox, 1976; O'Shea and Crassini, 1981). The enduring effectiveness of motion signals in the face of suppression implies that the neural events underlying adaptation transpire prior to the site at which suppression occurs (or, alternatively, that the two occur within parallel pathways). In contrast, the cognitive process termed *picture priming* is disrupted by suppression, as evidenced by the failure of a normally effective picture presented to a suppressed eye to facilitate performance on a subsequent picture-naming task (Cave et al., 1998). This finding implies that suppression temporarily cuts off the flow of information to those neural mechanisms responsible for registering information crucial for object recognition. In general, suppression provides a potentially powerful inferential "landmark" for pinpointing the relative sites of neural processes within the hierarchical stages of visual information processing.

Perceptual measures also disclose other potentially revealing properties of the neural events underlying rivalry. It is well known, for example, that visually presented probe targets are harder to detect when those probes are presented to an eye during suppression, compared to detection during dominance (Wales and Fox, 1970). Evidently, the neural events mediating suppression of a given rival figure generalize to other, new information presented to the same region of the eye viewing that suppressed figure. However, the loss in sensitivity accompanying suppression phases is surprisingly modest in view of the fact that during suppression a complex high-contrast figure is being erased from conscious awareness for several seconds at a time. It remains to be learned how such a profound loss of vision can be accomplished by neural operations that produce only a very modest loss in overall visual sensitivity.

Is rivalry occurring all the time?

Binocular rivalry admittedly is experienced under rather artificial conditions that have no resemblance to those typifying everyday visual experience. Indeed, one leading authority on visual perception has characterized the conditions producing rivalry as "optical trickery" (Gibson, 1966). However, an enduring idea in vision science is that rivalry is occurring *all* the time, including during everyday viewing. Alternations in perception are not seen, the argument goes, because normally the two eyes are viewing the same visual scene and, therefore, these alternations are not visually conspicuous. Known as *suppression theory*, this idea, odd as it may seem, has been seriously advocated by a number of vision scientists over the years (Asher, 1953; Hochberg, 1964; Wolfe, 1986).

How can we know whether normal vision entails chronic, inconspicuous binocular rivalry? Recall from the previous section that periods of suppression are accompanied by

decreased visual sensitivity relative to an eye's sensitivity during dominance. If binocular vision always involves alternating suppression, even when the two eyes view the same scene, losses in visual sensitivity should be a symptom of that alternating suppression. Of course, during normal vision one would not know which eye was temporarily suppressed, but by chance alone, a series of brief test probes presented to one eye should find that eye in the suppression state approximately half of the time. Thus, probe sensitivity should suffer compared to a condition where viewing is monocular and, therefore, dominance is ensured. When these kinds of comparisons are made, however, normal single vision shows no evidence of being accompanied by intermittent losses in visual sensitivity (Blake and Camisa, 1978; O'Shea, 1987). For this and related reasons, it is generally recognized that binocular fusion takes precedence over binocular rivalry. Only when the two eyes view explicitly conflicting images does vision lapse into reciprocal periods of dominance and suppression. This is an important fact to know, for it implies that the neural concomitants of rivalry should be measurable only when a viewer is actually experiencing rivalry and not when experiencing stable binocular single vision.

While suppression cannot be the sole mechanism of binocular single vision, there are still everyday viewing situations where suppression probably does contribute to perception. It is true that left and right foveas rarely receive dissimilar stimulation for any length of time; the oculomotor system seeks to correct this situation by altering the vergence angle until matching features are imaged on the two foveas. There are, however, locations on the two retinas where dissimilar monocular images strike corresponding retinal areas, an inevitable consequence of the geometry of binocular vision. Objects located well in front of or well behind the horopter do cast images on distinctly different areas of the two eyes, and the resulting disparities will be too large for the stereoscopic system to resolve. Yet one ordinarily does not experience the consequences—confusion or diplopia—of this dissimilar monocular stimulation. Binocular single vision, then, may be accomplished by two processes, binocular fusion and binocular suppression (Ono et al., 1977). The potent inhibitory process revealed during rivalry, in other words, may contribute to normal binocular single vision.

For some individuals with chronic eye misalignment (i.e., the condition called *strabismus*, described in more detail in Chapters 12 and 14), suppression may indeed be operating all the time throughout the entire binocular visual field. After all, the stimulus conditions eliciting rivalry suppression and strabismic suppression are comparable: corresponding areas of the two eyes receive discrepant inputs. (In effect, the eyes "disagree" about the nature of the stimulus located at a given region of visual space.) Indeed, this assumption of

similarity of mechanisms appears in classic texts on ophthalmology (e.g., Duke-Elder, 1949). Moreover, there is some evidence suggesting that the two forms of suppression are comparable psychophysically (Blake and Lehmkuhle, 1976; Fahle, 1983; Holopigian, 1989). Inspired by this possible link, several laboratories are utilizing visual evoked potentials to examine the development of rivalry and binocular interactions in very young infants (Birch and Petrig, 1996; Brown et al., 1999), one motive being to relate those findings to the onset of strabismic suppression.

Is rivalry equivalent to other forms of multistable perception?

Binocular rivalry is not the only phenomenon where perceptual experience fluctuates even though the physical input remains unchanged, a behavior sometimes called *multistability*. Other compelling examples include bistable figures (wherein an ambiguous figure fluctuates between alternative figure/ground organizations or between alternative perspective interpretations; see Logothetis, 1998), monocular rivalry (in which two physically superimposed patterns dissimilar in color and form rival for dominance; see Campbell et al., 1973), and motion-induced blindness (wherein a normally visible stationary pattern is erased from awareness by a superimposed global moving pattern; see Bonnef et al., 2001). In all these cases, binocular rivalry included, the brain is confronted with conflicting or ambiguous information about the nature of an object at a given location in visual space. And descriptively speaking, the brain resolves this conflict by “entertaining” alternative perceptual interpretations over time. Several investigators have commented on the similarities in temporal dynamics among these various forms of perceptual instability and have concluded, therefore, that all may stem from common neural operations (Andrews and Purves, 1997; Pettigrew, 2001). This commonality certainly deserves closer examination, perhaps using some of the established techniques (e.g., test probes) that have been used to characterize binocular rivalry’s properties.

Conclusions

Binocular rivalry is inherently fascinating: visual experience fluctuates between alternative perceptual interpretations even though the input to vision remains unchanged. It is not surprising, then, that rivalry has enjoyed enduring interest over the past century and a half. But it’s really only during the past decade that the study of rivalry has become widely viewed as a serious, powerful “instrument” to be exploited by neuroscience in its attack on the mind/brain problem. Rivalry’s increased popularity has been accompanied by a number of clever psychophysical studies documenting the involvement of context, attention, and meaning in the pro-

motion of dominance. Indeed, concrete evidence of rivalry’s importance in visual neuroscience is the inclusion of a chapter on this subject in this volume.

89 Sensorimotor Transformation in the Posterior Parietal Cortex

HANSJÖRG SCHERBERGER AND RICHARD A. ANDERSEN

THE POSTERIOR PARIETAL CORTX (PPC) of the primate brain is an important structure for sensorimotor integration. One of its roles is the formation of intentions, or high-level plans for movement. The PPC can be subdivided into several sub-regions that represent maps of intentions for the planning of saccadic eye movements, reach movements, and grasping movements. These intention-related regions in the PPC appear to participate in the multisensory integration and coordinate transformations necessary for the generation of movements, and these functions seem to be facilitated by a unique distributed code for space representation. In at least two regions, the response fields of neurons are coded in eye-centered coordinates, independent of the sensory input modality (vision or audition) and the motor action that was performed (reach or saccade). Moreover, these retinal response fields in the PPC are gain-modulated by the position of the eye, head, and limb. Hence, space is not coded in a single-defined spatial reference frame in the PPC, but in a distributed fashion that allows other groups of neurons to read out spatial target locations in a variety of reference frames. The PPC also seems to participate in decision processes for movement generation, consistent with its role in sensorimotor transformation. Adaptation processes may constantly optimize the alignment of neural representations in the PPC, and the circuits are even flexible enough to allow the representation of new stimuli when they become relevant for behavior.

Knowing how intentions are encoded in the PPC could lead to a potential medical application. Intentions could be used to control a neural prosthesis for paralyzed patients. Such a device would read out the activity of PPC neurons, decode movement intentions with computer algorithms, and use the predictions to control an external device such as a cursor on a computer screen or a robotic limb. In preliminary investigations in healthy monkeys, the number of parietal recording sites needed to operate such a device has been estimated using single neurons and local field potentials. Recently, the intended movement activity in the PPC of monkeys was used to position a cursor on a computer screen without the actual movement of the monkey's arm. This was obtained without extensive training, which strongly suggests that the neural signals in PPC are

indeed highly cognitive and represent high-level plans for movement.

Coding of intention in the PPC

We define intention as a high-level plan for a movement that specifies the type and goal of the movement, such as the wish "I want to pick up my cup of tea." Such a high-level movement plan would not necessarily contain all the details of the movement, such as the movement path, muscle activation patterns, and joint angles, but it would encode the end-point location of the movement and what kind of movement is to be made. Intentions are derived from the integration of sensory input and may occur at the beginning of a sequence of ever more specific movement plans along the sensorimotor pathway. In the example of picking up a cup of tea, necessary specifications include which arm to use, the movement trajectory and speed, and the details of the muscle force pattern. These movement specifications may be included in the movement plan closer to the motor output stage and may not be present at the earlier, or higher-level, stages of movement planning.

Evidence that the PPC is involved in high-level cognitive functions for sensorimotor transformation first came from the observation of neurological deficits after PPC lesions (Balint, 1909). Patients with PPC lesions do not have a primary sensory or motor deficit; however, they have difficulties in estimating the location of stimuli in space or may be unable to plan movements appropriately (Geschwind and Damasio, 1985). The observations suggest that a disconnection occurs between the sensory and motor systems in the sensorimotor pathway (Goodale and Milner, 1992). Human functional magnetic resonance imaging (fMRI) experiments and monkey electrophysiological recordings further supported the concept that the PPC is neither strictly sensory nor motor, but encodes high-level cognitive functions related to action (Andersen, 1987; Goodale and Milner, 1992; Mountcastle et al., 1975). The monkey is a particularly good model for the study of the PPC, since its sophisticated eye-hand coordination is similar to that of humans and the PPC in both species seems to perform similar functions (Connolly et al., 2000; DeSouza et al., 2000; Rushworth et al., 2001).

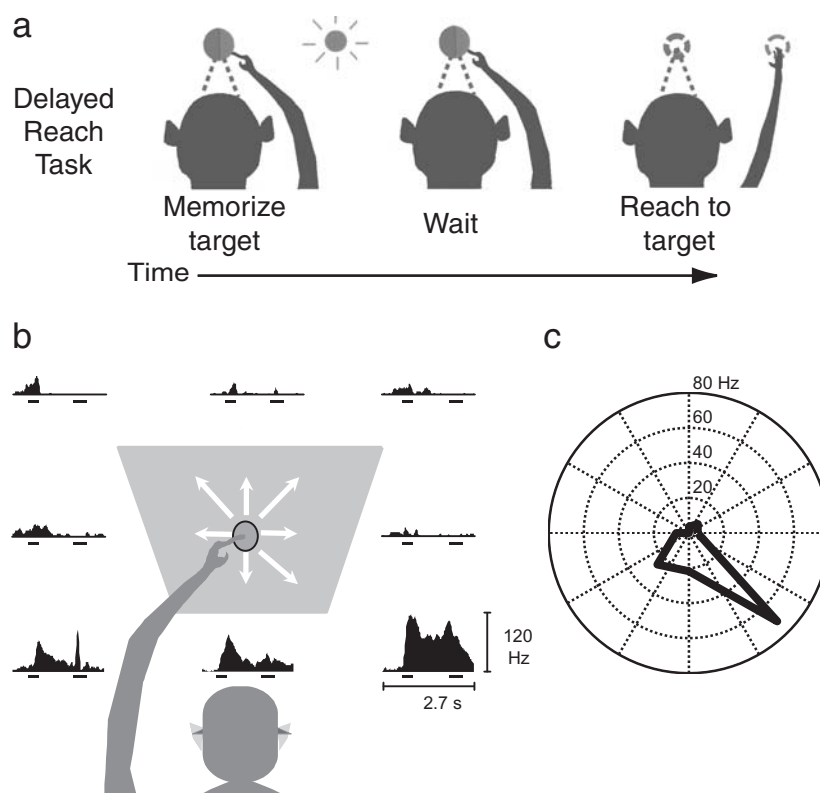

FIGURE 89.1. Spatial tuning of reach-related activity in PPC in a delayed reach task to separate sensory from motor components of behavior. *a*, Paradigm: animals memorized the location of a briefly flashed visual target, then waited in complete darkness for a go signal and made a reach to the remembered target location. *b*, Activity of a typical PPC cell with reach-related activity during stimulus presentation, waiting, and movement period of the task. Activity is maximal in the right-down direction for this cell. Each histogram depicts the cell's activity in one of eight tested reach

directions (*white arrows*; left-down direction occluded). Each histogram shows a spike density histogram representing the average action potential firing rate of all trials in the particular reach direction, and the short horizontal bars indicate the time of the target flash and the reach. *c*, Spatial tuning of the average firing rate during the waiting period (same cell as in *b*). Mean firing rate is plotted as amplitude along the movement direction, illustrating the strongest responses for right-down. (Data from Batista et al., 1999.)

PLANNING ACTIVITY IN THE PPC For separating sensory from motor components of behavior, the so-called memory task has been particularly useful (Hikosaka and Wurtz, 1983). In this task, a subject is first cued to the location of a movement by a briefly flashed stimulus, but must withhold the movement response until a go signal occurs (Fig. 89.1*A*). A typical PPC cell shows a burst of activity during the cue and at the movement period, indicating its relation to both sensory and motor components of the movement. During the memory period, cells in many parietal areas are also active, even in the dark (Gnadt and Andersen, 1988; Snyder et al., 1997). Figures 89.1*B* and 89.1*C* show the activity of a PPC neuron while the animal performed a delayed-reach task to targets in eight different directions (Fig. 89.1*B*). The histogram corresponding to each movement direction depicts the average firing rate of the neuron during the trial. The activity of the cell strongly increased during stimulus presentation, the waiting period, and the movement period of the task—in this example most strongly, in the right-down

direction. The increased activity during sensory, planning, and movement periods of the trial indicates that the PPC is neither a purely sensory nor a purely motor area but is involved in the high-level planning of movements, consistent with a role of this area in sensorimotor transformations.

The neuron in Figure 89.1 shows strongest activity for stimuli and movements down and to the right while being essentially silent for movements in the opposite direction. This *directional tuning* of activity is illustrated in the polar plot in Figure 89.1*C*, with the mean firing rate during the waiting period plotted as amplitude along the movement direction. Directional tuning is very common for many PPC neurons, with different neurons coding for different preferred directions. Hence, the combined activity of many neurons can code the direction of movements quite precisely.

To demonstrate that the activity during the delay period does not simply represent the sensory memory of the target, we used a paradigm in which the animals planned movements to two stimuli. For example, it has been shown that

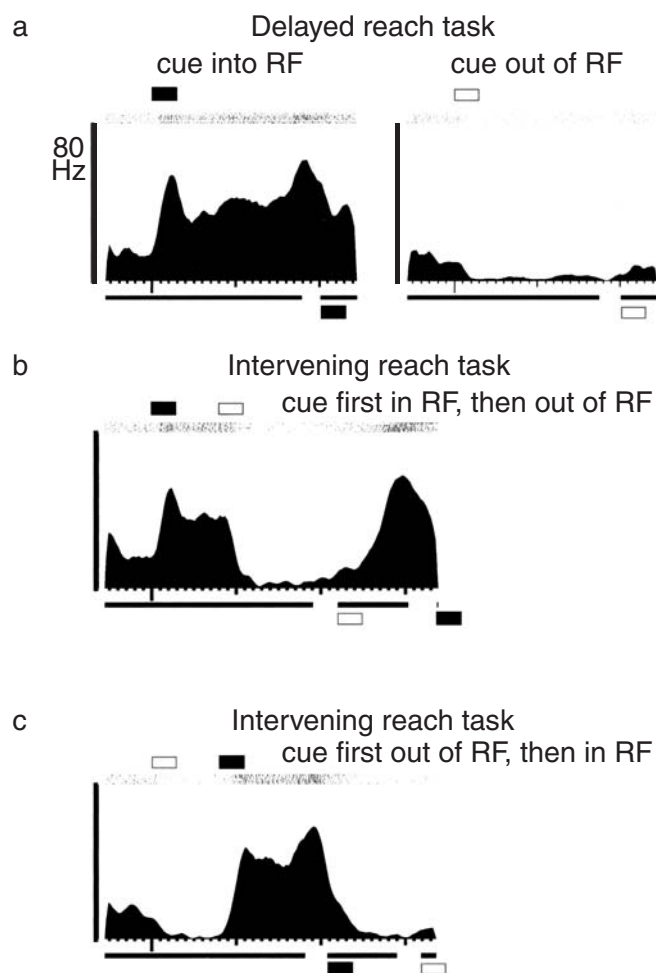

FIGURE 89.2. Example of a PRR neuron during the intervening reach task. Each panel in *a–c* shows, from top to bottom: timing of the cue stimulus into (filled bar) or out of (open bar) the response field (RF); spike rasters of 10 trials; spike density function (using a triangular kernel); timing of the button presses (horizontal bars) in one representative trial; and the acquired target (filled: in RF; open: out of RF). Vertical bar: calibration of firing rate. *a*, Delayed reach task with strong activity of the cell during the stimulus, delay, and movement periods when movements are planned inside the RF (left panel) and no activity when planned out of the RF (right panel). *b*, Activity of the same cell during an intervening reach task, when the first cue was shown in the RF and a second cue was presented out of the RF. *c*, Same cell with an intervening reach task, with the first cue out of the RF and the second cue in the RF. The cell was active when a reach was planned to the target location in the RF, but not when the animal was remembering that location and planning a reach to a location out of the RF. (Modified from Batista and Andersen, 2001.)

the delay period activity of neurons in the lateral intraparietal area (LIP) represents only the next planned eye movement, even though the animal had to hold two cued locations in memory (Mazzoni et al., 1996a). More recently, a similar result was also found for reach movements in the parietal reach region (PRR) (Batista and Andersen, 2001). Figure 89.2 shows a typical PRR neuron during this exper-

iment. In the delayed-reach task (Fig. 89.2A), the cell showed strong activity during the stimulus, delay, and movement periods when the movement was to a target inside of the response field of the cell (left panel) and no activity when the movement was to a target outside of the response field (right panel). On randomly chosen trials, an intervening reach task was used (Figs. 89.2B, C). In one task (B), a cue was first shown within the response field of the cell, and the animal began to plan, but not execute, a reach movement to that target. The activity of the cell was highly elevated. However, a second target was briefly shown outside the response field, and the animal had to change his plan to reach to the second target first. During this period, the cell was not active. After reaching to the second target, the animal had to reach to the remembered location of the first target that had been presented within the response field, and the cell became vigorously active again. The cell was active when a reach movement was planned to the target location within the response field of the cell, but was not active when the animal was remembering that location but planning a reach elsewhere. Corresponding results were found for the intervening reach task when the first cue was presented outside of the response field and the second in the response field of the cell (Fig. 89.2C). The delay period activity of PRR neurons therefore represents only the next planned reach movement, even though the animal had to remember two cued locations. The finding that nearly all PRR cells showed this behavior in these double movement task experiments rules out the coding of sensory memory in the delay period activity for most PRR neurons. This memory is most likely represented elsewhere or in a very small subpopulation of PRR cells.

TEMPORAL EVOLUTION OF PLANNING ACTIVITY Further evidence supporting the view that the PPC is involved in sensorimotor transformations comes from studies that elucidate the dynamic evolution of PPC activity during the task, changing in nature from sensory to cognitive to motor with the evolution of the task. For example, it was demonstrated in a delayed eye movement task (Platt and Glimcher, 1999) that the early activity of LIP neurons varied as a function of the reward probability or the probability that a stimulus location became a saccade target. However, during later task periods, the cells coded only the direction of the upcoming eye movement. In another study of LIP (Breznen et al., 1999; Sabes et al., 2002), monkeys were trained to make eye movements to specific locations cued on an object, and the object was rotated between the extinction of the cue and the saccade. At the beginning of the trial, LIP cells were found to carry information about the location of the cue and about the orientation of the object, both of which are important to perform the task. However, near the time of the eye movement, the same neurons encoded the direction of the

intended movement. Finally, in a study investigating the neural activity of PRR neurons when monkeys reached to auditory versus visual targets in a memory reach task (Cohen and Andersen, 2000), it was found that, during the cue period, visually cued trials carried more information about target location than did auditory cued trials. However, the amount of spatial information increased during the auditory trials, and the activity in the visual and auditory trials was not significantly different when the reach occurred. These studies emphasize the temporal evolution of activity in the PPC to reflect sensory, cognitive, and motor signals at different stages during a task.

DECISION PROCESSES FOR MOVEMENT PLANNING Recording experiments have found that the neural activity in LIP is related to the decision of a monkey to make an eye movement. Both the prior probability and the amount of reward associated with a particular movement influenced the neural representation of visual activity in LIP, which points to a role of this area in decision making (Platt and Glimcher, 1999). As monkeys accumulated sensory information for the planning of an eye movement, activity in LIP and the prefrontal cortex was found to increase, consistent with the idea that these areas are weighing decision variables for the purpose of eye movement planning (Coe et al., 2002; Gold and Shadlen, 2001; Shadlen and Newsome, 1996; Thompson et al., 1996).

Monkeys and humans have been shown to choose between two targets for a reach, depending on eye position and the stimulus locations in space, essentially favoring targets that tend to center the reach with respect to the head (Scherberger et al., 2003). We recently investigated the neural activity in PRR during this choice paradigm in the monkey and found that the neural activity of single PRR cells was only transiently related to the visual stimulus at the beginning of the trial, which was essentially identical for both choices. Later in the trial, the activity closely reflected the animal's choice of target for a reach (Scherberger and Andersen, 2001). This result suggests a role for PRR in decision processes for the generation of reach movements similar to that for LIP in decision processes for eye movements. Moreover, eye position gain effects have been shown in PRR and in LIP, and these gain effects may bias the decision of animals to choose targets based on the eye position. These and other findings suggest that decision making for movement planning is a distributed process that may involve many cortical areas including the PPC, and the particular areas involved may depend on the specific sensory input and motor actions considered.

INTENTION AND ATTENTION Given the fact that the PPC sits at the interface between sensory and motor systems, it is perhaps not surprising that the issue of how to distinguish intention from attention in this area has been of considerable research interest. To separate sensory from movement

processing, antisaccade and antireach paradigms have been used in which animals were trained to make movements in the opposite direction to a briefly flashed visual stimulus. Activity in the medial intraparietal area (MIP) has been shown to code mostly the direction of the movement plan, not the location of the stimulus (Eskandar and Assad, 1999; Kalaska, 1996). In LIP, the reverse has been reported for eye movements (Gottlieb and Goldberg, 1999); however, recently it has been reported that most LIP cells also code the direction of the planned eye movement after a brief transient response linked to the stimulus (Zhang and Barash, 2000). The antisaccade and antireach results suggest that the PPC contains both sensory- and movement-related responses and is involved in the intermediate stages of sensorimotor transformations.

In an experiment specifically designed to separate spatial attention from intention, monkeys were trained to attend to a flashed target and plan a movement to it during a delay period (Snyder et al., 1997). However, in one case the plan was for a saccadic eye movement, while in the other case the plan was for a reach. In other words, during the memory period, the only difference in the task was the type of movement the animal was planning. Figure 89.3 shows two intention-specific neurons from PPC, one from LIP (*A*) and one from PRR (*B*), while the animal planned an eye or arm movement to the same location in space. The activity of the LIP neuron showed a transient response due to the briefly flashed stimulus followed by activity during the delay period when the animal was planning an eye movement (left histogram) but not when the animal was planning an arm movement to the same location (right histogram). In contrast, the PRR neuron showed no elevated activity in the delay period when an eye movement was planned but a strong activity for the planning of an arm movement. Such results were typical in the PPC: LIP was much more active for the planning of eye movements, whereas PRR was more active during arm movement planning. PRR includes MIP, 7a, and the dorsal aspect of the parieto-occipital area (PO); however, MIP contains the highest concentration of reach-related neurons. These results from LIP and PRR strongly argue for a role of the PPC in movement planning.

INTENTIONAL MAPS The experiments mentioned above indicate a topographical separation of intentions within the PPC (Fig. 89.4). While area LIP seems to be specialized for the planning of saccades (Gnadt and Andersen, 1988), MIP and area 5 are more dedicated to the planning of reach movements (Buneo et al., 2002; Kalaska, 1996; Snyder et al., 1997). Other groups have identified areas PO, 7m, 7a, and PEc as additional reaching-related areas within the PPC (Battaglia-Mayer et al., 2000; Ferraina et al., 1997, 2001; MacKay, 1992). Furthermore, the anterior intraparietal area (AIP) seems to play a specialized role for grasping, as demon-

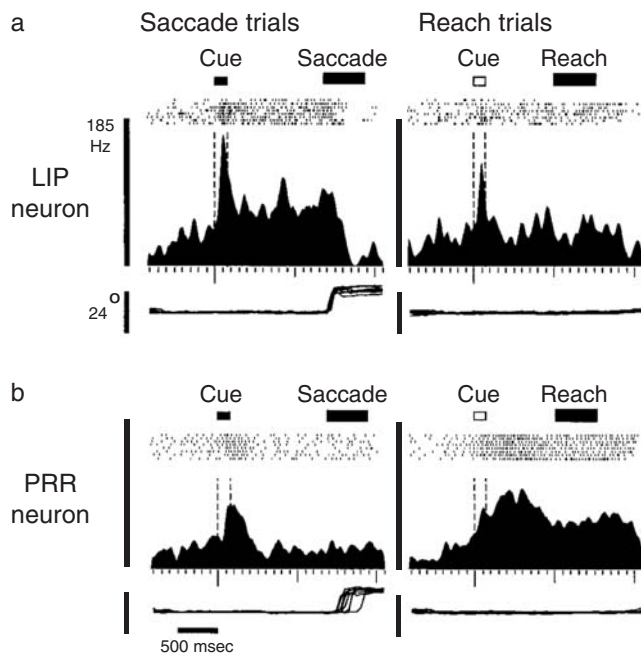

FIGURE 89.3. LIP and PRR neuron activity during a delayed saccade and delayed reach movement task. *a*, LIP cell showing elevated activity during the delay period (150 to 600 msec after the cue) before a saccade (*left*) but not before a reach movement (*right*). *b*, PRR cell showing no saccade activity (*left*) but showing reach activity (*right*) during the delay period with both movements planned to the same location in space. The neural activity in the delay period depended specifically on the movement intention. In all panels, short horizontal bars indicate the timing of the target flash (filled: saccade cue; open: reach cue), and long horizontal bars indicate the timing of the motor response (saccade or reach). Each panel shows a spike raster (eight trials aligned on cue presentation, every third action potential shown) and the corresponding spike density function (computed as in Fig. 89.2). Thin horizontal lines indicate the animal's vertical eye position during each trial. Vertical bars indicate calibration of firing rate and eye position. (Modified from Snyder et al., 1997.)

strated by Sakata and colleagues (1995). Cells in AIP respond to the shape of objects and the formation of the hand during grasping. Recent results of fMRI studies in humans were found to be consistent with the electrophysiological findings in the monkey. Rushworth et al. (2001) found that a peripheral attention task activated the lateral bank of the intraparietal sulcus, while the planning of manual movements involved activity in the medial bank. Connolly et al. (2000) reported a similar result using event-related fMRI. A specialized area for grasping has also been identified in the anterior aspect of the intraparietal sulcus in humans, which may be homologous to the monkey area AIP (Binkofski et al., 1998). Simon et al. (2002) also found a systematic anterior-posterior organization of activations associated with grasping, pointing, and eye movements. All this suggests that the parietal cortex is composed of distinguishable subregions both in monkeys and in humans.

Sensory integration and space representation in the PPC

COORDINATE FRAMES Sensorimotor transformations include the integration of different sensory modalities, such as vision, sound, and touch, to develop movement plans. Since different sensory modalities represent space in different reference frames, for example, vision in retinal or eye-centered coordinates, sound in head-centered coordinates, and touch in body-centered coordinates, the question of how these senses are integrated becomes particularly important. On the motor output side, different motor actions similarly require the representation of target location in different reference frames according to the natural coordinates of the moving muscles. The surprising finding that several movement planning areas in the PPC represent space in an eye-centered coordinate frame independent of the sensory input and motor output may provide a unifying scheme for multimodal sensory integration and the development of high-level movement plans.

In area LIP, it was recently established that cells were involved in the planning of eye movements, regardless of whether the eye movements were triggered by a visual or an auditory stimulus (Grunewald et al., 1999; Linden et al., 1999; Mazzoni et al., 1996b). In further experiments directly addressing the question of the underlying reference frame, it was found that the majority of neurons coded auditory targets, similar to visual targets, in eye-centered coordinates, and with many response fields of LIP neurons gain-modulated by eye position (Stricanne et al., 1996). These findings suggest that LIP is involved in the sensory integration of visual and auditory signals and that many LIP neurons are encoding these signals in eye-centered coordinates. Earlier stages of auditory processing that project to LIP seem to encode auditory targets in head-centered coordinates, also with gain modulation by eye position (Wu and Andersen, 2001). Such a change of reference frame is con-

sistent with a current model of auditory target processing, where auditory signals are represented in head-centered coordinates, and gain-modulated by eye position, in order to transform them to an eye-centered representation at a subsequent stage (Xing and Andersen, 2000b).

Based on the findings in LIP, one wonders, how are sensory stimuli encoded for reach movements in PRR. One prediction would be that PRR codes sensory stimuli as motor error, that is, in limb coordinates; another possibility would be that PRR also codes in eye-centered coordinates. To test this hypothesis, monkeys were trained to reach to visual targets on a reach board from two different initial arm positions while their gaze was fixating in two different directions (Batista et al., 1999). Figure 89.5*A* depicts the four conditions: on the left side with the same eye position but different initial hand positions, and on the right side with the same initial hand position but different eye positions. The activity of one typical PPR neuron is shown in Figure 89.5*B*. Gray-scale values on each panel represent the cell's activity for reach movements from the illustrated initial hand position to the particular location on the board. As can be seen, the response field of the cell did not change with changes of the initial hand position (*left column*) but instead shifted with the gaze direction (*right column*). This finding was confirmed throughout the population of recorded neurons (Fig. 89.5*C*), where the response fields of the majority of neurons correlated better with the task when viewed in eye-centered as opposed to limb-centered coordinates. This result indicates that PRR codes intended limb movements to visual stimuli in eye-centered coordinates similar to how LIP codes for intended eye movements.

FIGURE 89.5. Encoding of reach target locations in eye-centered coordinates in PRR for visual and auditory stimuli. *a*, Delayed reach task in four conditions: same eye position but different initial hand positions (*left side*) and different eye position but same initial hand position (*right side*). *b*, Activity of one typical PPR neuron during the delayed reach task to a visual stimulus. On each panel, gray-scale values represent the cell's activity in the delay period for a reach from the illustrated initial hand position to the particular location on the board. The response field of the cell did not change with changes of the initial hand position (*left column*) but shifted with gaze direction (*right column*). *c*, Population response of the experiment in *b*, each circle represents one neuron. *x*-axis: correlation coefficient between responses for the same eye position but different hand positions (*a*, *left side*); *y*-axis: correlation coefficient between responses for the same initial hand position but different eye position (*a*, *right side*). Response fields of most neurons correlated better with eye-centered as opposed to limb-centered coordinates. *d*, Same experiment as in *b* and *c*, but with reaches made to auditory target locations in complete darkness. Axes and symbols as in *c*. Again, for most of the cells, the correlation was larger between response fields with the same eye position than between response fields with the same initial arm position. (*a–c* modified from Batista et al., 1999; *d* modified from Cohen and Andersen, 2000.)

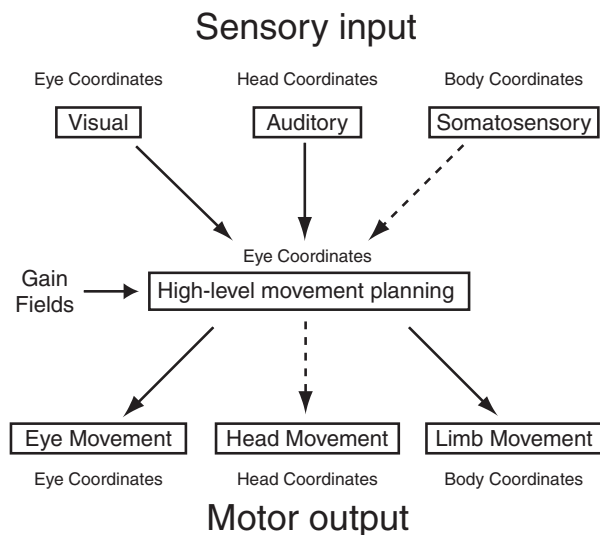

FIGURE 89.6. Multisensory integration and coordinate transformation in the PPC. Sensory input is transformed into a common eye-centered coordinate frame for high-level planning of movements that are subsequently transformed into various motor output coordinate frames. *Dotted arrows*: speculated transformations. Gain fields may provide a mechanism for coordinate transformations.

The possibility that PRR codes reach intentions independent of the sensory stimuli, similar to LIP, led to the counterintuitive prediction that many PRR neurons would encode reaches to auditory stimuli in eye-centered coordinates as well. This idea was tested in another study (Cohen and Andersen, 2000), where monkeys performed reach movements to auditory targets in complete darkness while the animal's initial hand position and gaze direction were systematically varied as described above (Fig. 89.5.4). Again, in the majority of cells, the correlation between response profiles with the same eye position was found to be much larger than between response fields with the same initial arm position (Fig. 89.5.5D). This result confirms that a majority of PRR neurons code reaches to auditory stimuli in eye-centered coordinates, even though the sensory stimulus, which is initially coded in head-centered coordinates, could easily be converted to body- and then limb-centered coordinates without the involvement of any eye-centered reference frame.

The above-mentioned results suggest that populations of LIP and PRR neurons both use a common eye-centered coordinate frame for space representation, independent of whether the sensory input is visual or auditory and regardless of whether the output is to move a limb or to make an eye movement. These findings lead to a general scheme of space representation in the PPC, where sensory input is converted to eye-centered representations in the PPC and high-level movement plans are formed that can be read out by motor output structures in their natural coordinates (Fig. 89.6). Currently, we do not know if somatosensory signals

coding the position of the hand are also coded in eye-centered coordinates in LIP and PRR and how head movements are coded in the PPC (*dotted arrows*). These are interesting questions for future research.

A possible reason for the use of a common reference frame in the PPC could be to facilitate the planning of coordinated movements, for example, during eye-hand coordination. A particular reason why an eye-centered representation has evolved in the PPC might be that vision is the most dominant and accurate spatial sense in primates.

There is a problem when using an eye-centered representation for the encoding of intentions in the PPC. Movement plans would need to be updated in eye coordinates every time an eye movement occurred before the movement plan was executed. This updating of movement plans during intervening saccades was indeed found in the superior colliculus (SC) (Mays and Sparks, 1980) and in LIP (Gnadt and Andersen, 1988) for eye movement plans, as well as for reach movement plans in PRR (Batista et al., 1999) and in human psychophysical reach experiments (Henriques et al., 1998).

GAIN FIELDS The gain modulations of the eye-centered response fields in LIP and PRR by eye, head, and limb position signals may provide a general mechanism for converting stimuli from various reference frames into eye-centered coordinates and, likewise, may allow other areas to read out signals from LIP and PRR in different coordinate frames, including eye, head, body, and limb-centered schemes (Fig. 89.6). It has been shown computationally that gain effects could be an effective mechanism for coordinate transformations in neural networks (Salinas and Abbott, 1995; Zipser and Andersen, 1988). Such a mechanism would also be very flexible, since the information of a group of eye-centered neurons that is gain-modulated by various body part positions could be subsequently read out in multiple frames of reference (Pouget and Snyder, 2000; Xing and Andersen, 2000b). The number of cells necessary for representing all possible combinations of eye, head, and body positions can remain within reasonable limits if, in each area, only those variables are encoded that are necessary to perform its specific functions (Snyder et al., 1998). Space representation in at least some areas of the PPC is thus distributed and composed of retinotopic response fields that are gain-modulated.

A similar gain mechanism could also provide the means for the remapping of eye-centered response fields in the PPC during intervening eye movements, which was demonstrated to occur during saccade planning in LIP in the double saccade paradigm (Gnadt and Andersen, 1988; Mazzoni et al., 1996a) and during reach planning in PRR in the intervening saccade paradigm (Batista et al., 1999). In a recent computational model, it was demonstrated that dynamical neural networks could be trained to perform the double saccade task (Xing and Andersen, 2000a). The model com-

prised eye-centered response fields that were gain-modulated by eye position and a shift of activity within eye-centered visual maps that corrected for intervening saccades, demonstrating that gain field mechanisms are sufficient for the saccade updating of eye-centered response fields in the PPC.

We highlighted the role of gain fields in the PPC for the updating of neural maps and for the coordinate transformations between different reference frames. It is clear, however, that gain mechanisms play an important role for other brain functions as well, such as decision making, attention, and object recognition (Salinas and Thier, 2000) and may be a general strategy of neural computation.

COORDINATE TRANSFORMATION Sensorimotor transformation in the PPC converts sensory input signals into motor plans for action. One essential step in achieving this goal is the transformation of the target location from the coordinates of its sensory input into the coordinates of the motor output. While we have highlighted a common eye-centered reference frame for the representation of intentions in the PPC and its possible role for multisensory integration, it is less well understood how intentions are transformed further downstream into motor commands (Fig. 89.6).

In the case of a reaching movement to a visual target, the target location of the reach has to be transformed from visual coordinates to the motor coordinates of the limb. This could be archived in various ways. In a *sequential* model, the eye-centered representation would be transformed sequentially first into a head-centered representation, then into a body-centered representation, and finally into the coordinates of the limb by sequentially considering the eye position, head position, and limb position. Alternatively, in a *combinatorial* model, the eye-centered target location could be combined at a single stage with the eye, head, body, and arm positions to compute the target in limb-centered coordinates (Battaglia-Mayer et al., 2000). However, such a combinatorial approach might require an unrealistically large number of cells for implementation in the PCC. In a third *direct* model, the current position of the limb is encoded in eye coordinates and compared with the eye-centered target position to directly generate the motor vector in the coordinates of the limb (Fig. 89.7A). This approach would require only a few computational stages and would rely only on variables in eye-centered coordinates.

This direct model is supported by findings of a recent study of area 5, a somatosensory cortical area within the PPC, where single neurons were found to encode target locations simultaneously in eye- and limb-centered coordinates (Buneo et al., 2002). Figure 89.7B–E shows the activity of a typical neuron for a reach movement with the same motor error in four conditions with different initial hand and eye fixation positions. The activity of the cell varied substantially

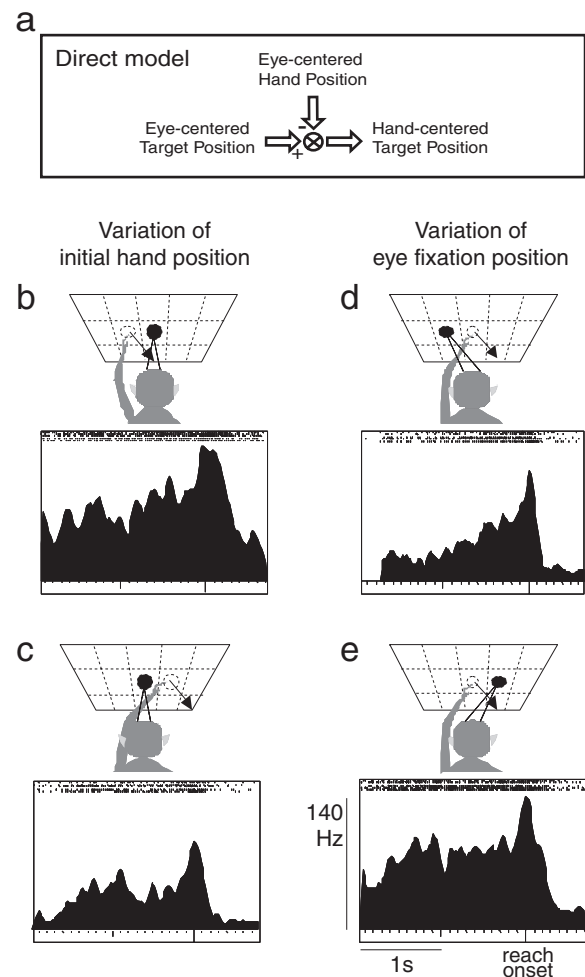

FIGURE 89.7. Direct visuomotor transformation for reaching in area 5. *a*, Direct transformation model. *b–e*, Activity of an area 5 neuron that simultaneously codes the target location in eye- and limb-centered coordinates, shown in a delayed reach movement task with different initial eye and arm positions. Each panel illustrates on top the different initial arm and eye positions for the same reach movement vector (arrow), and below the neural activity (spike rasters and spike density function). Thin bars (in *e*) calibrate time and firing rate. The activity of the cell varies substantially in the task when the initial arm position (*b*, *c*) or the eye position (*d*, *e*) is varied. However, the neural activity is very similar when the initial hand positions and target locations are identical in eye coordinates *b*, *e* and *c*, *d*. (Modified from Buneo et al., 2002.)

when either the initial hand position (*B*, *C*) or the eye fixation position (*D*, *E*) was varied, but was very similar between conditions with the same eye fixation and initial hand position relative to the target (*B*, *E* and *C*, *D*). Hence, the activity of the cell could be best described when both the target location in eye coordinates and the initial hand location in eye coordinates were taken into account. This finding is consistent with the PPC transforming target locations directly between these two reference frames.

Cells in PRR code the target location in eye-centered coordinates with a gain modulation by the initial hand

position, also in eye-centered coordinates (Buneo et al., 2002). Therefore, a convergence of input from cells in PRR onto area 5 could perform this direct transformation from eye- to limb-centered coordinates by using a simple gain field mechanism and without having to rely on intermediate coordinate frames or a large number of retinal, head, and limb position signals. On the other hand, psychophysical evidence has supported the above-mentioned sequential model (Flanders et al., 1992; McIntyre et al., 1997, 1998). The different results may reflect an underlying context dependence of the coordinate transformations for reaching, where direct transformations are preferred when both the target location and the hand are visible, while a sequential scheme may be preferred otherwise. Only future experiments can reveal the mechanisms for generating motor commands under different sensory conditions.

Plasticity: adaptation and behavioral significance

Plasticity is the ability of the brain to change the neural representation of a particular brain area either qualitatively or quantitatively. In the PPC, both learning and adaptation are important features in the context of sensorimotor transformations. An example for learning in the PPC was recently revealed in an electrophysiological study of LIP (Grunewald et al., 1999) where the responses of LIP neurons to auditory stimuli during a passive fixation task were investigated before and after the animals were trained to make saccades to auditory targets (Fig. 89.8). Before the saccade training, the number of cells responding to auditory stimuli in LIP was statistically insignificant; however, after training, about 12% of the cells showed significant responses to auditory stimuli, while the percentage of cells responding to visual stimuli (~45%) did not change (Fig. 89.8A). The amount of location information present in the neural responses for auditory stimuli before training was insignificant, but after training significant location information was present (Fig. 89.8B). The location information for visual stimuli was present before and after training. This indicates that at least some LIP neurons become active for auditory stimuli only after the animal has learned that these stimuli are relevant for oculomotor behavior.

Similar de novo representations of stimuli are suggested by the results of Sereno and Maunsell (1998). They reported that shapes of objects were encoded in LIP cells during a passive fixation task after the animals were trained to discriminate these objects in an eye-movement task. More recently, Toth and Assad (2002) showed that the activity of LIP cells represent color information of a visual stimulus during a delayed-saccade task if color information was behaviorally relevant to solve the task. These studies demonstrate the ability of the PPC to newly represent sensory stimuli that are behaviorally

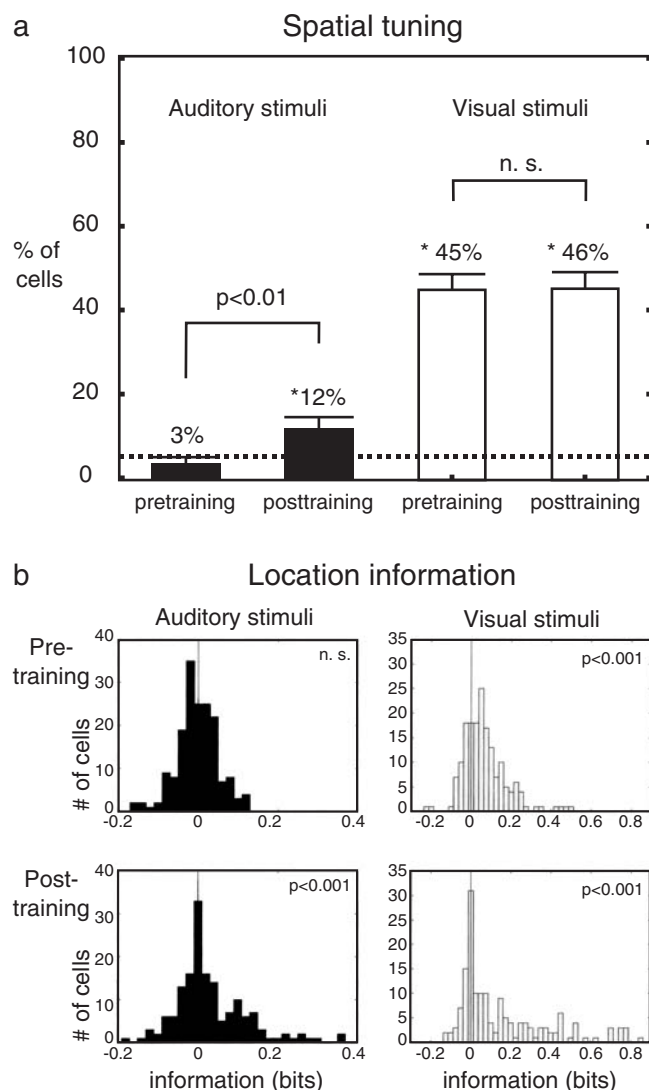

FIGURE 89.8. De novo representation of auditory stimuli in LIP. *a*, Proportion of cells that showed significant spatial tuning for auditory and visual stimuli in a fixation task before and after the animal had been trained to make auditory saccades. *x*-axis: pre- and post-training conditions for trials with auditory (filled bars) and visual stimuli (open bars); *y*-axis: number of cells with significant (Kruskal-Wallis test) tuning to auditory and visual stimuli. Error bars: standard deviation; *: significant difference from false-positive level (dotted line); *p* values above brackets indicate a significant difference in pairwise comparison (Fisher-Irwin test). *b*, Location information in each cell to auditory (left column) and visual targets (right column) before (top row) and after training (bottom row). Each panel shows a histogram of the location information (corrected for baseline) for each cell population. Vertical line: no location information present; *p* values: significance level (Wilcoxon test) that location information is present in the population. Spatial tuning and target location information for auditory stimuli was present after the animal was trained to make auditory saccades but not prior to training. (Modified from Grunewald et al., 1999.)

relevant, and point to a context-dependent flexibility in the neural representation of the PPC during sensorimotor transformation.

Neural plasticity also seems to be at work in the continuous fine-tuning of neural representations in the PPC to keep the various sensory and motor signals in register. An experiment specifically designed to disrupt this alignment is prism adaptation. Human subjects initially missreach to visual targets when wearing displacing prisms, but when provided with appropriate feedback about their errors, they gradually recover and reach correctly (Held and Hein, 1963). This suggests that a recalibration between sensory and motor coordinate frames has taken place. Clower et al. (1996) demonstrated in a positron emission tomography (PET) study that prism adaptation selectively activates the contralateral PPC to the reaching arm, which directly links the PPC to the adaptation effects, in perfect agreement with its role in sensorimotor transformation. The neural mechanisms underlying prism adaptation and associative learning in the PPC are largely unknown and likely involve other brain areas as well.

Neural prosthesis: reading out reach intentions

As we have seen, the activity in the PPC contains strong, reliable intention signals for eye and arm movements. Instead of demonstrating only correlations between the neural activity and behavior, it would be very important to test this relationship more directly. One type of experiment is illustrated in Figure 89.9, where the reach intentions of a monkey are recorded in PRR and then used to move a cursor on the display screen. The cursor location displays our prediction of where the animal is intending to reach based on the neural activity. This provides visual feedback to the animal, indicating where the reach will end up based purely on the animal's intention, that is, without the animal actually moving its arm. This sensory feedback provides a "closed loop" in the information flow of sensorimotor transformation, which enables the subject to learn and adapt its movement intentions in order to improve the accuracy of the reach predictions.

In a preliminary study, we used the PRR activity of two monkeys to predict in real time one out of two reach directions (Meeker et al., 2002). The animal performed a modified delayed-reach task in which a cursor was moved on the computer screen by interpreting the intended movement activity of the animal without its making an actual reach. This was achieved without extensive training of the animal, which suggests that PRR represents high-level reach intentions and is capable of adapting to this new behavior. A corresponding off-line analysis of single-cell recordings from PRR suggested that a reliable prediction of one out of eight movement directions is possible with only

FIGURE 89.9. Schematic of an experiment to read out intentions. First, the activity of a single PRR neuron is recorded, and a database is constructed representing the neural activity for reaches in different directions. In test trials, the monkey then fixates and touches the center of a display screen, and a target is briefly flashed in either the preferred or the nonpreferred direction of the cell. Based on the response of the neuron in this single trial and the statistics of the cell's activity in the database, a prediction is made about whether the animal is intending to reach either in the preferred or in the nonpreferred direction of the cell, and a cursor is moved to the predicted location on the screen to give the monkey visual feedback. The animal is rewarded if the prediction corresponds to the cued target location, and it does not move its arm.

a very small number of simultaneously recorded neurons—on the order of 10 to 15 (Meeker et al., 2001; Shenoy et al., 2003).

The high-level movement planning activity in the PPC could, in theory, be used in paralyzed patients to control a neural prosthesis. Patients paralyzed by strokes, trauma, or neuropathies can often still think about making a movement but are unable to activate the appropriate muscles to execute it. A cortical prosthesis could record the movement intentions, interpret the intentions in real time using computer algorithms, and convert the decoded movement signals to control an external device. Useful devices could include a computer interface for communication, a robot limb, or muscle stimulators inside the patient's body that would ultimately restore the patient's to move paralyzed limbs.

Several groups are currently working to develop such a prosthesis, mainly using signals recorded from motor cortex (Chapin et al., 1999; Isaacs et al., 2000; Serruya et al., 2002; Taylor et al., 2002; Wessberg et al., 2000). While these groups certainly have demonstrated the possibility of using the movement signals in motor cortex for reading out movement plans, the use of more cognitive signals in PRR may

also have its advantages. First, the high-level cognitive nature of the signals in PRR may require only a few neurons to decode the end point of a reach movement (as opposed to decoding an entire movement trajectory). Next, sensory feedback is necessary for closing the loop and to facilitate learning and neural plasticity. Since many paralyzed patients have severed somatosensory feedback, which plays a prominent role in the primary sensory and motor cortical areas, visual feedback may become even more relevant. PRR is tightly linked to visual cortical areas, which provide perhaps its most dominant sensory inputs. Finally, after paralysis, motor cortex undergoes substantial degeneration, as has been shown in animal recording and human imaging studies (Bruehlmeier et al., 1998; Lotze et al., 1999; Wu and Kaas, 1999). Since the PPC is more closely related to the intact visual system, degeneration effects might be less severe in the PPC after paralysis. The field of neural prosthesis is young, and it is too early to tell whether a single part of the brain will afford the most optimal control. It is quite likely that the most effective prosthesis will be one that can tap into signals from multiple areas and take advantage of their different natural specializations.

Perhaps the most limiting factor for the success of a neural prosthesis is the lack of stability and reliability of chronically recorded neural signals, a problem that is largely independent of the brain area from which the neural signals are recorded. In this respect, it is noteworthy that we have recently found gamma band oscillations in the local field potential (LFP) signals during the delay period both in LIP when monkeys are planning an eye movement (Pesaran et al., 2002) and in PRR during reach planning (Scherberger et al., 2001). The spectral power in the gamma band of the LFP is tuned in both areas to the direction of the planned movement and changes its strength with the behavioral state, that is, it becomes stronger when the animal plans a movement and rapidly decreases during the movement execution. An “off-line” analysis of the LFP signal in PRR estimated that 50 to 100 recording sites would be sufficient to reliably predict one out of eight movement directions in a delayed reach movement task using the LFP signal alone (Scherberger et al., 2001). Since the LFPs reflect the activity of groups of cells in cortical columns rather than single cells, LFP activity is more stable and easier to record than that of single cells with chronic electrodes. Using the LFP to decode reach intentions in the PPC and perhaps elsewhere may therefore be an important step in the development of a neural prosthesis.

Conclusions

The PPC is an important area for sensorimotor integration and the formation of high-level cognitive plans for movement. The PPC is divided into a map of intentions, with dif-

ferent subregions representing the planning for saccades, reaches, and grasping movements. Each region contains a map of its working space and seems to be specialized for multisensory integration and coordinate transformation with respect to its particular action. In PRR and LIP, these maps are encoded in eye-centered coordinates independent of their sensory input and the motor plan. The activity in these maps is gain-modulated by eye, head, and limb position signals consistent with a distributed representation of space. This allows the direct transformation of spatial information into a variety of different reference frames. The distributed and abstract representation of intentions underscores the high-level, or cognitive nature of this area. The involvement of PPC in decision making and neural plasticity for space representation is consistent with its role in sensorimotor transformation. Efforts to read out and decode PPC signals to control a neural prosthesis will test our current theories of sensorimotor transformation as well as provide new leads to help paralyzed patients regain their motor integrity. These goals are central to this emerging field of *applied* systems neuroscience.

XI EYE MOVEMENTS

90 Gaze Control under Natural Conditions

ROBERT M. STEINMAN

Reason for studying the control of gaze

Little in visual neuroscience is of greater concern than a human being's ability to control the direction of *gaze* (the direction of the line of sight in spatial coordinates). Why? What could possibly make the human's control of gaze so important? The answer lies in the nature of the human *retina*, the receptor surface within the eye that *transduces* (translates) light, the *adequate* (most effective) stimulus for vision, into bio-electrical signals that are carried to the higher levels of the visual brain. These centers are responsible for our ability to see a world of colored objects, of various sizes and at various distances, moving or stationary with respect to each other, as well as moving or stationary with respect to ourselves. The retinal surface is very *heterogeneous* (diverse) with respect to its functional properties. A very small central depression (only about 1/40th of 1% of the retinal surface area), called the *fovea*, is responsible for our best visual acuity, that is, our ability to *discriminate* (distinguish) very fine details. The fovea is also responsible for our best color vision, while the regions outside of the fovea are particularly well suited for detecting very low levels of light and motion. The fact that the human retina had very heterogeneous functional properties was well established by the last quarter of the nineteenth century. (See Brindley, 1960, for many important older references and Oyster, 1999, for an up-to-date treatment of what is now known about the structure and function of the human eye.)

Why eye movements must be measured

One of the more intriguing aspects of human vision is the fact that the functional consequences of retinal heterogeneity are not experienced. Subjectively, our visual world is homogeneous. We perceive it as having good acuity and color representation throughout. Experiencing the visual world as homogeneous would not be possible if we could not move our eyes. Moving our eyes allows us to place selected visual objects in retinal regions specialized for processing different features. For example, we use the fovea for seeing colored details in brightly lighted environments, but shift to more peripheral retina when objects are too dim to be seen when they fall within the fovea (see Steinman and Cunitz, 1968, for the human oculomotor pattern near the absolute foveal threshold).

Two things were clear near the end of the nineteenth century, when the objective study of eye movements began. First, it was clear that the functional properties of the human retina were sufficiently heterogeneous to require the eye to move. Second, it had become clear from studies of reading, a particularly important and uniquely human eye movement behavior, that the way human beings move their eyes *cannot* be inferred from subjective impressions of what they were doing (Dodge and Cline, 1901; Huey, 1900; Javal, 1878). Objective measurement of human eye movements was required. This recognition encouraged the development of methods to measure human eye movements. These methods were developed and improved throughout the twentieth century, and a large body of knowledge about human eye movements was produced. See Collewyn (1998) for descriptions of many of the more popular contemporary methods of recording eye movements. See Hallett (1986), Steinman (1986), Kowler (1990), and Kowler (1991) for reviews of what has become a voluminous literature on human eye movements.

Why eye movements should be studied under ecologically relevant conditions

Virtually all of this knowledge was collected under unnatural, highly impoverished stimulating conditions. More often than not, the eye movements of only one eye were recorded. The head was immobilized on a biting board or a chin rest. The visual field was more often than not dark except for the fixation target, which was a tiny spot of light that lined up with the eye when it was centered in its orbit. Recordings were made while the single-point target remained stationary or moved during the recording. It is not clear, as we begin the second century of human eye movement research, that much of the knowledge we have, which is based on recordings made under such unnatural and highly impoverished conditions, applies to the way human beings actually control their gaze under more ecologically relevant conditions, that is, (1) when the human being's head and torso is free to move and (2) binocular gaze is recorded *accurately* as the human observes and manipulates (3) objects within arm's length in a (4) normally illuminated room. These conditions are particularly relevant for understanding the evolutionary success of our species. These are the conditions in which human beings fabricate and use tools, as well the conditions

in which they do most of their reading and other creative activities.

We have only just begun to study the way humans control their gaze under such natural conditions. I know of only five publications to date that meet the criteria listed above for studying human eye movements, *accurately* with respect to both space and time, under ecologically relevant conditions; namely, Epelboim (1998), Epelboim et al. (1995, 1997), Malinov et al. (2000), and Herst et al. (2001) (see Ballard et al. (1994), Land (1992), Land and Tatler (2001), Land et al. (1999), Smeets et al. (1996), and Land and Hayhoe (2001) for ecologically relevant experiments in which the eye movement recording methods were not sufficient to examine fine details of human performance). In addition, see Johansson et al. (2001) for an experiment in which objects were manipulated, condition (3) above, under less than ecologically relevant conditions. The authors recorded monocularly with a video-based eye-tracking system (effective bandwidth = 60 Hz) with the head immobilized on a biting board that “provided high stability of the head” (p. 6918). In short, we have just begun to study human eye movements accurately under the conditions in which humans evolved. At present, we still know very little about how gaze is actually controlled under natural conditions.

The first accurate, but unnatural, recordings of human fixation

It required half a century for investigators to get answers to two simpler questions, questions of interest ever since human eye movements were first recorded by Delabarre (1898): how well could gaze be kept on an attended target, and what kinds of eye movements were used to maintain gaze after fixation was achieved? Both of these questions had a bearing on a more fundamental question: how much does the image of an attended target move on the retina when the direction of gaze is maintained by rotations of the fixating eye within its orbit? This question was important because anatomical research early in the twentieth century revealed an even greater degree of retinal heterogeneity than was expected when human eye movement research began. There was a cellular specialization, called the *Central Bouquet* (Rochon-Duvigneaud, 1943) at the center of the fovea. It had a diameter of about only one-third of a degree of visual angle. This specialized region was filled with a densely packed group of rod-shaped cones. Clearly, the highest-quality human vision would require an exceptional ability to fixate an attended object. It had to be able to place the retinal image of the attended target exactly at the foveal center, and it had to be able to keep it there long enough for its finest details to be discriminated.

The problem encountered as soon as one tries to study the human being's control of gaze stems, in no small measure,

from the human's remarkable ability to control his or her gaze. Once it became possible to actually measure how good it was, free from artifacts, it became clear that gaze control was exquisite. Gaze could be placed and kept on an object with remarkably little variability, at least under the very unnatural conditions that were required to measure these minuscule behaviors. That is, the head had to be immobilized as much as possible, and the fixation target had to be placed on the line of sight when the eye was in its primary position in its orbit. Fixation did not seem nearly this good when measurements were first made by photographing light reflected from the curved surface of the cornea. This method, which was introduced by Dodge and Cline (1901), is called the *corneal reflex* method. It was used by Dodge, his collaborators, and many others, for 50 years, providing the bulk of the existing eye movement literature until 1950, when a new and much more accurate method came into vogue. Gaze during maintained fixation, as recorded with the corneal reflex method, was quite variable even when an experienced subject attempted to maintain gaze. But it was hard to know why because deviations in the direction of the beam reflected from the surface of the cornea could be caused by two motions: by a rotation of the eyeball or by a translation of the head. A translation of the head would bring the beam of light falling on the cornea to a different location on its curved surface. Changes in the position of the recording light falling on the photographic paper caused by rotations of the eyeball were of interest. Changes in position caused by head translations were not. They were artifacts. A technique was required to prevent them, or some way of recording them and subtracting them from the records was required (subtracting them was exceedingly difficult, perhaps even practically impossible; see Ratliff and Riggs, 1950). The human cornea is quite curved, which means that even a tiny translation of the head introduces a quite large artifact into the records. Clearly, the quality of human fixation, and the nature of retinal image motion, could not be known until this problem was solved. The very best biting board was not good enough to eliminate it (see Barlow, 1952, for a particularly heroic attempt to hold the head rigidly in place).

The first step toward the solution of this problem (known to the author) was made by Adler and Fliegelman (1934). They used the *optical lever technique* to measure human fixational eye movements. In this method, a very small, flat (plane) mirror is mounted on the eye, and eye movements are recorded when a beam of light, reflected from this mirror, falls onto photographic paper moving behind a slit at the front of a movie camera. The use of a *flat* mirror at the fulcrum of the optical lever, instead of the curved corneal surface, removes the head translation artifact from the records because the angle of incidence of the recording light beam does not change when the surface reflecting it to the photographic paper is flat. The angle of incidence does

change if the curved surface of the cornea is used, as had been the case in prior research. The optical lever technique easily produces records with very good spatial resolution because it has an inherent 2× magnification factor; that is, a 1 degree change in the angle of incidence results in a 2 degree change in the angle of reflectance (see Nachmias, 1959, for an explanation).

By 1934 it was also possible to record on rapidly moving photographic paper. This allowed a high degree of temporal as well as spatial resolution. Even the very smallest fixational eye movements could be seen in Adler and Fliegelman's (1934) records. They reported that when a human being maintained fixation, eye movements consisted of *rapid shifts* averaging about 15 min arc; *waves*—inconsistent in direction, extent, and duration with peak-to-peak (p-p) displacements of 2½ to 5 min arc; and *fine vibratory movements*—50 to 100 per second, with p-p extents of about 2¼ min arc. These were important results, but their validity was still in doubt because Adler and Fliegelman's subjects had been required to maintain fixation on a relatively nearby target (only 2 m away). With such a target, the slightest movement of the subject's head with respect to the fixation stimulus would confound head translations relative to the fixation stimulus with motions of the image of the fixation target on the retina. The sizes of the various fixational eye movements they reported were also questionable. These authors apparently did not understand that their optical lever magnified the extent of eye rotation. Their quantitative descriptions were twice as big as those that should have been reported. These facts made the significance of Adler and Fliegelman's results uncertain at best. Ratliff and Riggs (1950) solved these problems and, in doing so, provided a valid method for studying the finest features of the human eye movement pattern. Their improvements also made it possible for them to make inferences about the nature and extent of the retinal image motions of their fixation targets. Ratliff and Riggs' technique also laid the foundation for stabilizing retinal images in the presence of fixational eye movements, a type of research that engaged many investigators between 1950 and 1980. Their landmark paper began by summarizing the status of knowledge about high-frequency tremor during maintained fixation. In the authors' words:

The summary of the studies of physiological nystagmus [one of the terms used to describe the small high-frequency component of the eye movement pattern during maintained fixation; *high frequency tremor* was the other] indicates that there is . . . evidence to support three different positions . . . (1) the eye is in motion . . . and there are fine vibratory motions . . . (2) the eye is in motion, but there is little evidence of vibratory motions . . . (3) The eye is essentially motionless during short periods of fixation. (Ratliff and Riggs, 1950, p. 690)

Why were things so unclear in 1950, after 50 years of objective human eye movement research? The big problem

stemmed from the fact that it was not possible to separate motions caused by head movements from those caused by eye movements. Ratliff and Riggs (1950) introduced a simple way to get around this. Again, in their words:

Originally it was planned to use the simultaneous records of head and eye movements to determine the exact motions of the retinal image [during maintained fixation], because . . . both . . . must be known to determine the motions of the image on the retina. However, it became apparent . . . that the center of rotation of the head is not even approximately a fixed point. At times the center of rotation may be at the point of contact of the upper teeth with the biting board [a dental impression used to restrict head movement]. At other times it may be at the point of articulation of the vertebral column with the cranium. Since the center of the head cannot be determined with accuracy, the angular movements which are recorded are of little use in determining the linear extent of the movement of the eye due to head movements . . . a better method . . . was needed. (Ratliff and Riggs, 1950, pp. 692–693)

They avoided the problem of eye translations by using the optical lever technique, introduced by Adler and Fliegelman (1934). They improved it, however, by mounting their small, flat mirror in a tight-fitting scleral contact lens. (Adler and Fliegelman had stuck their mirror directly on the eye and held it in place with a dab of vegetable gum.) The contact lens allowed Ratliff and Riggs to record for much longer periods of time. The contact lens also eliminated the need for the subject to hold the eyelid up with a finger while recordings were made. Ratliff and Riggs' most important contribution, however, was the way in which they eliminated the confound produced by head translations relative to the target. Head movement artifacts were eliminated simply by using a collimating lens in front of the eye. This lens placed the fixation target at optical infinity. This arrangement allowed the head to translate on the biting board without causing the retinal image of the target to be displaced on the retina. The fixation target, once it was viewed through the collimating lens, was simply too far away for head translations to affect the position of its retinal image significantly.

Ratliff and Riggs' (1950) records were valid, but they were hardly representative of natural fixation. The target was fixated monocularly while the head was immobilized as much as possible on a biting board. Even under these very restricted conditions, valid measurements could only be made of eye rotations on a single meridian, usually the horizontal. Nachmias (1959) introduced the first convenient variant of the optical lever method that could be used to make simultaneous, valid, albeit still very unnatural measurements of eye rotations on both horizontal and vertical meridians without confounding vertical with torsional eye rotations. Many important human oculomotor characteristics were observed under such unnatural conditions, and some of their physiological underpinnings have been worked out in primate models by recording electrophysiological brain activity in the oculomotor systems of monkeys while

they performed a variety of oculomotor tasks. The bulk of this research was done with a magnetic eye movement recording method introduced by Robinson (1963).

Instrumentation continued to develop, and by the last decade of the twentieth century, it finally became possible to observe how a human being controlled gaze under relatively natural conditions, that is, with the head and torso free to move naturally as objects within arm's reach were observed and manipulated. Doing this required solving the problem Ratliff and Riggs (1950) had managed to get around by putting their targets at optical infinity. Observing gaze control with nearby objects requires measuring the smallest translations (<0.1 mm) of the head, as well as its roll, pitch, yaw, and two-dimensional binocular eye movements. All of these angles have to be measured to at least 1 arc min for the measurements of gaze to be at least twice as good as the performance of the oculomotor system, the biological system under study. See Epelboim et al. (1995) for a brief description of the instrumentation developed to do this. This unique instrumentation made possible the first accurate, natural studies of human gaze control. These studies have called into question the significance of many observations that had been made earlier under less natural conditions. These new naturalistic observations will be described after some highlights from earlier, somewhat less natural, research are reported. These observations clearly implied that studying the human being's control of gaze under unnatural conditions could be perilous. They could mislead the investigators. There were clear hints that this might be the case as early as 1953 when Riggs et al. published their pioneering study of stabilized retinal images. Their study reported a result whose significance was not appreciated for more than 25 years. This publication will be described in some detail after some necessary background and definitions are presented.

Background and definitions

Foveal creatures like ourselves make two very different kinds, or types, of eye movements. In the simplest classification, proposed by Steinman et al. (1990), these two kinds of eye movements are simply called *fast* and *slow*. This reduces the number of postulated oculomotor subsystems from five or more to only two (see Dodge, 1903; Hallett, 1986; Robinson, 1968, for descriptions of many more oculomotor subsystems). Steinman et al. (1990) justify their reduction by pointing out that the traditional classifications are based primarily on the stimulating conditions usually used to study one or another of these putative subsystems. The classifications do not seem to be based on any well-established differences in oculomotor performance, physiology, or anatomy. The simpler classification seems to be catching on, as evidenced by its adoption in a popular introductory perception text (Sekuler and Blake, 2002, pp. 364–370). In this

classification, eye movements are simply called either fast or slow on the basis of three oculomotor performance characteristics, namely, their (1) peak velocities, (2) acceleration characteristics, and (3) susceptibility to voluntary control. The initiation, size, and direction of the fast eye movements, which are called *saccades*, are under voluntary control. They accelerate very rapidly and attain their relatively high peak velocities early. Saccades do not require visual targets. Their peak velocities are somewhat lower, and the size of the smallest voluntary saccade is larger when no targets are visible, but their main performance characteristics are the same. As a consequence, humans can shift their gaze to look at something that may appear anywhere in a completely dark visual field almost as well as they can shift their gaze to look at something visible in peripheral vision. Said differently, saccades are not influenced by properties of the visual field. The eye will drift in an idiosyncratic direction in total darkness (often down) when the head is immobilized, however, because the low-velocity compensatory eye movements, called *slow control*, require input from a visible stimulus moving on the retina (Steinman et al., 1967, 1973).

Slow (or *smooth*) eye movements are different. They accelerate gradually, and their maximum velocity is less than half of that achieved by the fastest saccades. The susceptibility of these slow eye movements to voluntary control is also much more limited. Normally, they cannot be initiated voluntarily if nothing is moving on the retina. Smooth eye movements will respond reflexively to a moving object or frame in the visual field, *but only if* the observer is not provided with a stationary object which can be used to keep gaze in place. Objects or frames that are moving in the visual field can be ignored, but gaze can stay in place only if the visual field contains a visible stationary target. Head movements can also cause the retinal images of objects and frames to move, and if, *but only if*, the subject attends to these motions will they be tracked with smooth eye movements. If smooth eye movements are made by paying attention to a moving object, the response is called *smooth pursuit*. If smooth eye movements are made by paying attention to a large frame rather than to an object, many oculomotor researchers call these slow eye movements *optokinetic reflexes* (OKN), rather than smooth pursuits. This distinction seems to be based entirely on tradition, and not on the characteristics of the eye movements themselves or any known differences in their anatomical or physiological underpinnings. Note, however, that if the subject chooses to attend to a stationary object or frame, smooth eye movements will not be observed. Gaze will be maintained. So, what the person wants to attend to is under voluntary control, but when it comes to slow, or smooth, eye movements, properties of the attended stimulus determine the nature of the oculomotor response once the subject selects the stimulus. (See Kowler et al., 1984, for experimental results showing the degree to which selective atten-

tion determines the outcome when moving and stationary stimuli are present in the visual field at the same time, and see Kowler, 1990, for the most comprehensive treatment available of the importance of cognitive factors in controlling human eye movements.)

Head movements also provide another kind of input to the oculomotor system. The oculomotor system receives input from the hair cells in the semicircular canals of the vestibular system as well as from the retina. These hair cells respond to accelerations of the head, causing the eye to rotate in the direction opposite to the head's rotation. The eye's angular velocity, resulting from vestibular stimulation, is similar (~95%) to the head's angular velocity (Collewijn et al., 1983). These involuntary counterrolling eye movements, called the *vestibulo-ocular reflex* (VOR), can be canceled almost completely if the observer fixates an object attached to the head, such as the tip of the nose if it is illuminated and if it is long enough to be seen. The VOR cannot be made to operate voluntarily if the head is not allowed to move. Once it can move, what VOR does depends on what the subject is attending to. The velocity of the slow eye movements (smooth pursuits or OKN) that a subject uses to track a smoothly moving object or frame *can* be adjusted voluntarily to specified fractions of the target's velocity, but smooth eye movements *cannot* be made voluntarily without a target moving on the retina, and smooth pursuit velocity *cannot* exceed the velocity of the moving target. Subjects asked to get ahead of a smoothly moving target can do this, but only by making saccades ahead of the target. They cannot lead the target with smooth pursuits (Steinman et al., 1969).

Each type of eye movement accomplishes different things. The fast, voluntary eye movements, saccades, are used to fixate an attended object, that is, to place its retinal image within the fovea. Said differently, saccades are used to place gaze where, within the visual field, we want gaze to fall. Human saccades can attain peak velocities of about 550 deg/sec. Their peak velocity depends on their size. Larger saccades are faster. This velocity/amplitude relationship has been dubbed the *main sequence*, a term borrowed from star brightness magnitudes in astronomy which was probably introduced to impute some kind of special significance to this rather common phenomenon. Very small saccades, called *microsaccades* (smaller than 10 or 12 min arc), have velocities of only a few degrees per second. These tiny saccades are the smallest voluntary human behaviors (see Haddad and Steinman, 1973; Steinman et al., 1973, for a discussion of their nature and functional significance).

Saccades of all sizes are used to bring attended objects to fall at the *center of best vision* or *optimal locus* (Cornsweet, 1956) at the foveal center. Saccades of about 0.5 to 1.5 degrees of visual angle are used to read a line of ordinary text. Saccades can also be used to reestablish fixation quickly if an object suddenly moves away from the optimal locus.

Saccades can shift gaze among objects in the visual field very rapidly. We are not ordinarily aware of making these rapid gaze shifts, and it came as a surprise when it was discovered that such high-velocity jumps were used to read. Subjectively, one has the impression that our eyes glide smoothly across the text as we read each line of words. We can easily make ourselves aware of the relatively large gaze shift we use to move from the end of one line to the beginning of the next, but the jumps among the words are perceived as being smooth. They are not. The reading eye movement pattern is shown in Figure 90.1. This figure is somewhat unusual because it shows the reading eye movement pattern of a subject who is reading under relatively natural conditions. The subject is seated with the head and torso free as he reads a standard text located about 30 cm in front of his eyes. Only left eye movements are reproduced in this figure, but recording was binocular (the right eye movements were very similar to the left). Translations as well as rotations of the head are shown. The top graph in Figure 90.1 shows head rotations; the bottom graph shows rotations of the left eye. The pattern of head rotations varied during the trial. A 2 degree head rotation to the right was made during the third and fourth seconds as the eyes moved to the right across a line of text. There was a fast, large saccade (~25 degrees = about 10 cm on the page) that moved gaze to the left to the beginning of the next line of text near the middle of the fifth second, but the movement of the head was much slower, which meant that the head was still moving to the left as the eye was moving to the right as it read the new line of text. So, for about 0.5 second, the head and eye were moving in opposite directions.

Different head-eye coordinations were observed during other reading trials, and the second subject, who served in these experiments, also showed different kinds of head-eye coordination. Kowler et al. (1991) drew the following conclusions from this research:

Head rotations were larger when the head was free than when the head was on a bite board [and] the S.D.s of head rotations with the head free are about twice what is observed when subjects try to hold the head as still as possible without artificial support during maintained fixation. . . . The head moves during reading but not in a stereotypical pattern . . . in some instances it moved in the same direction as the reading saccades; in other instances it moved in the opposite direction. Eye rotations compensated well for head movements, producing a fairly stable line of sight during intersaccadic intervals. (pp. 421–422)

None of these head and eye movements are perceived subjectively when one reads, a fact which seems as remarkable now as it did when it was first discovered a little over a century ago.

The human being's slow, or smooth, eye movements have velocities ranging from as little as 3 minutes of arc per second up to peak velocities of about 200 degrees of arc per second.

FIGURE 90.1. Results of a sample reading trial. *Top*: Horizontal rotation of the left eye and the head as a function of time during reading. Upward deflection of the traces indicates rightward eye or head motion. *Middle*: Total movement of the head (head/pg), the rotational component (rot/pg), and the translational component (trans/pg) on the page of text. These traces represent the positions of an imaginary line connecting the midpoint of the center of rotation of the left eye with the page. *Bottom*: Horizontal position of the line of sight of the left eye on the page of text. (From Kowler et al., 1991.)

They tend to be involuntary in the sense that normally they cannot be made by willing them in the absence of something moving in the visual field. They will, however, always be made in anticipation of a future target motion. These *anticipatory smooth eye movements* can be as fast as 60 deg/sec (see Steinman et al., 1990, for records showing very fast anticipatory smooth eye movements, and see

Kowler, 1990, for a review of her research on anticipatory smooth eye movements). We also speak of *involuntary* or *noisy drifts*. Adler and Fliegelman (1934) called these slow eye movements *waves*. They are involuntary slow shifts of gaze. They are observed in the intervals between small saccades, which are made when an adult subject maintains fixation on a stationary object with the head immobilized. The involuntary slow eye movements, which have been shown to correct such noisy drifts, have been described as smooth pursuit of a stationary object whose retinal image moves because of noisy drifts (Nachmias, 1959). Steinman et al. (1973) ascribed these compensatory fixational slow eye movements to the operation of an oculomotor subsystem they dubbed *slow control*.

Findings encouraging questions about the relevance of unnatural research

THE ROLE OF NATURAL AND UNNATURAL RETINAL IMAGE MOTION IN VISUAL PROCESSING Riggs et al. (1953), who initiated a long line of research on stabilized retinal images, reported an unexpected result whose significance would not be appreciated for 26 years. They used the contact lens optical lever technique to allow a subject to view a simple fixation target under three conditions. The first condition allowed what they called *normal* vision, in which the subject viewed the stimulus monocularly with the head fixed on a biting board. They called this vision normal because the retinal image displacements of the fixating eye were the same as the displacements present under the fixation conditions they normally used, that is, with the head immobilized on a biting board. In the second condition, a mirror path in the optical arrangements stabilized the retinal image of the fixation target. When the eye moved, the target moved with it by the same amount, so its retinal image did not move on the retina. In the third condition, called *exaggerated motion*, the mirror path was arranged so that an eye movement caused the fixation target to move on the retina twice as much as it moved during normal fixation. The subject indicated whether the fixation target was visible during fixation trials, which lasted for many seconds. As expected, the stabilized target disappeared often and remained invisible for the longest period of time. The target also disappeared occasionally during normal viewing. This was not surprising. Many observers had noticed periodic fading of fixation targets (and more complicated displays) when they stared at them for many seconds with the head immobilized artificially. Fading was least likely in the exaggerated retinal image motion condition. This result came as a surprise, but little was made of it at the time. It clearly meant that transient stimulation was useful for visual processing, but its implications were otherwise ignored. It became important 26 years later when Skavenski et al. (1979) published the first accurate monocular recordings of the head and eye movements

FIGURE 90.2. Representative horizontal (H) and vertical (V) head position and gaze of subject AAS (*left*) and RMS (*right*) while they fixated a target at optical infinity with their heads supported on a biting board or while they were standing as still as possible. Records

begin on the left. The vertical lines show 1 second intervals, and the vertical scales on the right show 1 degree of visual angle. Upward changes in these position traces signify rightward or upward rotations. (From Skavenski et al., 1979.)

of seated and standing subjects fixating a target located at optical infinity.

Figure 90.2 clearly shows that the head moves quite a lot when a human being tries to sit or stand as still as possible. A good deal of this head movement is compensated for by eye movements, but considerable retinal image motion remains. The eye traces in the records reproduced in Figure 90.2 show gaze. They would be horizontal straight lines if head movements were compensated for perfectly. There are very few instances where this can be seen in the records of both subjects when they sat or stood. Their gaze was considerably more stable when their heads had artificial support, as shown by the top two records in Figure 90.2. Note that in the two more natural conditions in which the subjects were sitting or standing still without artificial support, there was considerable uncompensated head motion. This led to considerable retinal image motion—enough to minimize, perhaps even to prevent, any fading of the fixation target. The retinal image velocities observed while they were sitting and standing were quite similar to those which had proved to be so effective in preventing fading in the exaggerated retinal image motion condition in the Riggs et al. (1953)

publication about stabilized images. The implications of these results, in the authors' words, were as follows:

[T]he gain of the compensatory machinery is tuned to guarantee that the retinal image will always move at some appreciable speed which would not be the case if the gain of compensation approached 1 when the amplitude of body rotation was small. . . . Note that subjects whose heads are supported on bite-boards occasionally report periods of target fading which means that retinal image speeds seen on a bite-board are only marginal for maintaining vision . . . [and] once we pay attention to the fact that compensation is mostly less than perfect . . . we are forced to consider how we see a perceptually clear world during such image motion. Oculomotorists have assumed that the quality of vision is a consequence of the stability of the retinal image [caused by the virtual perfection of oculomotor compensation]. The retinal image is not actually stable so perceptual clarity must depend in part on visual as well as on oculomotor activities. (Skavenski et al., 1979, pp. 681–682)

The significance of Figure 90.3 is quite similar to that of Figure 90.2. Here we see recordings made under even more natural conditions. Figure 90.3 shows head and *binocular* eye recordings of four subjects who attempted to maintain

FIGURE 90.3. Representative horizontal eye and head movements of four subjects (R.S., H.S., L.K., and H.C.) while they fixated a distant object as they moved their heads. Records begins on the left, and the time-scale marks signify 1 second intervals. The head position trace (H/10) shows the position of the head to 1/10th of its actual value. Right eye position (RE) is just below the head, with

left eye position (LE) just below it, and the bottom trace in each graph (LE-RE) shows vergence. Upward changes in position traces in these records show rightward movements, and upward changes in vergence traces signify convergence. (From Steinman and Collewyn, 1980.)

fixation on distant targets (5000 or 35,000m away) as they actively oscillated their heads about their vertical axis at different frequencies and amplitudes. Once again we see considerable oculomotor compensation for head rotations, but it is far from perfect, which means that there was considerable residual retinal image motion. All four subjects reported seeing clearly throughout these trials. Some jitter of the visual field was reported at the highest head oscillation frequencies, but vision was always fused and clear despite such violent retinal image motions. Now that binocular record-

ings were finally made, a very surprising result can be seen: there was considerable difference in the degree of compensation by each of the subjects' eyes. This led to considerable variation in their vergence angles (the oscillations evident in the bottom trace in each subject's graphs, labeled "LE-RE," for "left eye-right eye"). This result was not expected. Such large variations in vergence angles should not have been observed when binocular fixation was maintained on such distant targets. The implications of these results, in the authors' words, were as follows:

It is not easy to study binocular eye movements accurately in freely moving subjects or to stabilize retinal images under such conditions. Furthermore, it was not believed to be necessary to study freely moving subjects. Almost all investigators . . . believed that natural visual and oculomotor performance, and their interaction, could be understood despite the fact that their subjects' heads were immobilized. Two assumptions underlie this belief. First, it is assumed that the oculomotor system compensates almost perfectly for motions of the body. . . . Second, it is assumed that compensatory oculomotor activities are almost perfectly yoked in the two eyes. Once these two assumptions are made, the fusion, stability and clarity of the visual world during normal activity can be explained. These explanations, however, rest on what we now know is an idealized view of the operation of the oculomotor system. (Steinman and Collewijn, 1980, pp. 427–428)

These results also suggest that much will be found under natural conditions that could not have been anticipated from what was known from research performed under the more common, much less natural conditions usually employed.

THE MICROSACCADE, FUNDAMENTAL OCULOMOTOR ACTION OR LABORATORY CURIOSITY The microsaccade has a long history in the study of human eye movements research. It first became prominent as what Adler and Fliegelman (1934) called *rapid shifts*, which were observed during attempts to maintain fixation. Adler and Fliegelman claimed that their extent was about “15 minutes of arc.” Once this value is corrected for their computational error (see above), these saccades would be 7.5 min arc, an acceptable value for what has been called a *microsaccade* since Zuber et al. (1965) introduced this term. Generally speaking, saccades smaller than 10 or 12 min arc along a single meridian have been placed in this category ever since accurate estimates of fixational eye movements began to be made about 50 years ago. Ditchburn (1955), who trained as a physicist and shifted his research interests to human vision after World War II, believed that transient stimulation provided by these microsaccades, which he called *flicks*, was essential for maintaining clear, high-quality color vision. Many subjects, but by no means all, whose fixational eye movements have been recorded since the optical lever technique came into vogue showed microsaccades in their eye movement pattern during maintained fixation. The status and significance of microsaccades came into question when Steinman et al. (1967) reported that simple instructions would reduce their frequency appreciably (by 50% or more) and even eliminate them completely. These reductions in microsaccade rates had no adverse effects on the quality of vision. This observation was followed by a series of publications, including some which showed that saccades as small as microsaccades were in the voluntary behavioral repertoire and others which showed that microsaccades could be used to track small target steps reliably. These experiments were summarized by Steinman et al. In 1973, by which time it was generally

accepted by most oculomotorists that microsaccades, which are present only in the behavior of adult human beings whose heads are being held artificially while they attempt to maintain fixation, were a laboratory curiosity rather than an important oculomotor behavior (Kowler and Steinman, 1979). Ditchburn (1980) preferred to believe otherwise, and his comment on one of the papers in this series led to an exchange of letters (Kowler and Steinman, 1980). This exchange should be of interest to anyone wondering about the significance of microsaccades. The significance of microsaccades for processing visual contrast and spatial detail was discussed in Steinman and Levinson (1990). This review also claims that microsaccades are not likely to contribute to any kind of visual processing. In addition, it reviews the extensive literature on stabilized images and also claims that microsaccades do not play a significant role in vision. When it first became possible to study the control of gaze under relatively natural conditions (Steinman and Collewijn, 1980), it became clear to the investigators that microsaccades were not common, perhaps even absent, in the fixational eye movement pattern once the head was free to move naturally. Nailing this down has become important now that microsaccades are beginning to be taken seriously in the primate oculomotor community (e.g., Bair and O’Keefe, 1998; Martinez-Conde et al., 2000; Rucci et al., 2000). For this reason, we randomly sampled 3375 saccades made by four subjects in two naturalistic sequential looking tasks and found that only 2 (0.06%) could be classified as microsaccades, that is, smaller than 12 min arc (Malinov et al., 2000). The implications of these results, in the authors’ words, were as follows:

We have another reportable, albeit expected result. Namely, microsaccades were extremely unlikely. . . . Those, who have studied human eye movements under natural conditions with instrumentation sufficiently sensitive (noise $\leq 2'$) to measure microsaccades, have rarely seen microsaccades (Steinman & Collewijn, 1980, were probably the first). But as far as we know, the actual likelihood of finding a microsaccade under natural conditions has never been reported, in part because: (i) other issues were under study; and microsaccades had lost their significance by 1980. They were laboratory curiosities, confined to human adults, whose head were supported artificially. (Malinov et al., 2000, p. 2089)

There is no reason to believe at this time that the situation has changed, so I would be cautious about accepting work imputing an important role to such behaviors in infrahuman primates, particularly inasmuch as it takes a lot of fixation training before monkeys even begin to show microsaccades in their fixational eye movement pattern (Skavenski et al., 1975; Steinman et al., 1973). We turn next to some relatively recent work on a subject that has forced a major revision of our thinking about the performance characteristics of one of the classical oculomotor subsystems: vergence.

NATURAL SMOOTH AND SACCADIC VERGENCE The oculomotor *vergence subsystem* was one of Dodge's (1903, 1907) five types of eye movement. He described these eye movements, which he called *type V*, in the following way:

The fifth type is in several respects unique. It consists, primarily, of movements of convergence and divergence . . . [when] the stimulus falls on disparate points of the two retinae, and the movements of the two eyes are consequently not in the same but in opposite directions. The most conspicuous of the differentiae of this type are the relative slowness of the movements. . . . Whereas movements of the first type [saccades] through 10° occupy about 40σ [msec]; eye movements of the fifth type . . . occupy about 400σ [msec]. (Dodge, 1903, pp. 327–328)

The slowness and smoothness of Dodge's type V eye movement were stressed in the oculomotor literature until quite recently, when Erkelens et al. (1989a) used the unique eye movement recording system developed at the University of Maryland to examine how vergence actually operated under much more natural conditions than had been possible before. These observations made it clear that studying human eye movements under unnatural conditions had given a very misleading impression of how the human oculomotor systems performs when it adjusts gaze in three dimensions. These experiments and the implications of their results, in the authors' words, were as follows:

We studied ocular vergence responses made under relatively natural viewing conditions as a first attempt to determine whether vergence responses obtained under such conditions could be predicted from descriptions of vergence responses to the isolated motion-in-depth cues that had been studied separately in previous experiments. We undertook to study vergence under relatively natural conditions because it has become increasingly clear in recent years that oculomotor performance, as well as its visual consequences cannot be predicted from studies undertaken under constraints that had been necessary and eventually became traditional in laboratory settings (Skavenski et al., 1979; Steinman and Collewijn, 1980; Collewijn et al. 1983; Steinman et al., 1985). . . . We found that ocular vergence in response to a target seen to be changing its position in depth in a normally lighted room, replete with natural cues to depth, had shorter delays and better dynamics than could have been expected from reports of previous experiments. . . . Changes in vergence often preceded changes in the distance of the target when the distance of the target was under control of the subject. The most accurate vergence tracking (smallest tracking error) was observed when voluntary movements of the upper torso . . . provided the changes in the distance of the target. (Erkelens et al., 1989b, pp. 418–419)

Figure 90.4 shows an example of one subject's slow or smooth vergence eye movements produced by changing the distance between the subject and the target in this experiment.

The next publication in this series of naturalistic experiments, by Erkelens et al. (1989a), yielded even more surprising results. Once again, the experiment and the

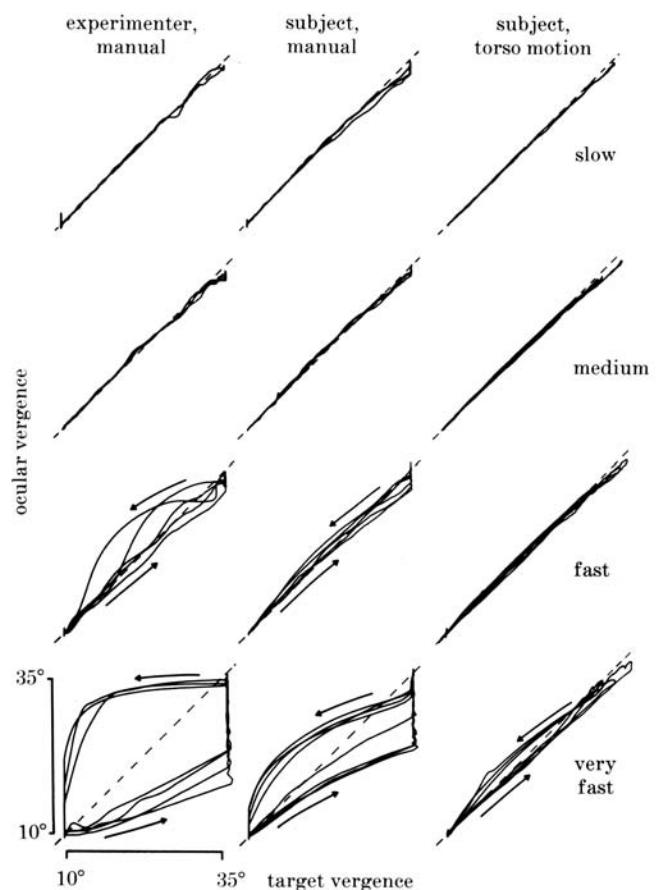

FIGURE 90.4. Typical relations between ocular-vergence and target-vergence angle of subject H.C. in response to slow (*first row*), medium (*second row*), fast (*third row*), and very fast (*bottom row*) changes in target distance. The three columns represent the three ways in which the distance of the target was varied. The diagonal dashed lines represent perfectly accurate vergence tracking. (From Erkelens et al., 1989b.)

implications of its results will be given in the authors' words:

In the preceding paper . . . we reported that the vergence subsystem makes timely and fast responses over a large dynamic range when it is provided with its 'natural input'. . . . We also showed that the vergence subsystem, like other oculomotor subsystems, is largely under voluntary control once it is provided with its natural input. . . . The present experiments . . . examined (1) shifts of gaze between stationary target objects . . . at different distances . . . along the median plane . . . and (2) shifts of gaze between objects that lay off to the side of the median plane as well as at different distances. . . . We examined . . . both [because they] are required for effective functioning in natural situations. We had no basis for predicting the quality of oculomotor performance. . . . We found that symmetrical vergence responses, as large as 30° , were largely smooth and attained maximum speeds as high as 200°s^{-1} . When . . . targets required asymmetrical vergence responses . . . vergence responses . . . were mediated almost exclusively by unequal saccades. . . . Such a dominant role for saccades in producing large vergence responses consistently has been rarely suspected. . . . We

FIGURE 90.5. Representative binocular eye movements of three subjects (C.E., H.C., and R.S.) when they shifted gaze between light-emitting diodes (LEDs) located along each subject's median

plane. The small bar on the lower right shows a 1 second interval. The vergence shifts shown were mainly smooth. They were also very fast. (From Erkelens et al., 1989b.)

conclude that unequal saccades are generated normally in asymmetric vergence, and that traditional schemes . . . are incorrect. (pp. 442–443)

Figure 90.5 shows the very fast *smooth* vergence responses made by each of the three subjects, who shifted gaze between two targets located at different distances along their median plane. Figure 90.6 shows their asymmetrical *saccadic* vergence responses made when they shifted gaze between targets which were not located on their median plane. Note that under natural conditions, virtually all vergence changes are asymmetric and saccadic because targets are rarely located along the median plane and never stay there very long. The slightest movement of the body creates conditions favorable for saccadic rather than smooth vergence changes. Once this is appreciated, smooth vergence, like microsaccades, seems to be primarily a laboratory curiosity. It can be demonstrated, but it is hard to set up and almost impossible to maintain if the subject's head is not immobilized artificially.

The second paper on vergence under naturalistic conditions concluded as follows:

There is a great deal left to do now that we have shown that the control of vergence can be studied in the laboratory in ways that make sense with respect to the way vergence must operate in everyday life. We must now determine with our accurate, high-

bandwidth instrumentation, how the saccadic and slow subsystems function, synergistically, when gaze shifts between stationary objects . . . within the three-dimensional visual field in which human beings locate, track and manipulate objects of interest to them. We must refine our techniques to allow the subject's head to be free while he interacts with objects within reach of his hands. Once this is done, we will begin to have some idea of how cognitive, oculomotor and manual motor skills interact to guarantee our success as a species. (p. 464)

The reader should consult Judge (1991), who reviewed the status of vergence eye movements shortly after these two papers were published to gauge the novelty of these results with respect to how they fit with the traditional vergence literature, a literature that began with what Dodge (1903) called type V eye movements.

SUMMARY OF RECENT ECOLOGICALLY RELEVANT RESEARCH
The instrumentation developments required to study gaze under natural conditions were finished in 1992 and the first publication based on its use appeared in 1995, 3 years shy of the hundredth anniversary of the first publication reporting a method for recording human eye movements (Delabarre, 1898). In all, five papers meeting the requirements for studying gaze control under *natural* conditions have appeared so far (Epelboim, 1998; Epelboim et al., 1995, 1997; Herst et al., 2001; Malinov et al., 2000; see Steinman, 1995, for a detailed explanation of why and how the unique

FIGURE 90.6. Representative binocular eye movements of three subjects (C.E., H.C., and R.S.) when they shifted gaze between a LED far away and to the right of the subject's median plane and a LED nearer and to the left of the subject's median plane. This target arrangement required asymmetrical vergence responses. The

dashed trace shows the position of the left eye; the solid trace shows the position of the right eye and vergence, that is, the difference between the positions of each eye. The small bar on the lower right shows a 1 second interval. The vergence shifts shown were mainly smooth. They were also very fast. (From Erkelens et al., 1989a.)

eye movement recording instrumentation at the University of Maryland was developed). In this series of experiments, the subject's head and torso were completely free as two-dimensional binocular gaze was recorded. The subject either looked at a sequence of targets in a specified order (look-only condition) or tapped a similar sequence of targets (tap condition). They were required to complete each sequence as rapidly as possible without making any errors. The targets were arranged in randomly selected locations on a work table in a well-illuminated chamber, which contained many objects and frames that provided excellent information about the location of the subject and targets within the three dimensions of the workplace. Data were also collected when the subject chose the order in which the targets would be fixated or tapped.

Only the main findings of these experiments will be summarized here. The source papers (listed just above) should be consulted for details. These results could not have been expected on the basis of prior work done under much less natural conditions. Highlights of the analyses completed and published so far are as follows: (1) just looking at a sequence of targets, solely to fixate each target accurately, and looking at a similar sequence to guide tapping, are fundamentally different tasks. The seemingly more complicated task, using vision to guide tapping, was easier, more pleasant, and took less time to complete than the task in which the subject did much less, namely, simply fixate each target in a sequence; (2) visual search (using a saccade to *find* the next target) is a separate and different saccadic activity from *looking from one target to the next in the sequence* in both looking and tapping tasks; (3) looking for its own sake, looking to guide tapping, and visual searching are synergistic, interacting in beneficial ways; (4) subjects almost *always* look at the target they are about to tap before tapping it, but are *convinced* that they do not do this often once a particular target pattern has been learned; (5) cyclopean gaze, on average, is more accurate than gaze from either eye, demonstrating that under natural conditions (6) subjects show no sign of a *dominant eye* when they use their eyes to perform visually guided motor tasks despite the fact that they do show a dominant eye when a conventional *phoria cover test* is performed; (7) microsaccades, when the head is free, are exceedingly rare (see the section "The Microsaccade, Fundamental Oculomotor Action or Laboratory Curiosity"); (8) vergence tends to be set 25% to 45% *beyond* the attended plane; in other words, subjects do *not* adjust binocular gaze to intersect at the attended target, but rather adjust their eyes to intersect much farther away; (9) subjects fixate no more accurately than a given task demands, implying that at least for ordinary visuomotor tasks, any part of the foveal floor which is good enough to do the job will be used; (10) the *main sequence*, like other characteristic oculomotor performance, is controlled from the top down, that is, high-level task demands, such as its objec-

tives or goals, set the control parameters in the oculomotor *plant* (its physiological machinery) automatically; it does this without any conscious effort; and (11) once the head, as well as the eye, is free from restraint, the head is most likely to begin to move before, or at the same time, as the eye. The way the four subjects of these experiments actually controlled their gaze when they only looked at and when they tapped sequences of targets can be visualized by going to the following web page: <http://brissweb.umd.edu>.

Some highlights of these publications, the first accurate reports of how human beings control gaze under ecologically relevant conditions, are reproduced in Figures 90.7 to 90.10. The reader should consult the source papers (cited above) for detailed explanations of how these data were collected and what they have been taken to mean. Examining the visualizations available at the web page (cited just above) after reading these source papers will also promote understanding of the significance of these figures.

The basis for achieving accurate gaze control lies in the human being's ability to call upon one or the other compensatory subsystem at different times and to varying degrees. This ability is built in. Choosing a particular behavioral objective (goal or purpose) sets the parameters in the oculomotor plant without any explicit, conscious efforts on the subject's part. Furthermore, under natural conditions, gaze control is lax, perhaps even lazy. One could just as easily call it *efficient*. Why should the oculomotor system set its parameters so as to make it do more work than is needed to get a particular job done? In short, it should not come as a surprise that gaze is not set to be as accurate as possible all the time. Evidence for this, as well as demonstrations of the human being's control of gaze by adjusting parameters of oculomotor subsystems, is clear when gaze is studied under conditions approximating those that are commonplace in the workaday world. It may be here, *and only here*, that the nature and extent of the human being's exquisite control gaze becomes apparent. Much of the oculomotor literature, which is based on research done with the head restrained and targets beyond arm's reach, has probably told us very little of lasting value despite a century of active research. Fortunately, methods are now available which make accurate, ecologically relevant research possible, so one can hope that a second century of oculomotor research will not be needed before we actually know how human beings control gaze as they do other things that are important for their success as a species.

Acknowledgments

This chapter is dedicated to the memory of Dr. Julie Epelboim (1964–2001), who contributed enormously to making the ecologically relevant research referred to in this chapter possible, as well as using this approach to collect the

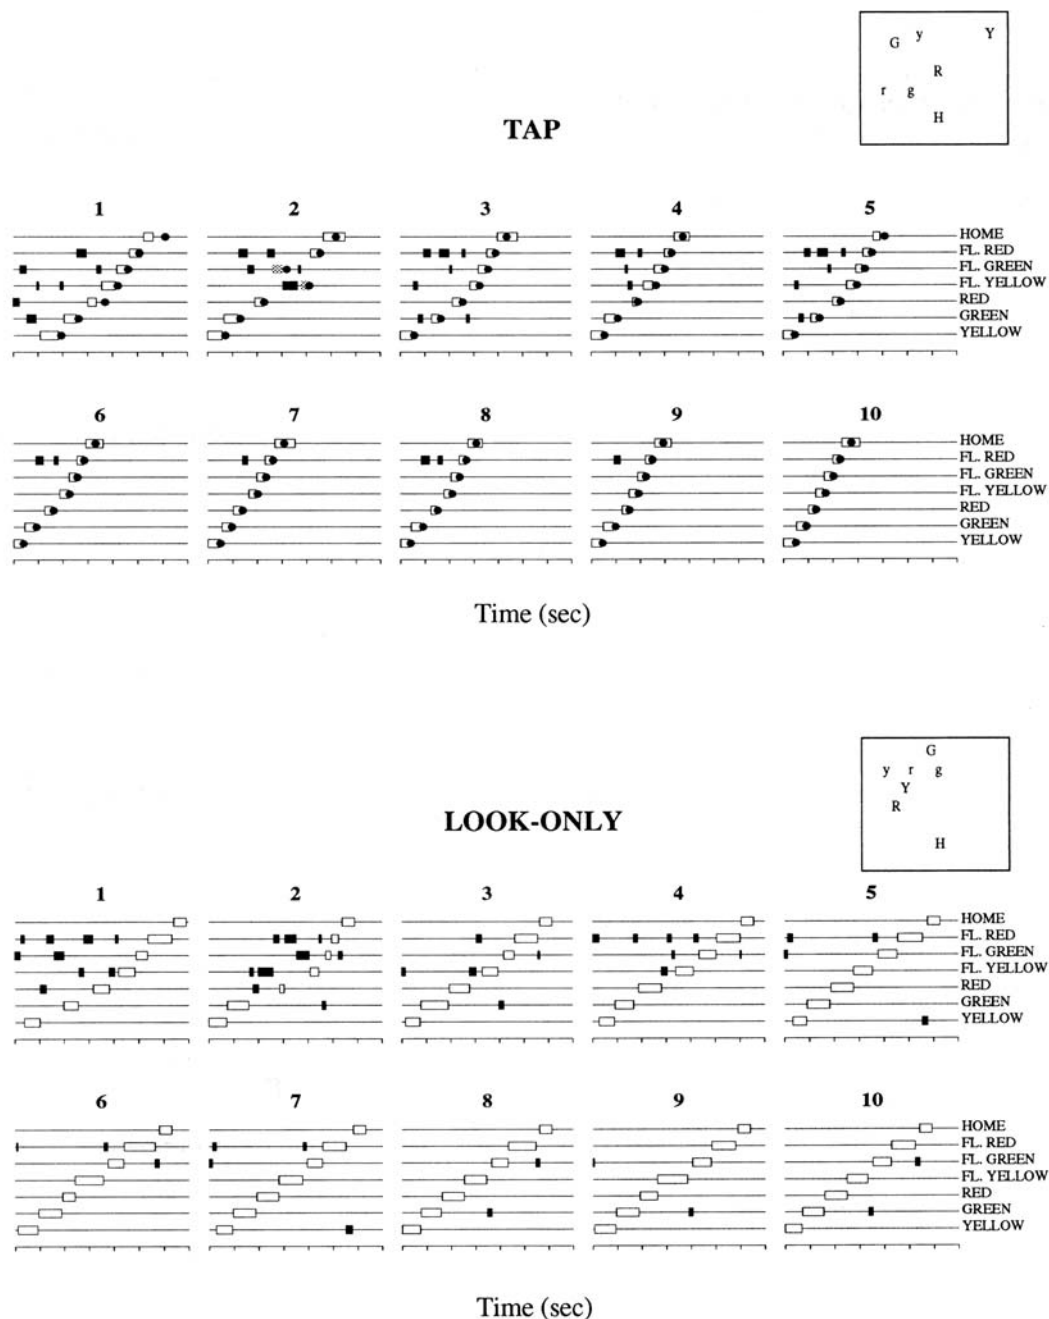

FIGURE 90.7. Look/tap diagrams for a 10 blocks of tapping trials and 10 blocks of looking-only trials. Each diagram represents one repetition with the same target configuration. The repetitions are numbered 1 to 10 above each diagram. The positions of targets on the work table for each block are shown in the rectangle signifying the colors of the six LED targets and a home button: Y, yellow; G, green; R, red; y, flashing yellow; g, flashing green; r, flashing red; H, home. Time is shown on the abscissa. Each horizontal line

the right. Boxes and dots on each horizontal line show when the subject looked at or tapped that target. Open boxes show sequence episodes, solid boxes show search episodes, and shaded boxes show looking episodes preceding tapping errors (see text). Widths of boxes show durations of looking episodes. Solid circles show the times of the taps. See the text for a full explanation, but it is clear that the visuomotor coordination during the two tasks was different. Looking for its own sake was not the same as looking to guide tapping. (From Epelboim et al., 1995.)

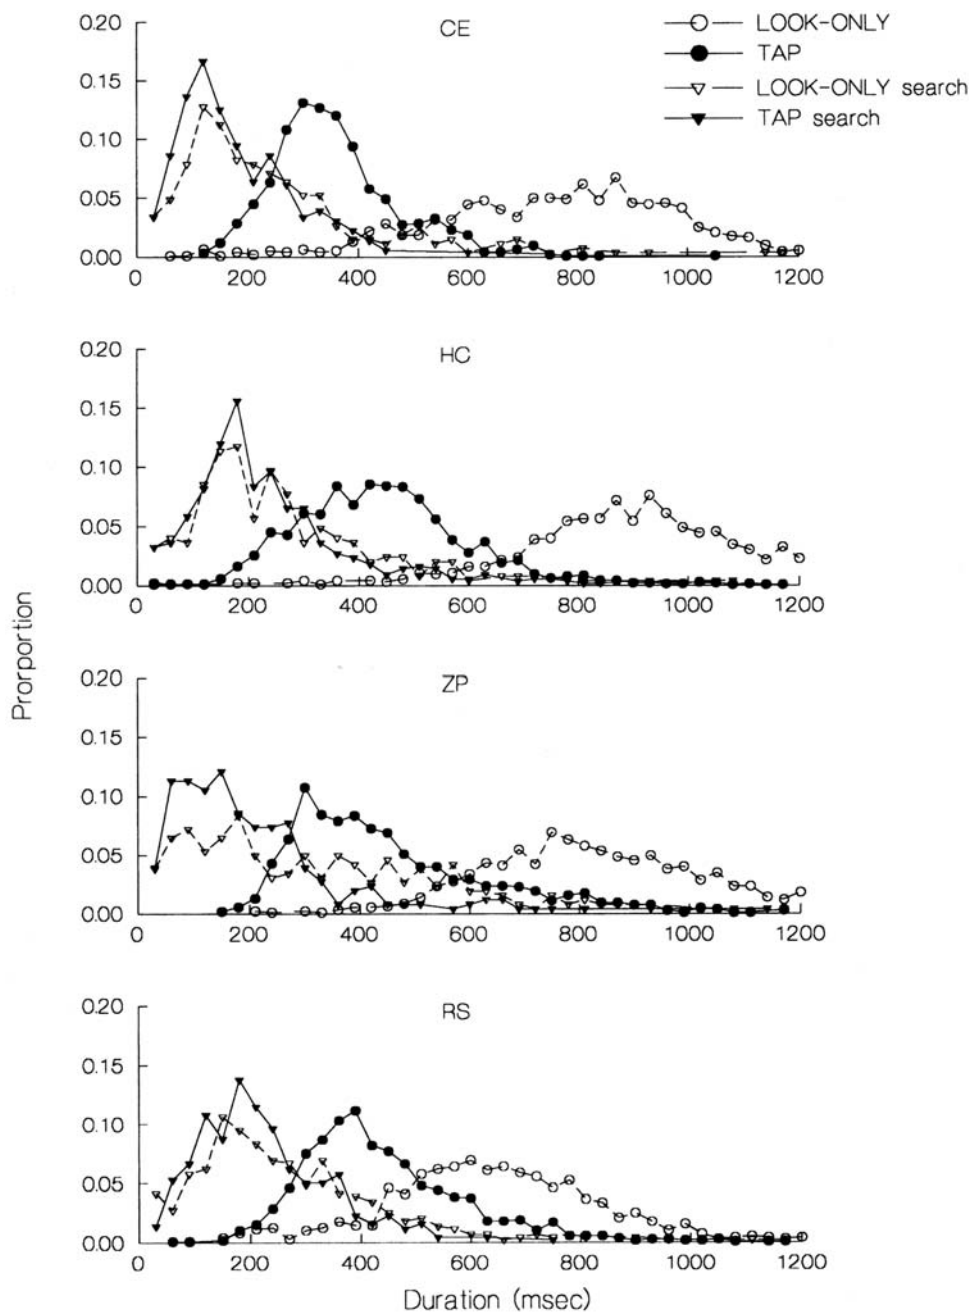

FIGURE 90.8. Distributions of sequence (*circles*) and search (*triangles*) episode durations (milliseconds). Data for tapping are shown as solid lines and solid symbols, and data for looking only are shown as dashed lines and open symbols. Bin width is 30 msec. Data for four subjects are shown in rows labeled C.E., H.C., Z.P., and R.S.. Each distribution is based on 950 to 1396 observations for sequence episodes and 247 to 552 observations for search episodes. All four

subjects showed that dwell-time distributions for search episodes were short and the same in both tasks, and dwell times were much longer during look-only trials. These results were taken to mean that saccades made to find targets are different from saccades made to move gaze through a sequence of targets. (From Epelboim et al., 1995.)

Figure 90.9. Gaze-shift peak speed (*left*) as a function of amplitude in space and eye-in-head peak speed (*right*) as a function of amplitude within the head of four subjects labeled C.E., H.C., Z.P., and R.S. These smooth curves are least square fits of the data. They show that the nature of the main sequence depends on the nature of the task, with higher velocities being found during

tapping than during looking only. The relatively small difference between the tasks shown by subject RS (bottom pair of graphs) can be explained by his age. He was 65 when these data were collected, so it was not surprising that his peak saccadic velocity was considerably lower than the highest velocities of the younger subjects. (From Epelboim et al., 1997.)

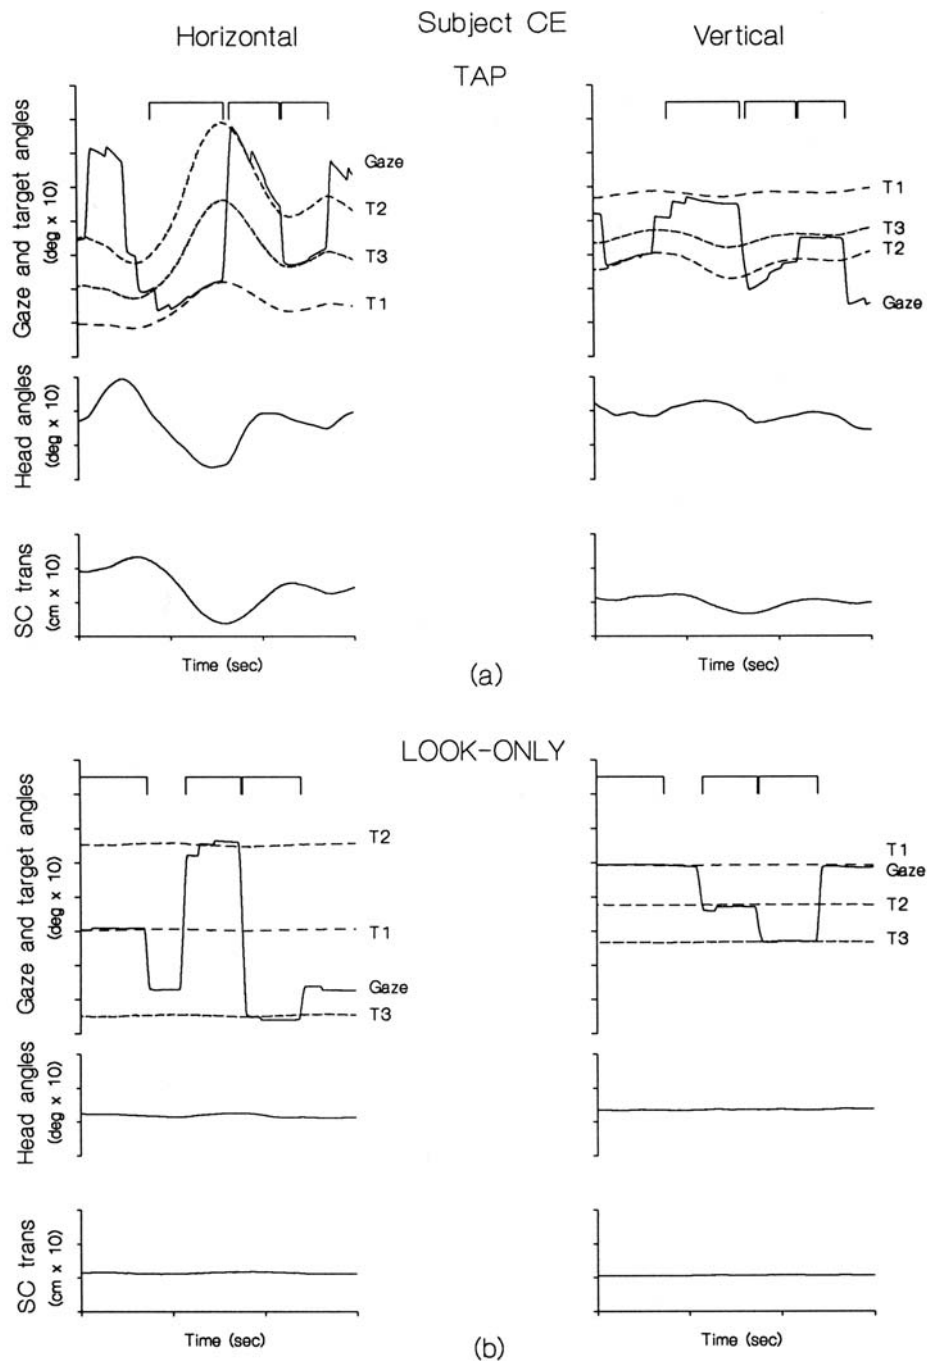

FIGURE 90.10. Analog records for subject C.E. during three segments of a tapping trial (a) and a looking-only trial (b). Horizontal components are shown on the left, and vertical components are shown on the right. The layout is the same for a and b. The top row shows gaze (solid lines) and target angles (dashed lines) for the right eye plotted as a function of time. Brackets above the graph show episodes during which CE was looking at each of the three targets

whose traces are shown. The second row shows head angles as a function of time. The bottom row shows translations of the sighting center of the right eye as a function of time. Gaze and head movements were used quite differently with respect to controlling the amount of retinal image motion when fixation was maintained during each task. (From Epelboim, 1998.)

data for her doctoral dissertation. Her obituary, including a list of her main publications, can be found in Herst et al. (2001). The research described in this chapter was supported, in part, by grants from the Chemistry and Life Sciences Directorate of the Air Force Office of Scientific Research, most recently, AFOSR Grant No. F496200210143.

91 Eye Movements in Daily Life

MICHAEL F. LAND

EYE MOVEMENT RESEARCH over the past 100 years has had two rather different goals. On the one hand, physiologists have directed their efforts at describing accurately the different types of eye movements—saccades, smooth pursuit, and so on, analyzing their mechanics and muscular physiology and searching for the neural machinery in the brain that generates them. On the other hand, many psychologists have been more concerned with the functions of eye movements, in particular with their roles in the execution of everyday activities (reading, driving, playing ball games, etc.). The main difference between the two traditions is that for the former, it is single eye movements that are the focus of interest, while for the latter, it is the sequences of eye movements, and more particularly the patterns of fixation that the eye movements produce, that are important. It is these sequences, and their relations to the actions they facilitate, that are the subject of this chapter.

While we are dimly aware that we look in the direction of the places where our actions are unfolding, we can get little further than this by introspection alone. What is required is a combination of objective eye movement recording synchronized to recordings of the actions to which the eye movements relate. Most of the studies reviewed here are of this type. The chapter is divided into two parts. The first part provides outline accounts of studies of real-life tasks. Drawing on these examples, the second part considers the nature of the eye movement strategies that accompany actions and other issues that relate to the joint control of eyes and motor behavior.

Part 1: The relations of eye movements to action in different activities

Activities involving the uptake of visual information can be divided into those that are basically sedentary—reading or typing, for example—and those such as carpentry or ball sports that involve more extensive movement. The former have been studied since eye movement recordings began (e.g., Dodge, 1900), but the latter have been open to investigation only since about 1960, when portable recording devices started to become available.

SEDENTARY ACTIVITIES: READING, MUSICAL SIGHT-READING, AND TYPING Although silent reading involves no overt action, it nevertheless requires a particular eye movement

strategy to enable the uptake of information in a way that allows meaning to be acquired. It is also one of best-studied (as well as the most atypical) examples of a clearly defined eye movement pattern. Erdman and Dodge (Dodge, 1900) first showed that the subjectively smooth passage of the eye across the page is in reality a series of saccades and fixations in which information is taken in during the fixations. Eye movements in reading are highly constrained to a linear progression of fixations to the right (in English) across the page, which allows the words to be read in an interpretable order. In this, reading differs from many other activities (such as viewing pictures), where order is much less important (Buswell, 1935). Reading is a learned skill, but the eye movements that go with it are not taught. Nevertheless, they are remarkably similar among normal readers. Eye movements during reading have been reviewed thoroughly recently, and only the principal facts need to be included here. Most of what follows is derived from an extensive review by Rayner (1998).

During normal reading, gaze (foveal direction) moves across the line of print in a series of saccades, whose size is typically seven to nine letters. Within limits this number is not affected by the print size, implying that the oculomotor system is able to make scaling adjustments to its performance. For normal print the saccade size is 1 to 2 degrees, and the durations of the fixations between saccades have a mean of 225 msec. In reading aloud, fixations are longer (mean, 275 msec). Most saccades (in English) are to the right, but 10% to 15% are regressions (right to left) and are associated in a poorly understood way with problems in processing the currently or previously fixated word. Words can be identified up to 7 to 8 letter spaces to the right of the fixation point, but some information is available up to 14 to 15 letter spaces; this is used in the positioning of subsequent saccade end points. From studies in which words were masked during fixations, it appears that the visual information needed for reading is taken in during the first 50 to 70 msec of each fixation. Adult readers typically read at a rate of about 300 words per minute or 0.2 second per word.

If changes are made to the text during the course of a fixation, both the duration of the current fixation and the size of the following saccade can be affected. This implies that the text is processed “on-line” on a fixation-by-fixation basis. Similarly, difficult words result in longer fixations, indicating that cognitive processes operate within single fixations. How

FIGURE 91.1. *a*, Fixations made by an expert accompanist while sight reading a passage from a sonata by Domenico Scarlatti at full speed. The shaded circles are fixations followed by glances down to the keyboard. Note that these have no detectable effect on the fixation sequence. *b*, Fixations during copy typing. The upper line of each pair shows the text being read, with fixations numbered in

order. The lower line shows the text as typed, and the diagonal lines show the letters being typed at the time of the indicated fixations on the upper row. The eye-hand span for this fast typist is about five letter spaces. (*a* from Land and Furneaux, 1997; *b* from Butsch, 1932.)

long it takes to process words all the way from vision to meaning is hard to assess, but in reading aloud, the time between fixating a word and speaking it (the eye-voice span) is about 1 second (Buswell, 1920).

Musical sight reading shares with text reading the constraint that gaze must move progressively to the right. It is, however, more complicated in that—for keyboard players—there are two staves from which notes must be acquired (Fig. 91.1A). Weaver (1943) recorded eye movements of trained pianists and found that they alternated fixation between the upper and lower staves, acquiring notes from the score at a rate of approximately 1.5 notes per fixation (making a note roughly equivalent to a word in text reading). This alternation means that notes that have to be played together are viewed at different times, adding the task of temporal assembly to the other cognitive tasks of interpreting the pitch and length of the notes. The time from reading a note to playing it (the eye-hand span) is similar to reading aloud: about 1 second. Furneaux and Land (1999) looked at the eye-hand span in pianists of differing abilities. They found that it did not vary with skill level when measured as a time interval, but that when measured in terms of the number of notes contained in that interval, professionals

averaged four compared with two for novices. Thus, the processing time is the same for everyone, but the throughput rate of the processor is skill dependent. The processing time did alter with tempo, however, with fast pieces having an eye-hand span of 0.7 second, increasing to 1.3 seconds for slow pieces.

Copy typing, like music playing, has a motor output, and according to Butsch (1932), typists of all skill levels attempt to keep the eyes 1 second ahead of the currently typed letter, which is much the same as in music reading. This represents about five characters (Fig. 91.1B). More recently, Inhoff and colleagues (Inhoff and Wang, 1992) found more variability in the eye-hand span and also showed that it was affected by the nature of the text. Using a moving window technique, they showed that typing starts to become slower when there are fewer than three letter spaces to the right of fixation, indicating a perceptual span about half the size of that used in normal reading. The potential word buffer is much bigger than this, however. Fleischer (1986) found that when typists use a read/check cycle of approximately 1 second each while typing continuously, they typically take in 11 characters during the read part of the cycle, and, exceptionally, strings of up to 30 characters can be stored.

These activities are all similar in that they involve the continuous processing of a stream of visual information taken in as a series of stationary fixations. This information is translated and converted to a stream of muscular activity of various kinds (or into meaning in the case of silent reading). In each case, the time within the processor is about 1 second. Once the appropriate action has been performed the original visual information is lost, so the process is more like a production line than a conventional memory system.

ACTIVITIES INVOLVING MOVEMENT The study of the gaze movements of head-free, fully mobile subjects required the development of eye trackers that were head- rather than bench-mounted. The first truly mobile apparatus for freely moving subjects was devised by Mackworth and Thomas (1962). It consisted of a helmet-mounted 8mm movie camera which viewed the scene ahead. Superimposed on this was a spot derived from the corneal reflex of one eye and conveyed to the camera by an inverted periscope arrangement. This device was successfully used to study eye movements in driving and flying, as well as during more stationary activities (Thomas, 1968). A decade later, small video cameras started to become available, making the recording process much simpler, and a number of video-based eye-movement cameras are currently available commercially. They typically consist of two cameras, one viewing the scene ahead and one viewing the eye. Commonly, the eye is illuminated with infrared light, which provides the eye camera with a “bright pupil” from infrared light reflected from the retina. This is tracked with appropriate software to provide the coordinates of eye direction, which can then be used to position a spot or a cross on the scene video, indicating the instantaneous direction of regard of the fovea. A variant of this design uses the outline of the iris to derive eye direction (Land, 1993). Such devices can be used for virtually any activity. Search-coil methods have also been used successfully to record gaze direction or eye and head direction separately (Collewijn, 1977). Their main limitation is that they can only be used within the magnetic field of the surrounding coils, which means that their versatility is not much greater than that of fixed-head methods.

EYE MOVEMENTS AND ACTIONS IN DOMESTIC TASKS Activities such as food preparation, carpentry, or gardening typically involve a series of different actions, rather loosely strung together by a “script.” They provide examples of the use of tools and utensils, and it is of obvious interest to find out how the eyes assist in the performance of these tasks.

Land et al. (1999) studied the eye movements of subjects while they made cups of tea. When tea is made with a teapot, this simple task involves about 45 separate acts (defined as “simple actions that transform the state or place of an entity through manual manipulation”; Schwartz et al.,

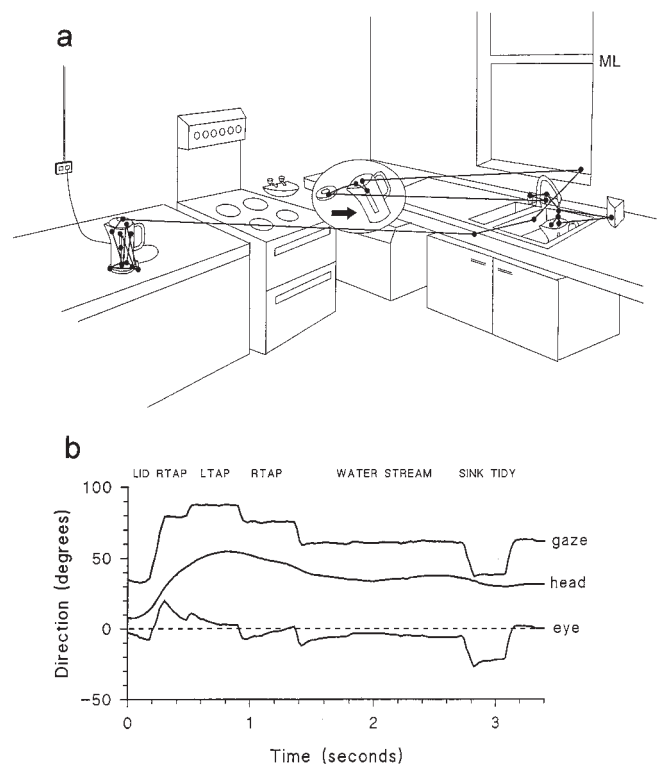

FIGURE 91.2. *a*, Fixations and saccades made during the first 10 seconds of the task of making a cup of tea (lifting the kettle and starting to fill it). Note that all but one of the fixations are on objects immediately relevant to the task. *b*, Plot of eye, head, and gaze movements toward the end of the task in *a*, showing the steady gaze fixations resulting from eye saccades and compensation for head movement by the vestibulo-ocular reflex. (From Land et al., 1999.)

1991). Figure 91.2 shows the 26 fixations made during the first 10 seconds of the task. The subject first examines the kettle (11 fixations), picks it up, and looks toward the sink (3 fixations), walks to the sink while removing the lid from the kettle (insert: 4 fixations), places the kettle in the sink and turns on the tap (3 fixations), then watches the water as it fills the kettle (4 fixations). There is only one fixation that is not directly relevant to the task (to the sink tidy on the right). Two other subjects showed remarkably similar numbers of fixations when performing the same sequence. The principal conclusions from this sequence are:

1. Saccades are made almost exclusively to objects involved in the task, even though there are plenty of other objects around to grab the eye.
2. The eyes deal with one object at a time. This corresponds roughly to the duration of the manipulation of that object and may involve a number of fixations on different parts of the object.

There is usually a clear “defining moment” when the eyes leave one object and move on to the next, typically with a combined head and eye saccade. These saccades can be used

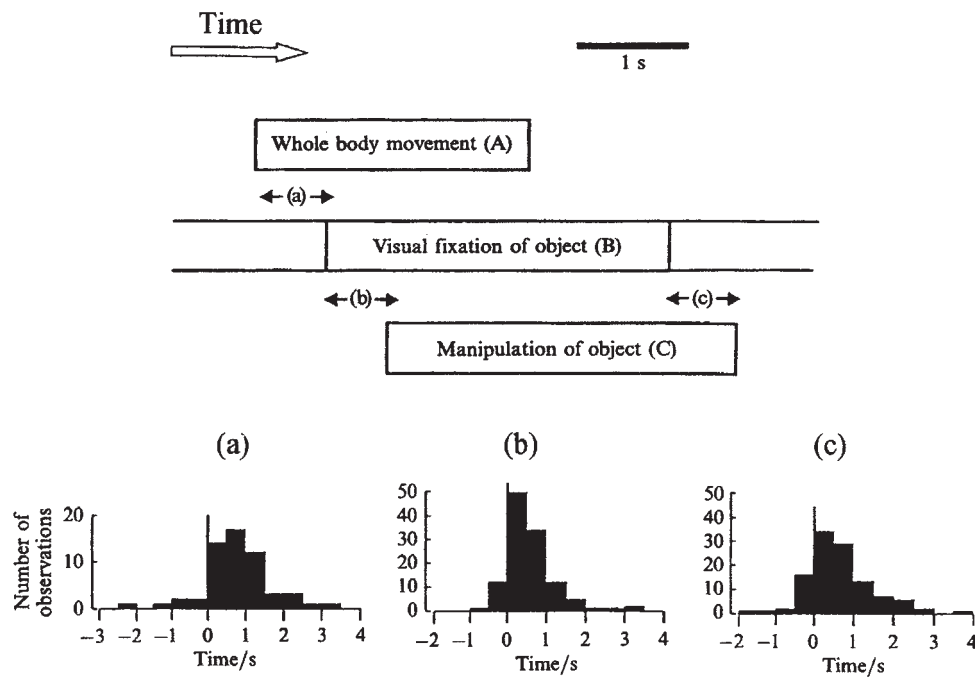

FIGURE 91.3. Timing of the relations of body, eye, and hand movements averaged from a total of 137 object-related actions during tea-making sessions by three different individuals. Movements of the whole body precede the first fixation by a mean of

0.61 second (a), and these precede the first signs of manipulation by 0.56 second (b). As each action draws to a close, fixation moves to the next object an average of 0.61 second before the end of the preceding action (c). (From Land and Hayhoe, 2001.)

to “chunk” the task as a whole into separate object-related actions, and they can act as time markers to relate the eye movements to movements of the body and manipulations by the hands. In this way, the different acts in the task can be pooled to get an idea of the sequence of events in a typical act. The results of this are shown in Figure 91.3. Perhaps surprisingly, it is the body as a whole that makes the first movement in an object-related action. Often the next object in the sequence is on a different work surface, and this may necessitate a turn or a few steps before it can be viewed and manipulated. About 0.5 second later, the first saccade is made to the object, and 0.5 second later still, the first indications of manipulation occur. The eyes thus lead the hands. Interestingly, at the end of each action, the eyes move on to the next object about 0.5 second before manipulation is complete. Presumably the information that they have supplied remains in a buffer until the motor system requires it.

Almost identical results were obtained by Hayhoe (2000) in a study of students making peanut butter and jelly sandwiches. She found the same attachment of gaze to task-related objects and the same absence of saccades to irrelevant objects. As with the tea making, gaze led manipulation, although with a somewhat shorter interval. This difference is probably attributable to the fact that the sandwich making was a sit-down task involving only movements of the arms. Two other differences that may have the same cause are the existence of more short-duration (<120 msec)

fixations than in the tea-making study and the presence of more unguided reaching movements (13%) mostly concerned with the setting down of objects. There was a clear distinction in both studies between within-object saccades, which had mean amplitudes of about 8 degrees in both, and between-object saccades, which were much larger, up to 30 degrees in sandwich making on a restricted table top and 90 degrees in tea making in the less restricted kitchen (Land and Hayhoe, 2001).

DRIVING Driving is a complex skill that involves dealing with the road itself (steering, speed control), other road users (vehicles, cyclists, moving and stationary pedestrians), and attention to road signs and other relevant sources of information. It is thus a multifaceted task, and one would expect a range of eye movement strategies to be employed. I will first consider steering, as this is a prerequisite for all other aspects of driving.

When steering a car on a winding road, vision has to supply the arms and hands with the information they need to turn the steering wheel the right amount. What is this control signal, and how is it obtained? As pointed out by Donges as early as 1978, there are basically two sorts of signal available to drivers: feedback signals (lateral and angular deviation from the road centerline, differences between the road’s curvature and the vehicle’s path curvature) and feedforward or anticipatory signals obtained

from more distant regions of the road up to 2 seconds ahead in time (corresponding to 90ft or 27m at 30mph). Donges (1978) used a driving simulator to demonstrate that each of these signals was indeed used in steering, although he did not discuss how they might be obtained visually.

Eye movement studies both on real roads (Land and Lee, 1994) and on a simulator (Land and Horwood, 1995) have confirmed Donges' two-level model of driving and have gone some way toward establishing how the eyes find the appropriate information. Earlier studies, mainly on U.S. roads that had predominantly low curvatures, had found only a weak relationship between gaze direction and steering (e.g., Zwahlen, 1993). However, on a winding road in Scotland, where continuous visual control was essential, a much more precise relationship was seen. Land and Lee (1994) found that drivers spent much of their time looking at the tangent point on the upcoming bend (Fig. 91.4*B*). This is the moving point on the inside of the bend where the driver's line of sight is tangential to the road edge; it is the point that protrudes into the road, and it is the only point in the flow field that is clearly defined visually. The angular location of this point relative to the vehicle's line of travel (effectively the driver's trunk axis if he or she is belted in) predicts the curvature of the bend: larger angles indicate steeper curvatures. Potentially, this angle is a signal that can provide the feedforward information required by Donges' analysis, and Figure 91.4*A* does indeed show that curves of gaze direction and steering wheel angle are almost identical. The implication is that this angle, which is equal to the eye-in-head plus the head-in-body angle when the driver is looking at the tangent point, is translated more or less directly into the motor control signal for the arms. Cross-correlating the two curves in Figure 91.4*A* shows that gaze direction precedes steering wheel angle by about 0.8 second. This provides the driver with a reasonable comfort margin, but the delay is also necessary to prevent steering from taking place before the bend has been reached.

FIGURE 91.4. Eye movements and steering. *a*, Simultaneous record of gaze direction and steering wheel angle during part of a drive on a winding road in Scotland. Note the extreme similarity of the two records. Cross-correlation shows that eye direction precedes steering by about 0.8 second. Brief glances off-road also occur. *b*, Contour plots showing the distribution of fixations by three drivers during right and left bends on a 1 km stretch of the same winding road as in *a*. Both are centred within 1 degree of the respective tangent points. Plots are normalized to the central value, which is approximately 0.12 fixations per $\text{deg}^2\text{s}^{-1}$. About 35% of fixations lie outside the 0.2 contour, and these are widely scattered. *c*, Time sharing between tasks. The driver's gaze alternates between the tangent point and the cyclist, spending approximately 0.5 second on each. Steering is linked to the road edge and suspended when looking at the cyclist. (From Land, 1998.)

Simulator studies showed that feedforward information from the distant part of the road was not sufficient on its own to provide good steering (Land and Horwood, 1995). When the near region of the simulated road was removed from view, curvature matching was still accurate, but position-in-lane control was very poor. To maintain good lane position required a view of the road only a few meters ahead, and this region provided much of the feedback information identified in the Donges model. Interestingly, this part of the road was rarely fixated compared with the more distant tangent point region, but it was certainly seen and used; it is typically about 5 degrees obliquely below the tangent point. Maurant and Rockwell (1970) had already concluded that lane position is monitored with peripheral vision. They also argued that learner drivers first use foveal vision for lane keeping, then increasingly move foveal gaze to more distant road regions and learn to use their peripheral vision to stay in the lane. Summala et al. (1996) reached similar conclusions. The principal conclusion from these studies is that neither the far-road feedforward input nor the near-road feedback input is sufficient on its own, but that the combination of the two allows fast, accurate driving (Land, 1998).

A feature of Figure 91.4A and similar records is that the eyes are not glued to the tangent point, but take time out to look at other things. These excursions are accomplished by gaze saccades and typically last between 0.5 and 1 second. The probability of these off-road glances occurring varies with the stage of the bend that the vehicle has reached, and they are least likely to occur around the time of entry into a new bend. At this point, drivers fixate the tangent point 80% of the time. It seems that special attention is required at this time, presumably to get the initial estimate of the bend's curvature correct. A confirmation of this came from Yilmaz and Nakayama (1995), who used reaction times to a vocal probe to show that attention was diverted to the road just before simulated bends and that sharper curves demanded more attention than shallower ones. The fewer and shallower the bends in the road, the more time can be spent looking off the road, and this probably accounts for the lack of a close relation between gaze direction and steering on studies of driving on freeways and other major roads.

Sometimes the eye must be used for two different functions at the same time, and as there is only one fovea and off-axis vision is poor, the visual system has to resort to time sharing. A good example of this is shown in Figure 91.4C, where the driver is negotiating a bend and so needs to look at the tangent point while passing a cyclist who needs to be checked on repeatedly. The record shows that the driver alternates gaze between the tangent point and cyclist several times, spending 0.5 second on each. The lower record shows that he or she steers by the road edge, which means that the coupling between eye and hand has to be turned off when

the driver views the cyclist (who would otherwise be run over!). Thus, not only does gaze switch between tasks, so does the whole visuomotor control system. Presumably, while looking at the cyclist, the information from the tangent point is kept "on hold" at its previous value.

This example has shown how the visual system is able to divide its time between different activities. In urban driving this is even more important, as each traffic situation and road sign competes for attention. To my knowledge, there has been no systematic study of where drivers look in traffic, but from our own observations, it is clear that drivers foveate the places from which they need to obtain information: the car in front, the outer edges of obstacles, pedestrians and cyclists, road signs and traffic lights, and so on. In general, speeds of 30 mph or less require only peripheral lane-edge (feedback) information for adequate steering. Thus, the necessity to use distant tangent points is greatly reduced, freeing up the eyes for the multiple demands of dealing with other road users. As with open-road steering, both foveal and peripheral vision are involved. Miura (1987) has shown that as the demands of traffic situations increase, peripheral vision is sacrificed to provide greater attentional resources for information uptake by the fovea.

BALL GAMES Some ball sports are so fast that there is barely time for the player to use his normal oculomotor machinery. Within less than 0.5 second (in baseball or cricket), the batter has to judge the trajectory of the ball and formulate a properly aimed and timed stroke. The accuracy required is a few centimeters in space and a few milliseconds in time (Regan, 1992). Half a second gives time for one or at most two saccades, and the speeds involved preclude smooth pursuit for much of the ball's flight. How do practitioners of these sports use their eyes to get the information they need?

Part of the answer is anticipation. Ripoll et al. (1987) found that international table tennis players anticipated the bounce and made a saccade to a point close to the bounce point. Land and Furneaux (1997) confirmed this (with more ordinary players). They found that shortly after the opposing player hit the ball, the receiver made a saccade down to a point a few degrees above the bounce point, anticipating the bounce by about 0.2 second. At other times, the ball was tracked around the table in a normal nonanticipatory way; tracking was almost always by means of saccades rather than smooth pursuit. The reason players anticipate the bounce is that the location and timing of the bounce are crucial in the formulation of the return shot. Until the bounce occurs, the trajectory of the ball as seen by the receiver is ambiguous. Seen monocularly, the same retinal pattern in space and time would arise from a fast ball on a long trajectory or a slow ball on a short one (Fig. 91.5A). (Whether either stereopsis or looming information is fast enough to provide a useful depth signal is still a matter of debate.) This ambiguity is

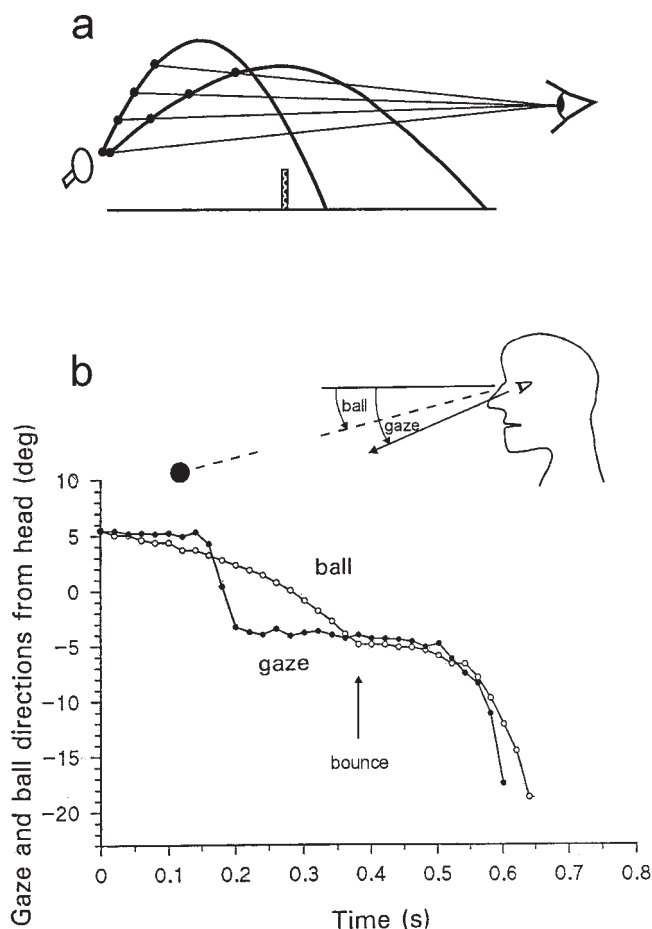

FIGURE 91.5. Anticipating the bounce in ball games. *a*, To the receiver of a table tennis stroke, there is little difference in the seen trajectory of a slow short ball and a faster long ball (ignoring stereopsis and looming). The position of the bounce is needed to disambiguate the real trajectory. *b*, Vertical gaze movements of a batsman in cricket facing a medium-pace ball from a bowling machine. He makes a downward saccade to the approximate bounce point about 140msec after the appearance of the ball, anticipating the bounce by almost 180msec in this case. He then tracks the ball for another 200msec. (From Land and McLeod, 2000.)

removed the instant the timing and position of the bounce are established. Therefore, the strategy of the player is to get gaze close to the bounce point (this cannot and need not be exact) before the ball does and lie in wait. The saccade that effects this is interesting in that it is not driven by a stimulus, but by the player's estimate of the location of something that has yet to happen.

In cricket, where—unlike baseball—the ball also bounces before reaching the batsman, Land and McLeod (2000) found much the same thing. With fast balls, the batsmen watched the delivery and then made a saccade down to the bounce point, the eye arriving 0.1 second or more before the ball (Fig. 91.5*b*). They showed that with a knowledge of the time and place of the bounce, the batsman had the infor-

mation he needed to judge where and when the ball would reach his bat. Slower balls involved more smooth pursuit. With good batsmen this initial saccade had a latency of only 0.14 second, whereas poor batsmen or nonbatsmen had more typical latencies of 0.2 second or more.

In baseball the ball does not bounce, and so that source of timing information is not available. Bahill and LaRitz (1984) examined the horizontal head and eye movements to batters facing a simulated fastball. Subjects used smooth pursuit involving both head and eye to track the ball to a point about 9ft from them, after which the angular motion of the ball became too fast to track (a professional tracked it to 5.5 ft in front; he had exceptional smooth pursuit capabilities). Sometimes batters watched the ball contact the bat by making an anticipatory saccade to the estimated contact point partway through the ball's flight. This may have little immediate value in directing the bat, because the stroke is committed as much as 0.2 second before contact (McLeod, 1987), but it may be useful in learning to predict the ball's location when it reaches the bat, especially as the ball often "breaks" (changes trajectory) shortly before reaching the batter. According to Bahill and LaRitz (1984), "The success of good players is due to faster smooth-pursuit eye movements, a good ability to suppress the vestibulo-ocular reflex, and the occasional use of an anticipatory saccade."

Part 2: issues and discussion

It is clear from the examples given in Part 1 that eye movements play a crucial role in the organization of actions, and that in general, the eyes begin to collect information before the action itself has begun (Fig. 91.3). Eye movements are thus a planned-in, proactive part of every action sequence and are not simply summoned up when more information is needed. In the discussions that follow, I explore how close are the relations, in space and time, between where we look and what we do, and what is the nature of the control structure that underlies both aspects of visually coordinated activity.

"DO IT WHERE I'M LOOKING" One of the first detailed studies of eye movements in relation to manipulative activity was performed by Ballard et al. (1992). They used a task in which a model consisting of colored blocks had to be copied using blocks from a separate pool. Thus, the task involved a repeated sequence of looking at the model, selecting a block, moving it to the copy, and setting it down in the right place (Fig. 91.6). The most important finding was that the operation proceeds in a series of elementary acts involving eye and hand, with minimal use of memory. Thus, a typical repeat unit would be as follows. Fixate (block in the model area); remember (its color); fixate (a block in the source area of the same color); pickup (fixated block); fixate

FIGURE 91.6. The block copying task. A copy of the Model is assembled from randomly positioned blocks located in the Source area. Typical movements of eyes and hand are shown, together with their timing in a typical cycle. The eyes not only direct the hands, but also perform checks on the Model to determine the color and location of the block being copied. (Modified from Ballard et al., 1992.)

(same block in the model area); remember (its relative location); fixate (corresponding location in the model area); move block; drop block. The eyes have two quite different functions in this sequence: to guide the hand in lifting and dropping the block and, alternating with this, to gather the information required for copying (the avoidance of memory use is shown by the fact that separate glances are used to determine the color and location of the model block). The only times that gaze and hand coincide are during the periods of about 0.5 second before picking up and setting down the block (as with other tasks, the eyes have usually moved on before the pickup or drop is complete).

The main conclusion from this study is that the eyes look directly at the objects they are engaged with, which in a task of this complexity means that a great many eye movements are required. Given the relatively small angular size of the task arena, why do the eyes need to move so much? Could they not direct activity from a single central location? Ballard et al. (1992) found that subjects could complete the task successfully when holding their gaze on a central fixation spot, but it took three times as long as when normal eye movements were permitted. For whatever reasons, the “do it where I’m looking” strategy is crucial for the fast and economical execution of the task. This strategy seems to apply universally.

HOW CLOSELY, IN SPATIAL TERMS, ARE EYE MOVEMENTS RELATED TO ACTIONS? In all the studies described in Part 1, the eyes look at points that are particularly informative for the ongoing action: in food preparation, it is the object being manipulated at the time; in steering, it is the tangent point; in ball games, the bounce point; and so on. How accurately these points are targeted by gaze depends on the spatial scale of the task. Thus, in reading, each fixation takes in about seven letter spaces, which with standard print at 40 cm means that saccades are about 1.33 degrees long, and so the maximum angular distance from any one detected letter is half this amount, 0.67 degree. At the other extreme, the average size of within-object saccades in both tea making and sandwich making was about 8 degrees, implying a maximum eccentricity of a viewed target of 4 degrees (Land and Hayhoe, 2001), which is six times greater than in reading. The difference is presumably due to the large size of culinary objects compared with letters.

Most other estimates are between these extreme values. For example, Johansson et al. (2001) used a high-precision eye tracker to study performance in a task in which a bar was grasped and lifted to make contact with a target switch, avoiding a projecting obstacle on the way (Fig. 91.7). They found that—as in other tasks—the eyes always fixated certain distinct landmarks (the grasp site, the target, and the surface to which the bar returned) and frequently but not always fixated the obstacle and the tip of the bar. They estimated the precision of fixation by determining the sizes of circles that enclosed 90% of the fixation points for all nine subjects: these were 3.3 degrees for the tip of the bar and 5.6 degrees for the obstacle. For the target itself, most fixations were within a 3 degree circle, and they regarded 3 degrees as the diameter of the “functional fovea” for this task. This implies a maximum target eccentricity of 1.5 degrees. (See also Chapter 90.)

FIGURE 91.7. Accuracy of fixation during a task in which a bar is lifted past an obstacle to make contact with a target and then set it down again. All fixations of nine subjects. Five landmarks are consistently viewed: on the LIFT the grasp site, left tip of the bar, target, and tip of the obstacle. On the RETURN the support surface is viewed rather than the grasp site. Black circles are fixations within 3 degrees of one of these landmarks (more than 90%), and gray circles are fixations outside these regions. Areas of circles indicate fixation durations. (Modified from Johansson et al., 2001.)

How far from the fovea can useful information be obtained? Again, this is likely to depend on the scale of the task. Shioiri and Ikeda (1989) studied the extraction of information from pictures, using a window which was contingent on eye position. They found that the maximum area over which high-resolution pictorial information could be extracted was about 10 degrees across: larger windows provided no extra information. This implies that no further “useful resolution” is available outside about 5 degrees from the fixation point. However, this cannot be universally true. Land et al. (1999) found that subjects could make accurate single eye-and-head saccades to appropriate objects that were up to 50 degrees from the current fixation point. Clearly, some information that permitted object identification was available even in the far periphery.

TIMING AND THE ROLE OF BUFFERS In continuous activities such as reading aloud, sight-reading music, and copy typing, we have seen that there is an eye-action delay of about 1 second. Much of this is no doubt the time needed for the complex transformations that convert written symbols into the actions of muscles. In steering a car, there is also a delay of slightly less than 1 second between viewing the tangent point position and adjusting the steering. Besides allowing processing to occur, a second function of the buffer—at least in driving—is that it makes it possible for information for one action to be “put on hold” while the eye deals with something else. A particularly clear instance of this is the behavior of the motorist to the cyclist in Figure 91.4C.

In “one-off” actions such as those involved in food preparation, there is also evidence of a buffer in which information for action is stored. Figure 91.3 shows that at the beginning of a typical tea-making action, the eyes lead manipulative action by about 0.5 second, and at the end they move on to the next object about 0.5 second before the present action is complete. In that 0.5 second, the final manipulative acts must be guided by information held in a store. It seems likely that throughout each object-related action, visual information passes through a 0.5 second buffer, much as in the continuous actions just discussed.

INTRINSIC SALIENCE AND TOP-DOWN CONTROL In both tea making and sandwich making (Land and Hayhoe, 2001), we were particularly impressed by the way gaze moved from one task-relevant object to the next, ignoring all other objects that were not involved in the activity. The proportion of task-irrelevant objects viewed (other than during periods of waiting—for the kettle to boil, for example) was under 5% in both studies (see Fig. 91.2). The conclusion must be that, in real tasks, the eyes are driven much more by top-down information from the script of the activity than by the “intrinsic salience” of objects in the scene. In one sandwich-making experiment involving four subjects, 50% of the

objects on the table were irrelevant to the task (pliers, scotch tape, forks, etc.). In the interval before the task commenced, while the eyes were scanning the table, the proportion of irrelevant objects fixated was 52%. When the task started, this was reduced to 18%. Presumably this represented a shift from target selection based on intrinsic salience to one based on task instructions. Shinoda et al. (2001) reached similar conclusions with a driving task that required the detection of stop signs; they found that detection was heavily affected by both task instructions and the local context (they are rarely detected midblock, compared with at intersections).

Most recent ideas on the generation of saccades to new targets involve a *salience map*. This is a two-dimensional surface, tentatively located in the superior colliculus, in which peaks of excitation correspond to objects in the image. These peaks compete with each other in a winner-take-all manner to reach a threshold that triggers a saccade. Some versions of this salience map concentrate exclusively on bottom-up properties of the image, such as orientation, intensity, and color (e.g., Itti and Koch, 2000), while others allow a degree of top-down control to influence the state of the map (Findlay and Walker, 1999). The studies reported here emphasize this top-down influence, since it is clear that eye movements are very closely coupled to the script of the action as a whole. As Johansson et al. (2001) put it: “The salience of gaze targets arises from the functional sensorimotor requirements of the task.” (The only problem here is that the word *salience* loses its original meaning of conspicuity, and its definition becomes almost circular—an object is salient if it gets looked at, for whatever reason.)

It is not really a surprise to find a strong top-down influence on eye movements in real tasks. In Yarbus’ famous recording of eye movements when viewing a picture (“An Unexpected Visitor,” Fig. 91.8) in which observers were asked different questions about the picture, the influence of the instructions in determining the pattern of eye movements was striking (Yarbus, 1967). In real tasks, the instructions come not from the experimenter, but from the learned internal script for the activity. However, the effect in either case is that a large measure of control is imposed on the choice of the objects that are fixated.

THE FUNCTIONS OF INDIVIDUAL FIXATIONS To what extent is it possible to attribute particular functions in the execution of a task to individual fixations? In the block copying study of Ballard et al. (1992), shown in Figure 91.6, the logic of the task dictates that the first fixation on the model establishes a color, the fixation on the source locates an appropriately colored block, the next one on the model checks position, and the final fixation on the copy directs the block to the right place. There are some “supernumary” fixations (there are about seven fixations per cycle instead of the

FIGURE 91.8. The painting “An Unexpected Visitor” (by I. E. Repin), with three of Yarbuss’ recordings of the eye movements of an observer looking at the picture with different questions in mind. The instructions were: (a) remember the clothes worn by the

people; (b) remember the positions of the people and objects in the room; (c) estimate how long the “unexpected visitor” had been away from the family. (Modified from Yarbuss, 1967.)

minimum of four required), so not all can have a neatly attributable function.

In tea making, Land et al. (1999) found that about one-third of all fixations could be clearly linked to subsequent actions. The remaining two-thirds were made after an action had been initiated, so that although they may well have had similar functions in guiding action, it was less clear how they were related to changes in motor behavior. [Of interest here was a subject, A.I., who had no eye movements, and who made head saccades instead (Land et al., 2002). These are slow and “expensive,” and in executing the task shown in Figure 91.2, A.I. made only one-third as many of these head saccades as normal subjects made eye saccades. As A.I. executed the task with normal speed and competence, the implication is that the rest of us make more saccadic eye movements than we really need.]

Land et al. (1999) found that the functions of fixations could be classified into just four categories, which were designated as locating, directing, guiding, and checking. *Locating* fixations are concerned with establishing the locations of objects, even though there was no associated motor activity at the time of the fixation. In a hand-washing task Pelz and Canoz (2001) also found a number of look-ahead fixations which anticipated future actions, and these are consistent with this category. *Directing* fixations accompany either a movement of the hand to contact an object (in which case

the object is fixated) or a movement of hand and object to a particular position (when the set-down position is fixated). Typically, only a single fixation is involved, and the eye usually moves away from the object or set-down point just before the hand reaches it. Thus, visual feedback is not involved in the last stage of the act. It seems that the main function of the directing fixation is to provide fovea-centered goal-position information to guide the arm. *Guiding* fixations are concerned with manipulations involving more than one object, for example, a kettle and its lid. Here both objects have to be guided relative to each other so that they dock in an appropriate way. Most tool use is of this nature (e.g., spanner and nut). It is more complicated than simple directing and usually involves a number of fixations that alternate between the two objects, and the action is normally completed under visual control. Some guided actions may involve more than two objects, for example, knife, bread, and butter. *Checking* fixations determine when some condition is met, for example, the kettle is full, the water boils, the top is off the bottle. These checking operations may require the eye to dwell on some appropriate region of an object, either in one long fixation or in a series of repeated fixations. When the specified condition is met, a new action is triggered. For example, when the kettle is full, the tap is turned off.

Interestingly, there are some things that are rarely if ever fixated during sequences of this kind. The hands themselves

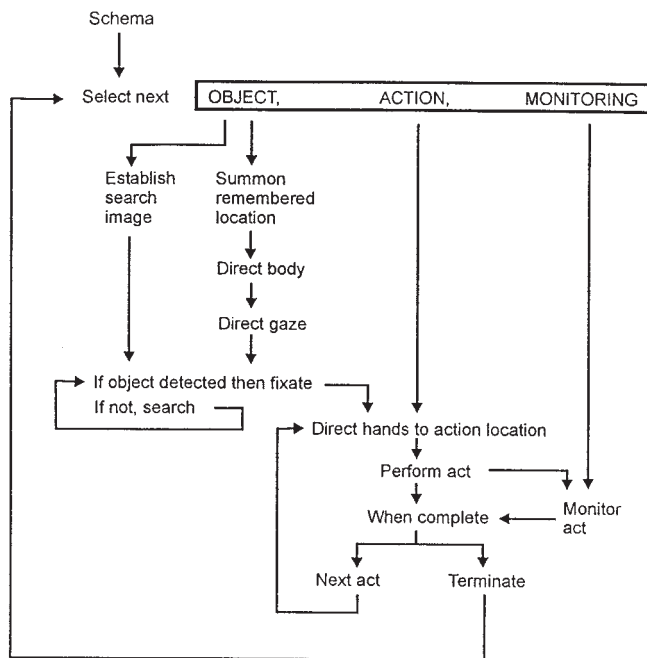

FIGURE 91.9. Scheme showing the flow of information in an object-related action. The eye movement system requires the identity and location of each object in the script or schema so that the eyes can guide the hands appropriately and monitor the results of the actions. Full explanation in text. (From Land and Hayhoe, 2001.)

are never fixated, and once objects have been acquired by the hands, they are not fixated either. The impression is that vision is a scarce and valuable resource, and is disengaged from action as soon as another sense can take over from it.

WHAT THE EYE-MOVEMENT SYSTEM NEEDS TO KNOW In a real-life task, the job of the eye movement system is to place the fovea in a position to obtain the information required for the next component of the activity. To do this, it must itself be supplied with appropriate information about where to look and what to look at.

Figure 91.9 is an attempt to identify the main information pathways during the performance of an object-related action during an action sequence like that of Figure 91.2. The most important function of gaze control is to shift the fovea from one object to the next in the “script” of the task as each action is completed. This means that the system must know which object to select and where it is located. This is far from simple. The object must be recognized somewhere in the visual periphery, which means that an appropriate search image must be activated across large parts of the visual field. Positional information is needed, and this can come from two sources: memory and immediate vision. In many instances, a subject would make an appropriate turn to the location of an object which was out of sight on the other side of the room, and it is a good assumption that the

object’s position was established in an earlier phase of the task in a locating fixation. There were several instances during tea making where an object was fixated 1 minute or more prior to its ultimate use, and when it was time to fetch the object, a memory saccade took gaze to within 20 degrees of it. This was then followed by one or two visually guided saccades finally resulting in fixation (Land et al., 1999). Object acquisition thus involves a complex interplay between object recognition, spatial memory, and vision.

When manipulation begins, the motor system of the arms and hands needs appropriate instructions about the action they must take. Vision may have a simple directing role here, or in the case of guiding, it may have a more active one, with gaze alternating between two objects as they approach each other. In addition, there are checking operations, and the eyes need to know where and what to check. This too must be part of the instructions that the gaze control system receives, presumably at the initiation of each new action.

In Figure 91.9, the script (schema) establishes the next action in the sequence. The gaze control system is supplied with information about the identity and location of the relevant object, and the motor system of the limbs with the manipulations to be performed on it. When the object is located manipulation begins, watched over by the eyes, which have been informed what to check to see that each operation is properly completed. When each sub-act is complete, a further manipulation of the same object may follow (lift milk jug, pour milk into cup, set down jug), or if there are no further sub-acts the action as a whole is terminated, the present set of instructions is abandoned, and those for the next action are sought.

Conclusions

In real-life tasks, the sequences of fixations that the eyes make are very closely bound in space and time to the actions they accompany. Eye movements generally precede manipulations, and they are proactive planned-in components of the action as a whole. There may be a delay of up to 1 second (sometimes longer) before the visual information manifests itself in action, and this implies the existence of a buffer within which transformations occur. Fixation patterns are specific to each activity, with the eyes reliably going to those points in the world from which the best information for that task can be obtained.

92 Selection of Targets for Saccadic Eye Movements

JEFFREY D. SCHALL

The perceptions of naked outlines, as in the diagrams of Euclid and the alphabetical characters, are to say the least of it, three parts muscular and one part optical. (Bain, 1855)

Vision is an active process. Primate visual behavior is organized around a fovea which provides high-acuity vision over a limited range of the central visual field (reviewed by Carpenter 1988, 1991). Consequently, to identify an object in the scene, the eyes must move so that the image of that object projects onto the fovea (Fig. 92.1). Saccadic eye movements are the rapid conjugate rotations of the eyes that redirect the focus of gaze to new points in the image. Saccades are produced in the context of ongoing behavior in a dynamic environment. For example, if the object of fixation is moving slowly, then fixation is maintained through production of pursuit eye movements. In addition, foveation of an object often precedes further action directed at the object, such as reaching and grasping (e.g., Biguer et al., 1984).

Gaze can be directed to only one item at a time, so some process must distinguish among possible locations to select the target for a saccade. Consequently, some items may be overlooked. The outcome of the selection process is purposeful in the context of visually guided behavior. Analyses of the pattern of eye movements have revealed certain regularities—such as concentrating on conspicuous and informative features of an image—in examining simple geometric stimuli (e.g., Findlay, 1997; Livsedge and Findlay, 2000; Motter and Belky, 1998; Zelinsky and Sheinberg, 1997), natural images (e.g., Melcher and Kowler, 2001; Viviani, 1990; Yarbush, 1967), or text (e.g., Livsedge and Findlay, 2000; O'Regan, 1990). When patterns of gaze are analyzed during performance of specific extended tasks (such as making a sandwich), certain regular patterns of saccades can be observed as well (e.g., Epelboim et al., 1995; Land and Hayhoe, 2001).

This chapter will review what is known about the neural basis of the process of selecting the target for a gaze shift. Although much is being discovered about the selection of targets for pursuit eye movements (e.g., Ferrera and Lisberger, 1997; Gardner and Lisberger, 2001; Kowler, 1990), space limits this chapter to the selection for saccadic eye movements.

Visual search, selection, and attention

To investigate how the brain selects the target for an eye movement, multiple stimuli that can be distinguished in some way must be presented. This experimental design is referred to as *visual search*. The visual search paradigm has been used extensively to investigate visual selection and attention (reviewed by Wolfe, 1998). In a visual search task, multiple stimuli are presented among which a target is discriminated. Search is efficient (with fewer errors and faster response times) if stimuli differ along basic visual feature dimensions, such as color, form, or direction of motion. In contrast, if the distractors resemble the target or if no single feature clearly distinguishes the stimuli, then search becomes less efficient (more errors, longer response times) (e.g., Duncan and Humphreys, 1989).

Saccade target selection cannot be discussed without consideration of the allocation of visual attention. In fact, it can be argued that visual target selection and the allocation of visual attention amount to the same thing. Visual attention is the topic of Chapters 101, 102, and 103. The focus of visual attention can be directed away from the focus of gaze. So the link between shifting gaze and directing attention is not obligatory (Crawford and Muller, 1992; Eriksen and Hoffman, 1972; Jonides, 1980; Klein et al., 1992; Posner, 1980; Remington, 1980; Reuter-Lorenz and Fendrich, 1992; Shepherd et al., 1986). Nevertheless, several lines of evidence indicate that covert orienting of visual attention and overt orienting of saccades depend on a common selection mechanism. First, perceptual sensitivity is reduced and saccade latency is elevated if attention is directed away from the target for a saccade (Deubel and Schneider, 1996; Hoffman and Subramaniam, 1995; Kowler et al., 1995). Second, directing attention in space can influence the trajectory of saccades (Kustov and Robinson, 1996; Sheliga et al., 1995). Third, bottom-up visual factors influence visual selection for attention and saccades in the same way. The visual conspicuousness of an oddball stimulus can drive covert (e.g., Theeuwes, 1991) and overt (Theeuwes et al., 1998) selection, and nontarget elements that resemble a designated target can get inadvertently selected covertly (e.g., Kim and Cave, 1995) and overtly (Bichot and Schall,

FIGURE 92.1. Gaze behavior of a monkey searching for a randomly oriented T among randomly oriented Ls. Each small dot plots the position of gaze sampled every 4 msec. The top panel plots eye position spatially. The bottom panel plots eye position in the horizontal (*thick*) and vertical (*thin*) axes as a function of time during the viewing period. The array appeared after the monkey fixated the central square. On this trial the monkey first shifted gaze to the left; this saccade corresponds to the first downward deflection in the plot of eye position in the horizontal axis (labeled *A*). Follow-

ing a sequence of eye movements around the perimeter of the array, the T was fixated for a brief period (labeled *B*), but the monkey made an errant saccade to another element. Following a shorter than usual fixation, gaze shifted back to the T, which was fixated for a sufficient period to earn reinforcement (labeled *C*). What neural processes led the monkey to foveate certain elements but not others in the array? What neural processes account for the variable amount of time spent foveating the various effectively identical elements? (Adapted from Schall and Thompson, 1999.)

1999b; Findlay, 1997; Motter and Belky, 1998; Zelinsky and Sheinberg, 1997). Fourth, cognitive strategies can override both covert (e.g., Bacon and Egeth, 1994) and overt (e.g., Bichot et al., 1996) oddball selection. Target selection is also influenced by implicit memory representations arising through short-term priming of location or stimulus features for covert (e.g., Maljkovic and Nakayama, 1994, 1996) and overt (Bichot and Schall, 1999b; McPeck et al., 1999, 2000; McPeck and Keller, 2001) orienting. In addition, experts are more likely than novices to fixate conspicuous but irrelevant parts of a visual image from their field of expertise (e.g., Chapman and Underwood, 1998; Nodine and Krupinski, 1998; Nodine et al., 1996). Finally, the pattern of visual fixation can be influenced by verbal instructions (Yarbus, 1967).

To explain observations like these, most models of visual search postulate the existence of a map of salience derived

from converging bottom-up and top-down influences (e.g., Cave and Wolfe, 1990; Itti and Koch, 2000; Koch and Ullman, 1985; Treisman, 1988; Wolfe, 1994). Other investigators have noted that the salience map is a useful construct to organize our understanding of how the brain selects the target for an eye movement (Findlay and Walker, 1999; Kusunoki et al., 2000; Thompson et al., 2001). *Salience* refers to how distinct one element of the image is from surrounding elements. This distinctness can occur because the element has visual features that are very different from those of its surrounding (a ripe red berry in green leaves). The distinctness can also occur because the element is more important than others (the face of a friend among strangers). The distinctness derived from visual features and importance confers upon that part of the image greater likelihood of receiving attention and a gaze shift. In the models of visual

search referred to above, one major input to the salience map is the maps of the features (color, shape, motion, depth) of elements of the image. Another major input is top-down modulation based on goals and expectations. The representation of likely targets that is implicit in and dependent on the feature maps becomes explicit in the salience map. Peaks of activation in the salience map that develop as a result of competitive interactions represent locations that have been selected for further processing, and thus covert orienting of attention and possibly but not necessarily a saccadic eye movement.

Preview of neural substrates

A network of structures in the brain produces and conveys the signals necessary to select a target and produce a saccade (Fig. 92.2). As readers of this volume know, visual processing begins in the retina but proceeds in earnest in primary visual cortex, where neurons respond selectively to stimuli possessing different features such as orientation or color (reviewed in Chapters 43, 44, 47, and 65). Visual processing is elaborated in a collection of distinct cortical areas that have various specializations (reviewed in Chapters 32, 33, 34, 66, 67, 76, 77, 78, 79, 81, 82, and 83). For example, area MT signals the motion of stimuli, and area V4 signals the color and form of stimuli. The extrastriate visual areas have been characterized as comprising separate processing streams. One stream passing into the temporal lobe is responsible for recognizing features and objects. Another stream passing into the parietal lobe is responsible for the sense of the body in space. Visual processing is not concluded in the parietal and temporal lobes; signals relay to and from the frontal lobes as well. For example, the frontal eye field is connected reciprocally with areas identified with both the dorsal and ventral processing streams (Baizer et al., 1991; Schall et al., 1995b; Stanton et al., 1995). Through this distributed network the characteristics of objects in the image can guide the direction of gaze, and goals and context can influence visual processing.

Movements of the eyes are produced by a network of neurons in the brainstem (reviewed by Scudder et al., 2002). This network shapes the pattern of activation of the ocular motor neurons that innervate the muscles generating the force that rotates the eyes to fixate the target. This network requires two inputs—where to shift gaze and when to initiate the movement. Key brain structures controlling the brainstem are the superior colliculus and the frontal eye field operating in a recurrent network through the basal ganglia and thalamus.

Pedagogically, it is easiest to review the experimental evidence by considering each part of the brain in turn. This style of presentation risks leaving the impression, most mistaken, that the various areas and structures operate in isola-

tion or sequence. In fact, the neural processes responsible for selecting a target and shifting gaze transpire concurrently in an interconnected network woven through the brain from front to back, top to bottom. Another caution involves summarizing information this way, for it is necessary to characterize the general properties of populations of neurons and impossible to describe the particularities of the diverse kinds of neurons actually observed. Moreover, because this is not an encyclopedia, the results of only a few of the many studies will be highlighted. The student is encouraged to consult the original research literature to gain a more realistic and critical understanding of the true diversity and complexity of the neuron populations that select the target for a saccade. In so doing, the alert reader will notice that the scope and depth of coverage of the various brain structures are proportional to this author's publications. Finally, the reader should be cautioned that many of the observations that will be described are the outcome of individual experiments in single laboratories that have not been independently replicated. This stipulation has two consequences. First, some of the observations and conclusions in this chapter will almost certainly need to be revised in light of new evidence. Second, many research opportunities exist to obtain such evidence that could make this chapter incomplete if not obsolete.

Superior colliculus

VISUAL RESPONSES The superior colliculus receives direct inputs from the retina, but it is also innervated by many cortical areas in the occipital, parietal, temporal, and frontal lobes (e.g., Fries, 1984). Visually responsive neurons in the superficial layers of the superior colliculus have spatially restricted receptive fields arranged in a precise retinotopic map (Fig. 92.3.4). They do not distinguish stimuli of different orientations, colors, or directions of motion (reviewed by Robinson and McClurkin, 1989). In experiments using macaque monkeys trained to fixate light spots for a fluid reward, the response of half of these neurons is enhanced if the stimulus is used by the monkey as a target for a saccadic eye movement (Goldberg and Wurtz, 1972; Wurtz and Mohler, 1976a). The enhancement can occur as either a larger initial response or an elevated activation after the initial visually evoked response. The enhanced activation can occur as well when a continuously visible stimulus is cued as the target for a saccade. This enhancement is a manifestation of the process that represents the location of a stimulus that will be the focus of a gaze shift. How this enhancement relates to selection of a target among alternative stimuli will be considered below.

SACCADE PRODUCTION The superior colliculus plays a central role in generating saccades guided by vision or other

FIGURE 92.2. Overview of structures responsible for guiding and producing saccadic eye movements. Only a select few connections are shown, and the intrinsic organization of structures is ignored. Saccades are produced through the activation of a network in the brainstem saccade generator (*dark gray*). One input to the saccade generator is the superior colliculus; another is frontal eye field (FEF). FEF projects directly to superior colliculus as well as indirectly through the basal ganglia. Superior colliculus is under inhibitory control through the basal ganglia; FEF projections to the basal ganglia can release this inhibition. Signals from superior colliculus are relayed to FEF through the mediodorsal nucleus (MD) of the thalamus (enclosed in the oval). Activation arising concurrently through this interconnected network specifies where and when to shift gaze. The visual guidance of saccades originates in signals conveyed through retinal projections to superior colliculus and dorsal lateral geniculate nucleus (LGNd). LGNd innervates primary visual cortex (V1). Signals are routed from V1 to the network of extrastriate visual areas. Inputs to area V4 are relayed through other areas (symbolized by pairs of arrows). Inputs from V1 to MT are direct and relayed. The connections between cortical areas are reciprocated (*double arrowheads*). In addition to intra-cortical connectivity, extrastriate cortical areas communicate with the pulvinar nuclei of the thalamus. Signals from area V4 are sent to areas in the inferior temporal cortex (IT). Similarly, visual signals are routed to posterior parietal cortex (PP). A collection of rather distinct areas comprise IT and PP cortex (*outlined boxes*). The areas associated with IT cortex are responsible for the perception of features, forms, and objects. The areas associated with PP cortex are responsible for the perception of the body in space. Visual processing does not finish in the temporal and parietal lobes, though, because these areas project to the frontal lobe, in particular to FEF, as well as to superior colliculus. Like superior colliculus, FEF projects, albeit more weakly, to the saccade generator in the brainstem. The diverse visual inputs to FEF and superior colliculus convey an elaborate representation of the image to the centers that specify which saccade to produce. Through the connections of visual areas with FEF and superior colliculus, the features of an image can guide gaze. However, gaze can shift to inconspicuous but informative points in the image according to arbitrary rules. Connections of prefrontal cortex (pfc) with FEF and superior colliculus (although not as strong) (*gray line*) convey the influence of context, which can supplement or override the outcome of visual processing.

sensory modalities as well as self-generated saccades (reviewed by Munoz et al., 2000; Wurtz et al., 2000; Chapters 97 and 98). Neurons in the intermediate layers of the superior colliculus also discharge immediately before and during saccadic gaze shifts (reviewed by Sparks and Hartwich-Young, 1989). Neurons in the intermediate layers can be distinguished by the relative magnitude of activation following presentation of a stimulus and initiation of a saccade. Certain neurons respond to visual stimuli but have weak or no modulation associated with the saccade. Other neurons have weak if any visual response but exhibit high firing rates immediately before and during saccades; these are referred to as *burst neurons*. A third kind of neuron typically has a clear visual response, with activation sustained throughout an interval before the saccade and an elevated firing rate immediately before the saccade; these have been referred to as *buildup* or *prelude neurons* (Glimcher and Sparks, 1992; Munoz and Wurtz, 1995). The rostral end of the superior colliculus is populated by neurons that are active during fixation and exhibit a reduced firing rate before and during saccades (Munoz and Wurtz, 1993). These fixation neurons are in a push-pull relationship with the buildup neurons elsewhere in the superior colliculus. The balance of activation across the pools of fixation and buildup neurons controls saccade initiation (e.g., Dorris and Munoz, 1998; Dorris et al., 1997).

Each buildup and burst neuron is most active before saccades of a particular direction and amplitude and is progressively less active before saccades deviating from the optimal. In other words, each neuron has a receptive or movement field that is larger than the precision of saccades. Thus, before each saccade, neurons over a rather broad

extent of superior colliculus are activated in a graded manner (Fig. 92.3A). The space of saccade direction and amplitude is mapped in the intermediate layers in a topographic fashion corresponding to the map of visual space in the superficial layers of the superior colliculus. To produce a signal leading to a saccade of a particular direction and amplitude, the activations of many cells in a region of the motor map seem to be combined in a vector fashion (Lee et al., 1988; van Gisbergen et al., 1987).

When a pair of potential targets is presented close together, a larger zone of activation occurs across the map (Fig. 92.3B). A saccade resulting from the vector average of the zone of activation directs gaze to a location between the targets (Chou et al., 1999; Findlay, 1982; Ottes et al., 1984). This tendency is not exclusively automatic, though, because

FIGURE 92.3. Pattern of activation in the superior colliculus. *A*, The left panel illustrates the visual field with a saccade (arrow) produced from the center to a target at 10 degrees azimuth and 0 degrees elevation. The vertical meridian is indicated by the row of circles. The right panel illustrates that the map of the superior colliculus as a mathematical formulation (Ottes et al., 1986) derived from a systematic survey of the direction and amplitude of saccades evoked by electrical stimulation of various parts of the superior colliculus (Robinson, 1972). A visually guided saccade to a point 10 degrees eccentric on the horizontal meridian is preceded by graded activation over an extended part of the superior colliculus map. The peak of activation (black) is centered at the appropriate point on the map, and surrounding neurons farther from the center of activation (gray) are progressively less active. The direction and amplitude of the saccade that is produced correspond to those specified by the location of the center of gravity of the activation in the superior colliculus map. *B*, Presentation of two nearby stimuli results in a broader zone of activation in the superior colliculus with two peaks. The center of gravity of the activation is a location between the two stimuli. This results in a saccade directing gaze to neither stimulus. The map of the superior colliculus representing each hemifield is shown. *C*, Presentation of eight stimuli produces activation in a large part of the superior colliculus map. The center of gravity of such balanced activation with multiple peaks amounts to a saccade with no amplitude. Thus, to produce a particular saccade, the activation in the superior colliculus map must evolve so that a single peak is present corresponding to the desired saccade direction and amplitude.

it can be influenced by cognitive factors (He and Kowler, 1989; Ottes et al., 1984, 1985).

If a circular array of stimuli is presented, then the spatial distribution of activation in the superior colliculus will be balanced around the map with multiple peaks (Fig. 92.3C). The vector combination of this distribution of activity amounts to a resultant with no length—not a very useful outcome. To produce a useful saccade, the activation in the map of the superior colliculus must be limited to the neurons contributing to generating just that saccade. Thus, if more than one location in the superior colliculus map becomes activated, then additional processing must resolve which of the peaks of activation should become dominant among the rest for an accurate saccade to just one among alternative stimuli. This additional processing is selection of the target.

TARGET SELECTION To learn how the superior colliculus contributes to selecting the target for a saccade, several investigators have presented monkeys with multiple stimuli among which to locate the target for an eye movement. In some studies, the target was identified by properties distinct from nontarget stimuli (Basso and Wurtz, 1998; Glimcher and Sparks, 1992; Olivier et al., 1999; Ottes et al., 1987). In other studies, the target location was specified by the properties of the stimulus at the central fixation point (Horwitz and Newsome, 2001; see also Kustov and Robinson, 1996) or by implicit cuing (Goldberg and Wurtz, 1972; Wurtz and Mohler, 1976a). The central observations were made primarily on the visually responsive prelude and buildup neurons. While the design of each study was different, the results can be summarized conveniently. Initially, when multiple stimuli are presented, activation arises at locations in the superior colliculus map corresponding to the potential saccade targets. Activation becomes relatively lower at locations that would produce saccades to nontarget elements and grows at locations corresponding to more conspicuous or important potential targets, ultimately yielding a burst that triggers the saccade produced by activation centered on just one location in the motor map.

One recent study presented monkeys with arrays of two, four, or eight stimuli among which one would be specified as the target (Basso and Wurtz, 1998). Visually responsive buildup neurons showed no difference in the initial response to target or nontarget stimuli in the response field (Fig. 92.4). The initial visual response decreased as the number of stimuli in the visual display increased from one to two, four, and eight. The attenuated activation following arrays with more potential targets was also seen in a delay period before the location of the target was cued. The modulation of the initial visual response was due in part to suppressive interactions across the visual field invoked by the multiple stimuli. However, some of the modulation of the visual response and all of the modulation of the delay period activity before the

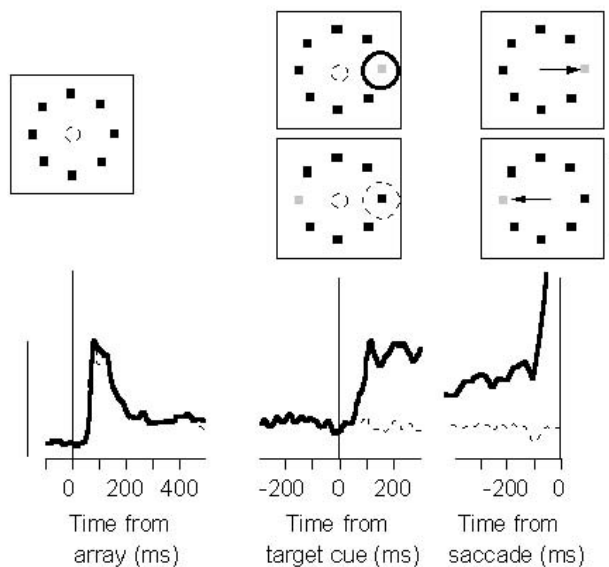

FIGURE 92.4. Activation of a visually responsive movement-related neuron in the superior colliculus of a monkey locating a target in an array of stimuli. The top panels illustrate the appearance of the stimuli and the production of the saccades under two conditions. The bottom panels illustrate the magnitude of activation of the neuron as a function of time from the indicated events. The activation when the stimulus in the response field was designated the target for the saccade (*thick*) is compared with the activation when a stimulus outside the response field is the target and the stimulus in the response field is ignored (*thin*). *Left*: the initial response to the array of identical stimuli is equivalent, regardless of whether the ultimate target or nontarget stimulus falls in the response field. During a succeeding delay, the activation was sustained at a moderate rate. *Center*: when one of the stimuli became visually distinct by dimming, the neural activity was modulated. If and only if the stimulus in the response field was specified as the target, the activation increased to a sustained higher level. The location of the response field is illustrated in the display panels; the line type corresponds to that used in the plot of activation. *Right*: the activation signaling whether the location in the response field was occupied by the target or a nontarget was sustained until the burst of activation immediately preceding the saccade. The plot of presaccadic activation when the saccade was into the response field was clipped for purposes of illustration. The scale bar for neuronal activation signifies 40 spikes per second. The scale bar for the visual display signifies 20 degrees. (Modified from Basso and Wurtz, 1998.)

target location was specified can be attributed to the predictability of the target location. This was tested by manipulating the probability of the target location in eight element arrays. When the particular location in arrays of eight elements that is in the response field is cued as the target on several successive trials, the visual response and delay period activity are greater than when the location in the response field is no more likely to be the target than any other location. Notably, this modulation based on recent experience takes some time across trials to develop, presumably constrained by the monkey's sense of expectancy. These data

indicate that the brain can develop a quotient of readiness to produce one or more saccades and that the degree of readiness are proportional to the experienced likelihood of target location (see also Dorris and Munoz, 1998; Glimcher and Sparks, 1992; Paré and Munoz, 1996).

Once the target location is specified by a change of appearance of one stimulus, the state of activation in the superior colliculus changes dramatically (Basso and Wurtz, 1998). Neurons with the specified target in their response field exhibit augmented activation, while the remaining neurons with nontarget stimuli in their response fields exhibit no change or a slight decrease in activity. This differential activation results in a concentration of activation centered on one point in the map corresponding to the saccade necessary to foveate the specified target. The process by which this activation becomes pronounced in just one region could arise through lateral inhibitory interactions within superior colliculus (Munoz and Istvan, 1998; Olivier et al., 1999; van Opstal and van Gisbergen, 1989) but probably also involve signals from cortical areas described below. Across the population of neurons, it took approximately 100 msec to represent uniquely the target in arrays of eight elements and approximately 50 msec in arrays with two elements. But once the target was selected, the magnitude of activity did not vary with the number of potential target locations. The prelude of additional activation representing the location of the target can be sustained for several hundred milliseconds until another stimulus signals the monkey to shift gaze. The pronounced saccade-related activation of the buildup neurons occurred when a saccade was generated into the response field, regardless of the stimulus configuration giving rise to that saccade, even if the saccade was to the nontarget.

SUMMARY The extensive evidence for the involvement of the superior colliculus in saccade target selection has led to the suggestion that superior colliculus can be understood in terms of a saliency map (reviewed by Findlay and Walker, 1999). However, we should not draw the unnecessary and mistaken conclusion that the superior colliculus performs this function uniquely and exclusively. In particular, because superior colliculus neurons do not discriminate visual features, inputs from the visual cortex must be used to select the target.

Primary visual cortex and the ventral stream

Selecting a particular element in an image requires the element to be distinguished from others. Such a distinction can be derived from differences in color, shape, motion, or depth. Therefore, selection of a target for a visually guided saccade must begin with neural signals that distinguish the features of elements in the image. A cornerstone of visual

neuroscience is the fact that neurons in the visual cortex respond selectively according to the color, shape, motion, and depth of stimuli. A signal sufficient to distinguish the features of visual objects is available in the first few spikes produced by neurons in primary and extrastriate visual cortex (Celebrini et al., 1993; Dinse et al., 1990; Muller et al., 2001; Oram and Perrett, 1992; Ringach et al., 1997; Sugase et al., 1999; Tovée et al., 1993; Vogels and Orban, 1991; von der Heydt and Peterhans, 1989).

Selectivity of neural responses for visual features forms the substrate for target selection; however, it is not sufficient because targets are distinguished only through a comparison to the features of other stimuli in the image. When more than one stimulus is presented, interactions occur between neurons responding to stimuli in neighboring parts of the scene. Modulation of responses by surrounding stimuli has been observed in neurons in primary visual cortex V1 (e.g., Blakemore and Tobin, 1972; Kapadia et al., 1995; Knierim and Van Essen, 1992; Polat et al., 1998; Rossi et al., 2001; Sillito et al., 1996; Zipser et al., 1996), as well as in areas MT and MST (Allman et al., 1985; Olavarria et al., 1992; Saito et al., 1986) and area V4 (Desimone and Schein, 1987). Note that this modulation does not occur for every neuron or in the same manner for all neurons, but space limits this description to the most general characteristics (see Chapters 45 and 46). The influence of surrounding stimuli on the response to a stimulus in the receptive field under most conditions takes some time to be expressed. Modulation of the response of neurons to a stimulus in the receptive field by stimuli present in the surrounding region provides the substrate for identifying the location of features that are conspicuously different from surrounding features.

AREA V4 Neural activity in extrastriate visual area V4 has been related to the guidance of saccades. Neurons in V4 exhibit modulated discharge rates before saccade initiation (Fischer and Boch, 1981) that seems to signal enhanced selectivity for the features of the stimulus at the location of the saccade (Moore, 1999). Also, the receptive fields of V4 neurons have been characterized as reducing in size to focus effectively around the target of the saccade (Tolias et al., 2001). This resembles a spatial shift of sensitivity within the receptive field in a spatial attention task (Connor et al., 1997).

Further information about how striate and extrastriate cortex select targets has been obtained in studies that present multiple stimuli to investigate the covert shift of attention. This is an extensive area of research that is reviewed in Chapters 101, 102, and 103. This line of research has been framed by the seminal observation that when two stimuli are presented in the receptive field of many neurons in area V4, the response to the preferred stimulus is modulated according to which of the two stimuli is selected for guiding a behavioral response (Chelazzi et al., 2001; Luck et al., 1997;

McAdams and Maunsell, 1999; Moran and Desimone, 1985; Reynolds et al., 1999). Similar observations have been made in area MT (Treue and Maunsell, 1999; but see Seidemann and Newsome, 1999). The common general conclusion is that when attention is allocated to one of the stimuli, the activation of the neurons selective for that stimulus becomes greater than the activation of the neurons selective for the nonselected stimulus.

For example, one study showed that neurons in V4 responded differentially to a stimulus in their receptive field, depending on whether the stimulus matched a cue stimulus presented in the fovea and so was selected for use in a perceptual judgment (Motter, 1994a, 1994b) (Fig. 92.5B). The initial visual response to the array was the same whether or not the stimulus in the receptive field matched the cue. After approximately 150 msec, the differential activation was manifest and persisted until the response was permitted. This selective activation did not depend on the feature specificity of neurons, did not require the continued presence of the foveal cue, and changed if the cue color was switched. Thus, neurons in prestriate areas produce signals sufficient for selecting among stimuli in the image according to the contrast among specific features.

INFERIOR TEMPORAL CORTEX Several studies have provided information on the role of inferior temporal cortex in selecting the target for a saccade. Chapters 77, 78, and 79 review the properties of neurons in inferior temporal cortex. Briefly, these neurons respond selectively to stimuli with particular combinations of features, ranging from conjunctions of color and shape to faces with specific identity or expression. The stimulus selectivity of neurons in inferior temporal lobe seems the same during both active scanning in a cluttered image and passive presentation (DiCarlo and Maunsell, 2000; Sheinberg and Logothetis, 2001), and investigators have described modulation of neurons to attended versus nonattended stimuli (e.g., Richmond and Sato, 1987; Sato, 1988). This chapter will concentrate on studies that have presented a target among multiple stimuli because it is under this condition that the process of target selection can be observed most directly.

The activity of neurons has been examined in inferior temporal cortex of monkeys making a saccade to the location of one stimulus in an array of stimuli that matched the appearance of a remembered cue stimulus (Chelazzi et al., 1998). One of the stimuli effectively activated the cell, and the other elicited little response. After the cue was presented, neurons discharged at a low rate throughout a delay period, although this activation was somewhat higher if the cue was an optimal stimulus. When the array of stimuli containing the target was presented with more than one stimulus in the large receptive field, the inferior temporal cortex cells exhibited an initial period of activation that did not vary with

FIGURE 92.5. Target selection by neurons in the temporal lobe. *A*, Activation in area V4 related to spatial selection between two stimuli presented within the neurons' receptive field. Under identical stimulus conditions, activation when attention was directed to the location of the preferred stimulus (*thick solid*) was greater than activation when attention was directed to the location of the non-preferred stimulus (*thin dashed*). The difference in activation did not occur in the initial response. The scale bar for neuronal activation signifies 30 spikes per second. The scale bar for the visual display signifies 5 degrees. *B*, Activation in area V4 related to selection and identification of the orientation of stimuli matching the color of a sample in the center. Under identical stimulus conditions, when the stimulus in the receptive field matched the sample (*thick solid*) activation was greater than when the stimulus in the receptive field did not match the sample (*thin dashed*). The scale bar for neuronal activation signifies 50 spikes per second. The scale bar for the visual display signifies 5 degrees. *C*, Activation in IT cortex related to spatial selection between two stimuli presented within the neurons' receptive fields. The receptive fields of neurons in IT are much larger than those of neurons in area V4, and the neurons are selective for complex objects. Under identical stimulus conditions, activation when attention was directed to the location of the preferred stimulus (*thick solid*) was greater than activation when attention was directed to the location of the nonpreferred stimulus (*thin dashed*). The difference in activation did not occur in the initial response. The scale bar for neuronal activation signifies 20 spikes per second. The scale bar for the visual display signifies 5 degrees. (*A* modified from Luck et al., 1997; *B* modified from Motter, 1994a; *C* modified from Chelazzi et al., 1998.)

regardless of its features is necessary to guide saccadic eye movements. Such a representation seems to be present in the parietal and frontal lobes.

Posterior parietal cortex

Two areas in posterior parietal cortex—area 7A and the lateral intraparietal area (LIP)—have been distinguished on functional and anatomical grounds. The organization and functional properties of these areas are reviewed in Chapter 89. Area LIP is reciprocally connected with extrastriate areas such as V4 and MT that represent the features of elements in the image, as well as areas in inferior temporal cortex that signal more complex objects (e.g., Bullier et al., 1996; Morel and Bullier, 1990). Area LIP also projects to the superior colliculus (e.g., Lynch et al., 1985; Paré and Wurtz, 2001) and the frontal eye field (Baizer et al., 1991; Schall, et al., 1995b; Stanton et al., 1995), where it can influence saccade production.

A number of neurophysiological experiments have described properties of neurons in posterior parietal cortex related to target selection, as well as covert and overt orienting. Many studies have reported that the response to a stimulus is enhanced if it is to be the target for a saccade (e.g., Ben Hamed et al., 2002; Bushnell et al., 1981; Colby et al., 1996; Mountcastle et al., 1981, 1987; Robinson et al., 1978, 1995). In fact, this enhancement can occur if the

array configuration. However, 150 to 200 msec after presentation of the array, the activation of the neurons evolved to represent the identity of the target. If the optimal stimulus was the target, then neural activation remained elevated, discharging even more once the saccade brought the optimal stimulus into the fovea. However, if the nonoptimal stimulus was the target, then the activation was attenuated and remained so after fixation of the nonoptimal stimulus.

The general conclusion of these studies is that multiple stimuli compete for an explicit neural representation, and the competition among stimuli can be biased by other neural signals derived from experience or instruction (Desimone and Duncan, 1995). Consistent with this general hypothesis, if monkeys are given preferential experience with particular stimuli, the selection process observed in inferior temporal cortex neurons adapts to enhance the representation of the learned object (Jagadeesh et al., 2001). Ultimately, though, any enhanced activity in inferior temporal cortex represents the features characterizing the target and does not indicate that it is a target per se. This is so for all visual areas in which neurons respond selectively to stimuli with different features. A more general representation of the location of a target

peripheral stimulus instructs a manual response with no gaze shift; this observation is commonly interpreted as a neural correlate of the monkey's shifting attention covertly to the stimulus (Bushnell et al., 1981; Robinson et al., 1978; reviewed by Colby and Goldberg, 1999; for an alternative point of view, see Lynch et al., 1977; Mountcastle et al., 1975; Snyder et al., 2000; Chapter 89). Other studies have shown that the response to a stimulus is attenuated if the stimulus appears at a location where attention is already allocated (Constantinidis and Steinmetz, 2001b; Powell and Goldberg, 2000; Robinson et al., 1995; Steinmetz and Constantinidis, 1995; Steinmetz et al., 1994). The current hypothesis is that posterior parietal cortex represents the location of stimuli to which attention should or will shift. The aforementioned studies provide less insight into the contribution of posterior parietal cortex to target selection because they were conducted with the presentation of a single stimulus.

Recent studies have investigated the responses of neurons in posterior parietal cortex in monkeys confronted with displays consisting of a target and one or more distractors (e.g., Constantinidis and Steinmetz, 2001a, 2001b; Gottlieb et al., 1998; Platt and Glimcher, 1997). Neurons in area 7a signaled the location of a stimulus of one color among distractors of another color (Constantinidis and Steinmetz, 2001a). The initial response to the array was attenuated relative to the response to a single stimulus. The initial response to the array did not distinguish the location of the oddball, but within 100 to 150 msec the activation increased if the oddball was in the receptive field and decayed if only distractors were in the receptive field (Fig. 92.6A). This neural activity is clearly sufficient to represent the location of a conspicuous target.

Other studies have examined how neural activity in area LIP participates in target selection (Gottlieb et al., 1998). In one study, monkeys shifted gaze to the object in an array of eight distinct objects that matched a sample stimulus. If the object in the receptive field was designated the target, neurons exhibited a significant elevation of activity (Fig. 92.6B). When the sample was presented during fixation in the center of the array, the augmented activity for the target arose more than 200 msec after the target was specified. This time is longer than that observed in a similar condition in the study of superior colliculus described above, presumably because more time was needed to encode the properties of the sample and locate the matching element.

Taken together, the results indicate that the visual representation in posterior parietal cortex represents the location of conspicuous and relevant stimuli, that is, likely targets for orienting either covertly or overtly. Thus, as with superior colliculus, it appears that neurons in posterior parietal cortex embody the properties of units in a salience map (reviewed by Kusunoki et al., 2000). One complication, though, with

FIGURE 92.6. Target selection by neurons in the parietal lobe. *A*, Response of neurons in area 7a to a target presented alone in the receptive field (*thin solid*), the oddball stimulus of the array in the receptive field (*thick solid*), and the distractors in the receptive field (*thin dashed*). Compared to the response to the target alone, the response to the array is attenuated, especially in the initial 100 msec. Following presentation of the array, the initial response does not distinguish whether the oddball or only distractors were in the receptive field, but the activation evolved to represent whether or not the oddball was in the receptive field. The scale bar for neuronal activation signifies 40 spikes per second. The scale bar for the visual display signifies 50 degrees; note the difference in scale compared to that for the temporal lobe receptive fields. *B*, Activation of an area LIP neuron when a monkey must locate a target that matches a central cue. *Left*: while fixating in the center of the array, presentation of a cue for 200 msec signifies which element of the array is the target. Under identical stimulus conditions, the neuron began to discharge more if the stimulus in the receptive field is designated as the target (*thick solid*). No modulation was observed if the stimulus in the receptive field was not a target (*thin dashed*). *Right*: the activation was greatest before and after the saccade to the stimulus in the receptive field. The scale bar for neuronal activation signifies 20 spikes per second. The scale bar for the visual display signifies 40 degrees. (*A* modified from Constantinidis and Steinmetz, 2001a; *B* modified from Gottlieb et al., 1998.)

the hypothesis that LIP and area 7a correspond to a salience map concerns the quality of the map of the visual field and the topographic pattern of connections with the frontal eye field or superior colliculus. Given the orderly map of the visual field at the outset of visual processing and the orderly map of saccade direction and amplitude at the formation of saccade commands, it seems most expeditious if the locations of salient targets for orienting were represented in at least a roughly topographic map. Most physiological studies of parietal cortex have found very rough if any topographic mapping of the visual field (e.g., Blatt et al., 1990) and no clear pattern of mapping between LIP and the superior colliculus (Paré and Wurtz, 2001). However, more recent studies have detected rather rough topography by mapping receptive fields of neurons in the parietal cortex with denser sampling and exploring a wider extent of the intraparietal sulcus (Ben Hamed et al., 2001; Platt and Glimcher, 1998; see also Sereno et al., 2001). It remains to be seen how posterior parietal cortex contributes to the selection of targets near the center of gaze because shifts of gaze less than 10 degrees are by far the most common during natural vision (Bahill et al., 1975).

Frontal eye field

The frontal eye field is an area in prefrontal cortex that contributes to the transformation of visual signals into saccade commands (reviewed by Schall, 1997; Schall and Thompson, 1999; see Chapter 96). Thus, the frontal eye field has two facets, one motor and the other sensory. The frontal eye field is not as well known as the extrastriate visual areas in occipital, temporal, or parietal lobes, so some of its basic functional properties will be reviewed.

MOTOR FUNCTION The evidence for the motor function of frontal eye field is compelling. Low-intensity microstimulation of frontal eye field elicits saccades (e.g., Bruce et al., 1985). This direct influence is mediated by a population of neurons that discharge specifically before and during saccades (Bruce and Goldberg, 1985; Hanes and Schall, 1996; Hanes et al., 1998). The neurons in frontal eye field that generate movement-related activity are located in layer 5 and innervate the superior colliculus (Segraves and Goldberg, 1987; Sommer and Wurtz, 2000, 2001) and parts of the neural circuit in the brainstem that generate saccades (Segraves, 1992). These neurons, in concert with counterparts in the superior colliculus (Dorris and Munoz, 1998; Schiller and Koerner, 1971; Sparks, 1978; Wurtz and Goldberg, 1972), provide the signals necessary to produce saccadic eye movements. Neurophysiological data indicate the sufficiency of the activity of presaccadic movement-related neurons in frontal eye field to produce gaze shifts (Hanes and Schall, 1996; Hanes et al., 1998). Reversible inactivation

studies provide evidence for the necessity of frontal eye field in normal saccade production (Dias et al., 1995; Sommer and Tehovnik, 1997). These findings complement earlier observations that ablation of frontal eye field causes an initially severe impairment in saccade production that recovers in some but not all respects over time (e.g., Schiller and Chou, 1998; Schiller et al., 1987).

VISUAL FUNCTION The evidence that frontal eye field is involved in visual function is equally compelling. Frontal eye field is connected with a large number of visual cortical areas in both the dorsal and ventral streams (e.g., Barone et al., 2000; Schall et al., 1995b). In fact, quantitative analyses of the connectivity between cortical visual areas indicate that frontal eye field is a uniquely well-connected node in the network of visual cortical areas (Jouve et al., 1998). Lateral frontal eye field, which is responsible for generating shorter saccades, receives visual afferents from the foveal representation in certain retinotopically organized areas, such as V4 and MT, from areas that represent central vision in caudal parts of inferotemporal cortex and from other areas having no retinotopic order, such as LIP. In contrast, medial frontal eye field, which is responsible for generating longer saccades, is innervated by the peripheral visual field representation of retinotopically organized areas, from areas that emphasize peripheral vision or are multimodal, and from other areas that have no retinotopic order. The afferents from visual cortical areas to frontal eye field are reciprocated through feedback projections (Barone et al., 2000; Schall et al., 1995b). Another source of visual signals to frontal eye field is the thalamus through the lateral segment of the mediodorsal nucleus, as well as parts of neighboring thalamic nuclei (Huerta et al., 1986; Stanton et al., 1988). Neurons in these nuclei are visually responsive (Schlag and Schlag-Rey, 1984) and can convey visual signals to frontal eye field (Sommer and Wurtz, 1998). Frontal eye field is also connected with specific areas in prefrontal cortex (e.g., Stanton et al., 1993). These prefrontal connections can influence frontal eye field according to the context of history and goals.

Physiological recordings in monkeys trained to shift gaze to visual targets have found that most neurons in frontal eye field have visual responses (Bruce and Goldberg, 1985; Mohler et al., 1973; Schall, 1991). Consistent with the extensive convergence of visual inputs in frontal eye field, the neurons typically do not exhibit any selectivity for stimulus features such as orientation, color, or direction of motion. The time at which visual neurons in frontal eye field respond to flashed stimuli coincides with the latencies of visual responses in dorsal stream areas such as area MT; in fact, many neurons in frontal eye field respond to visual stimuli before some neurons in V1 do (Schmolesky et al., 1998). Like the response of their counterparts in superior colliculus and posterior parietal cortex, the visual response of many frontal

eye field neurons is enhanced if the stimulus in the receptive field is the target for a saccade (Goldberg and Bushnell, 1981; Wurtz and Mohler, 1976b).

VISUAL TARGET SELECTION A series of investigations has described neural correlates of target selection for visually guided saccades by recording the activity of neurons in the frontal eye field of monkeys trained to shift gaze to a target in visual search arrays (Bichot and Schall, 1999a; Bichot et al., 2001a; Bichot et al., 2001b; Murthy et al., 2001; Sato et al., 2001; Schall and Hanes, 1993; Schall et al., 1995a; Thompson et al., 1996). Following presentation of an array with a single conspicuous target among uniform distractors, visually responsive neurons in frontal eye field responded initially indiscriminately to the target or the distractors of the search array in their receptive field (Fig. 92.7). However, before a saccade to the conspicuous target was generated, a selection process proceeded by which visually responsive neurons in frontal eye field ultimately signaled the location of the oddball target stimulus. If the target of the saccade was in the response field, the frontal eye field activity was greatest. If nontarget distractors were in the response field, the activity was suppressed. Clearly, the visual selection observed in frontal eye field depends on the afferents from the various visual areas conveying feature selectivity. However, frontal eye field also provides extensive feedback connections to extrastriate visual cortex (Barone et al., 2000; Schall et al., 1995b), so the possibility that the state of neural activity in frontal eye field can influence neural processing in visual cortex should not be overlooked.

Frontal eye field is commonly regarded as an oculomotor area of the cerebral cortex. Accordingly, the target selection process observed in frontal eye field neurons may amount to no more than saccade preparation. Experiments have tested the alternative hypotheses that the selection observed in frontal eye field corresponds to visual selection or is identical to saccade preparation. In one study, activity of frontal eye field neurons was recorded while monkeys maintained fixation during presentation of a search array with a single conspicuous oddball (Thompson et al., 1997). Although no saccade was made to the oddball, frontal eye field neurons still discriminated the oddball from distractors at the same time and to the same degree as when a gaze shift was produced even though the absolute level of activity was reduced (Fig. 92.7*B*). Thus, the visual selection observed in frontal eye field does not require saccade execution.

Another experiment created a condition in which monkeys frequently shifted gaze to a location different from that occupied by the oddball target in a search array. Even when gaze shifted away from the popout oddball of a search array, visual neurons in frontal eye field represented the current location of the target (Murthy et al., 2001). Given the evidence that attention is usually allocated automatically

FIGURE 92.7. Target selection by neurons in the frontal lobe. *A*, Activation of a visually responsive neuron in frontal eye field following presentation of a popout search array when the monkey produced a saccade to the oddball when the oddball stimulus appeared in the receptive field (*thick solid*) and when distractors appeared in the receptive field (*thin dotted*). Unlike previous figures, the representation of the stimulus in the response field is collapsed into a single diagram. The initial response to the search array did not discriminate the target from a distractor, but after 100 msec the activation representing the location of the distractors was suppressed, and the activation representing the location of the target was sustained or elevated. The bar on the abscissa indicates the range of saccade initiation times. The scale bar for neuronal activation signifies 100 spikes per second. The scale bar for the visual display signifies 15 degrees. *B*, Activation of the same neuron when the monkey withheld a saccade to the oddball. The conventions are the same as in *A*. Although the discharge rate was lower, the neural activity signaled the location of the target at the same time and to the same degree as when the saccade was produced. The scale bar for neuronal activation signifies 100 spikes per second. The scale bar for the visual display signifies 15 degrees. (*A* modified from Thompson et al., 1996; *B* modified from Thompson et al., 1997.)

to the conspicuous oddball in a search array (e.g., Theeuwes, 1991), the fact that the visually responsive neurons in frontal eye field represented the location of the oddball whether or not it was the target of the gaze shift suggests that the activation of this particular population of neurons in frontal eye field corresponds to covert orienting of visual attention.

TIMING OF TARGET SELECTION AND SACCADE INITIATION As illustrated in Figure 92.1, normal visual behavior is accomplished through a continuous cycle of fixation and visual analysis followed by another fixation and renewed visual analysis. The focus of gaze shifts two to five times every second. Curiously, the time spent fixating elements of an image varies to a degree that cannot be explained just by the properties of the image. Several studies have examined how fixation duration, the interval between saccades, varies (e.g., Hooge and Erkelens, 1996; Jacobs, 1987). In general, fixation duration seems to be adjusted according to the difficulty of finding the desired target, but moment-to-moment control of fixation duration based on the properties of the image does not seem to take place. Progress has been made in understanding the neural processes that control fixation duration.

The neural process of target selection occupies a certain amount of time that can be measured with reasonable accuracy. This provides an opportunity to determine how the time of visual target selection relates to the time of saccade initiation. This work is motivated by the general hypothesis that behavioral response times are occupied by more or less distinct stages of processing (Donders, 1868; Miller, 1988; Sternberg, 1969). Recent studies have investigated how the

time taken to select a target relates to the time taken to initiate the saccade.

A key element of the design of these studies was allowing monkeys to shift gaze as soon as they could to the target. This contrasts with the design of most other studies of target selection that impose arbitrary delays between presentation of stimuli and permitting responses. The delays are introduced to distinguish neural modulation associated with different stages of processing. The disadvantage of this approach is that the delays change the way in which subjects perform tasks. In other words, the delay amounts to more than just the passage of time, because during the delay interval the state of the monkey is different from what it would have been had the delay not occurred.

During search for a single conspicuous target in a search array, the large majority of visually responsive neurons in frontal eye field discriminated the target from distractors at a rather constant interval after search array presentation (Sato et al., 2001; Thompson et al., 1996) (Fig. 92.8). However, at least under the conditions of very efficient search, the time taken to form a representation of the location of the target does not correspond to or predict when a saccade will be initiated. In other words, during the search for a conspicuous target, the delay and variability of saccade

FIGURE 92.8. Relationship between the time of target selection and the time of saccade initiation during search for a conspicuous target. *A*, The distribution of saccade latencies is illustrated above plots comparing activation when the target (*thick solid*) or distractors (*thin dashed*) fell in the receptive field. The top pair of panels shows the activation on trials in which the monkey made saccades with the shortest latencies (shaded early portion of the latency distribution). The bottom pair of panels shows the activation on trials in which the monkey made saccades with the longest latencies (shaded tail of the latency distribution). The dashed arrows originate at the time of target selection in each group of trials. The neuron discriminated the target from distractors following a relatively constant interval after presentation of the search array. The scale bar for neuronal activation signifies 100 spikes per second. The scale bar for the visual display signifies 15 degrees. *B*, The time at which a conspicuous target was selected by frontal eye field neurons does not predict when the saccade is initiated. Instead, the time of saccade initiation is specified most directly by the activation of another population of neurons in frontal eye field and other structures of the oculomotor system. Saccades are initiated when the activation in the pool of presaccadic movement neurons reaches a threshold (*shaded bar*). The premovement activation begins to increase at the time that the visual neurons select the target (*dotted arrows*). The variability of saccade reaction time can be accounted for by randomness in the time taken by the premovement activity to reach the threshold. Trials with the shortest reaction times occurred because the movement-related activation happened to reach the threshold sooner (*darker gray*), and the trials with the longest reaction times occurred because the movement-related activation happened to reach the threshold later (*lighter gray*). (Modified from Sato et al., 2001; Schall and Thompson, 1999.)

FIGURE 92.9. *A*, Effect of target salience on time of target selection. When the target is conspicuously different from the distractors, search is efficient, with shorter reaction times and fewer errors, and the target is selected earlier by frontal eye field neurons (*top*). When the target is more similar to the distractors, search is inefficient, with longer reaction times, and the target is selected later by frontal eye field neurons (*bottom*). The scale bar for neuronal activation signifies 100 spikes per second. Conventions are as in previous figures. *B*, Relationship between the time of target selection and the time of saccade initiation during the search for a less conspicuous target. The activity of another frontal eye field neuron is shown from the group of trials in which the monkey produced sac-

cades with the shortest latencies (*top*) and from the group of trials with the longest latencies (*bottom*). The range of saccade latencies is indicated by the solid bar on the time axis. The stimulus conditions were identical but the time needed to locate the target varied, and saccade initiation was delayed until after the target was selected by the neuron. In other words, unlike efficient visual search, during inefficient visual search a significant fraction of the variability of reaction time is accounted for by variability in the time taken to achieve an explicit representation that locates the target among distractors. The scale bar for neuronal activation signifies 100 spikes per second. The scale bar for the visual display signifies 15 degrees. (Modified from Sato et al., 2001.)

latency cannot be accounted for by the delay of saccade target selection by frontal eye field neurons.

Frontal eye field neurons also exhibit activity mediating the selection of targets that are difficult to locate or may even be absent (Thompson and Schall, 1999, 2000). When the discrimination of the target is more difficult because the target more closely resembles the distractors, the time taken by neurons in frontal eye field to locate the target increases and accounts for a larger fraction but not all of the variability and duration of saccade latency (Bichot et al., 2001a; Sato et al., 2001) (Fig. 92.9).

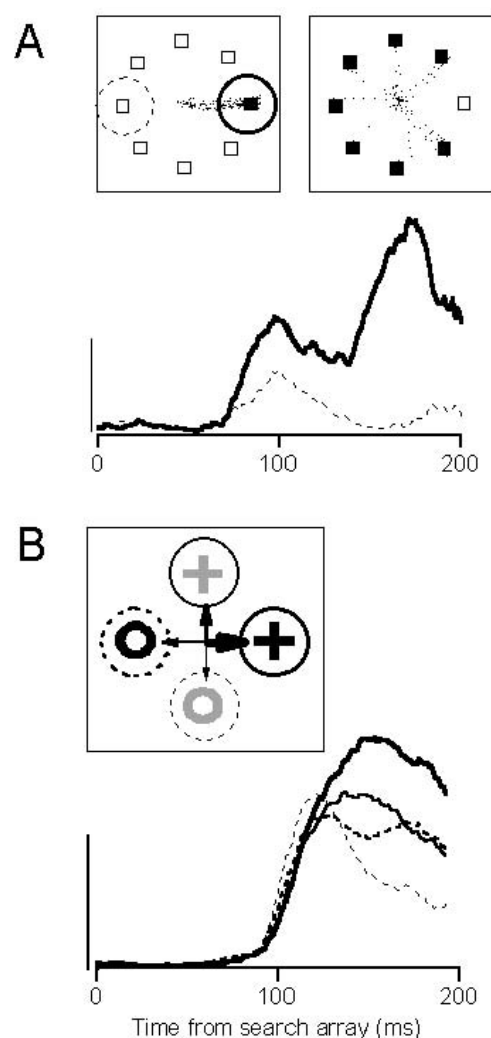

If the time of visual target selection during search does not account for the full duration and variability of saccade initiation times, then some other process must occur to prepare and produce the saccade. As described above, a population of neurons in frontal eye field and superior colliculus linked through the basal ganglia and thalamus provide the input to the brainstem network that produces the saccade. The activation of these particular neurons in frontal eye field and superior colliculus is necessary to produce a saccade; therefore, it is appropriate to identify the process of saccade preparation with the activation of these presaccadic movement neurons (also referred to as *buildup*, *prelude*, or *long-lead burst* neurons). Saccades are initiated when the activation in this network reaches a certain level that may vary across task conditions but appears to be constant within a condition (Hanes and Schall, 1996; Sparks, 1978). Most

of the variability of the latencies of saccades to a visual target can be accounted for by randomness in the rate of growth of activity to the threshold (Hanes and Schall, 1996) (Fig. 92.8).

Thus, the picture that emerges is that the process of visual selection occupies a certain amount of time that can be shorter and less variable if the target is conspicuous, or it can be longer and more variable if the target is less conspicuous. If subjects wish to prevent a saccade to a nontarget stimulus, then the preparation of the saccade can be delayed until the visual selection process has proceeded to a high degree of resolution. Neural activity mediating saccade preparation begins to grow as the selection process is completed, and (for reasons that are not clear) the rate of growth of activity leading to the movement varies apparently randomly such that sometimes gaze shifts sooner and sometimes later.

In higher primates, these two stages—visual selection and response preparation—are distinct and only loosely coupled. The variability of fixation duration during scanning behavior described earlier can be explained by variation in the movement preparation process independent of the visual selection process. In fact, occasionally it is possible for the saccade preparation process to become activated before identification of the currently fixated element and selection of the next target are completed. For example, during visual search, neurons in frontal eye field with no visual response

FIGURE 92.10. Visual selection of a learned target during popout search. *A*, The top displays show the saccades made by a monkey trained with only one instance of the visual search array—a red target among green distractors. When presented with an array in which the colors of the target and distractors were switched, instead of looking at the conspicuous green stimulus, this monkey looked only at one of the red distractors. The lower panel illustrates the activation of a single frontal eye field visual neuron in this monkey when the red target (*thick solid*) was in the receptive field and when green distractors (*thin dashed*) were in the receptive field. Unlike neurons recorded in monkeys that learned to perform generalized oddball search tasks, the initial visual response of this neuron discriminated the target from distractors. The scale bar for neuronal activation signifies 50 spikes per second. *B*, Visual selection of a remembered target during conjunction search. The top panel illustrates the pattern of gaze shifts produced by monkeys during conjunction search. The widths of the arrows indicate the incidence of correct saccades to the target (by far the most common of all) and of occasional errant saccades (much less common) to distractors having the same color or the same shape as the target (intermediate frequency) or having features opposite those of the target (least frequent). The wider arrow to the same shape distractors indicates more saccades to the distractor that had been the target in the previous experimental session. The bottom panel plots the activity of a frontal eye field neuron during conjunction search trials when the stimulus in its receptive field was the target (*red cross, thick solid*), the distractor with the same shape as the target (*thick dashed*), the distractor with the same color as the target (*intermediate dashed*), or the distractor sharing neither feature with the target (*thin dashed*). When this neuron was recorded, the target was the same shape as the target of the previous session. The scale bar for neuronal activation signifies 50 spikes per second. (*A* modified from Bichot et al., 1996; *B* modified from Bichot and Schall, 1999a.)

and only presaccadic movement activity can exhibit partial activation for nontarget stimuli that resemble the target (Bichot et al., 2001b). Such inappropriate activation of movement neurons can, if excessive, result in premature, erroneous saccades such as that shown in Figure 92.1. Independence of visual selection and response preparation is also necessary to explain the production of saccades that are not directed to the location of the selected target. For example, it is possible to shift gaze in the direction opposite a visual target, referred to as *antisaccade*. In monkeys producing antisaccades, visually responsive neurons in the superior colliculus and frontal eye field respond if the target falls in the receptive field, and movement neurons are active for saccades into the movement field whether it is a prosaccade or an antisaccade (Everling and Munoz, 2000; Everling et al., 1999).

EFFECTS OF LEARNING ON TARGET SELECTION As described at the beginning of the chapter, experts look at things differently from novices. This means that selection of targets for gaze shifts is influenced by experience. In one experiment to study the effects of experience on gaze behavior and associated neural activity in frontal eye field, monkeys were

trained exclusively with search arrays that contained a single item of a constant color among distractor items of another constant color (e.g., a red target among green distractors) (Bichot et al., 1996). As an experimental control, other monkeys were trained to produce a saccade to the oddball of both color configurations of the search arrays (i.e., a red target among green distractors and a green target among red distractors). The control monkeys shifted gaze to the oddball stimulus regardless of the feature that defined it, but the experimental monkeys persistently directed gaze to stimuli possessing the learned target color even if the target and distractor colors were switched (Fig. 92.10A). In other words, when experimental monkeys were presented with the search array complementary to that with which they were trained, they shifted gaze to the distractors (that were the color of the overlearned target) and not to the oddball target (that was the color of the overlearned distractors). As described above, frontal eye field neurons in control monkeys do not exhibit feature selectivity in the initial response, but their activity evolves to signal the location of the oddball stimulus. In monkeys trained exclusively on targets of one color, however,

about half of frontal eye field neurons show selectivity for stimuli of that color. This selectivity was manifest as a suppression of the initial visual response to the distractors (Fig. 92.10A).

How might this initial selective response arise in frontal eye field? One possibility is that appropriate bias signals are delivered to frontal eye field from other prefrontal areas. Other studies have demonstrated that the selective properties of prefrontal neurons can change according to rules or strategies (e.g., Wallis et al., 2001; White and Wise, 1999).

When objects of interest cannot be located only by their visual features, knowledge gained through experience is necessary. For example, visual search for a conjunction of features (such as a red cross among red circles, green crosses, and green circles) requires an explicit memory representation to identify the target (e.g., Bacon and Egeth, 1997; Treisman and Sato, 1990). A study of frontal eye field was conducted in monkeys trained to perform a visual search for a target defined by a unique combination of color and shape (e.g., a red cross). The color-shape combination that defined the target remained fixed during a data collection session but was changed randomly between sessions. Two separate contextual influences were exerted on gaze behavior and the neural selection process: visual similarity of distractors to the target and the history of target properties (Bichot and Schall, 1999a, 1999b) (Fig. 92.10B).

The evidence for the influence of visual similarity was revealed by the pattern of occasional erroneous saccades during conjunction search. Erroneous saccades tended to direct gaze to distractors that resembled the current target. Similar observations have been made with human observers during covert (Kim and Cave, 1995) and overt orienting (Findlay, 1997; Motter and Belky, 1998). When monkeys successfully shifted gaze to the target following the initial indiscriminate response, frontal eye field neurons not only discriminated the target from distractors but also discriminated among the nonselected distractors. More activation was present for distractors that were the same shape or color as the target than for distractors that shared neither feature of the target. One consequence of this observation is that stimuli that are not selected overtly may still influence subsequent processing because of the differential neural representation.

The history of stimulus presentation across sessions also affected the selection process during conjunction search. If an error was made, monkeys showed a significant tendency (in addition to the visual similarity tendency just described) to shift gaze to the distractors that had been the target in the previous session. Recordings from frontal eye field neurons during trials with correct saccades to the conjunction target revealed a corresponding discrimination among distractors with more activation for distractors that had been the target

during the previous session. This effect was evident across sessions that were more than a day apart and persisted throughout experimental sessions.

SUMMARY The extensive evidence for the involvement of frontal eye field in saccade target selection has led to the suggestion that superior colliculus can be understood in terms of a salience map (reviewed by Thompson et al., 2001). However, we should not draw the unnecessary and mistaken conclusion that frontal eye field performs this function uniquely and exclusively.

Dorsolateral prefrontal cortex

The source of the modulation observed in frontal eye field derived from experience is not known. It is reasonable to suppose that rostral areas of prefrontal cortex are involved given the evidence for prefrontal cortex instantiating rules (e.g., Miller and Cohen, 2001). The activity of neurons in prefrontal cortex areas rostral to frontal eye field has been described during tasks that required visual target selection (Constantinidis et al., 2001; Ferrera et al., 1999; Hasegawa et al., 2000; Rainer et al., 1998; see also Boussaoud and Wise, 1993; Kim and Shadlen, 1999). In some of these studies the selection of the target appeared as more of an all-or-none activation, largely because the responses began after the selection process was completed in visual areas of the cortex. However, a common feature of dorsolateral prefrontal cortex is the presence of activity during enforced delay periods in which monkeys must remember specific aspects of the stimuli to guide the eventual response. The characteristics of this delay period activation have been described in numerous studies.

One study presented monkeys with two stimuli, a bright target and a distractor with brightness that was varied across trials from that of the dim background to that of the bright target (Constantinidis et al., 2001). In this way, the discriminability of the target from the distractor was varied. After an instructed delay in which the stimuli were removed, monkeys shifted gaze to the location occupied by the brighter stimulus. The activation during the delay period varied according to the brightness of the stimulus in the receptive field and the performance of the monkeys. Neurons remained active during the delay period even if the stimulus in the receptive field had been the distractor. This result provides further evidence that nonselected stimuli are represented by differential activation (Bichot and Schall, 1999a; but see Rainer et al., 1998). This affords an opportunity for the properties of the nonselected stimuli to influence subsequent performance. Also, the magnitude of the activation varied such that if the distractor was more similar to the target, the activation evoked by the distractor was more similar to the activation evoked by the target. This was

observed when the properties of a cue stimulus outside the receptive field guided target selection (Kim and Shadlen, 1999) and also in an investigation of the tactile modality (Romo et al., 1999).

To summarize, the studies of dorsolateral prefrontal cortex have indicated that neurons may not participate directly in the target selection process but can encode the properties of selected and nonselected stimuli. Further work is needed to discover how the function of dorsolateral prefrontal cortex influences target selection in the more caudal parts of the brain.

General summary

Vision occurs naturally in a continuous cycle of fixations interrupted by gaze shifts. The guidance of these eye movements requires information about what is located where in the image. The identity of objects is derived mainly from their visible features. Single neurons in the visual pathway represent the presence of specific features by the level of activation. Each point in the visual field is represented by populations of neurons activated by all types of features. Topographic representations are found throughout the visual and oculomotor systems; neighboring neurons tend to represent similar visual field locations or saccades.

When confronted by an image with many possible targets, the visual system compares the features of elements across the visual field. The retinotopic maps of the visual field facilitate local interactions to implement such comparisons; in particular, a network of lateral inhibition can extract the locations of the most conspicuous stimuli in the visual field. The process of these comparisons can be influenced by knowledge so that inconspicuous but important elements in the image can be the focus of gaze. This selection process results in a state of activation in which neurons with potential targets in their receptive field are more active and neurons with nontargets in their receptive field are less active.

The outcome of this selection process can be represented at a level of abstraction distinct from the representation of the features themselves. This is why the hypothetical construct of a salience map is useful. The state of neural selection of a salient target relative to surrounding nontarget elements amounts to the covert allocation of attention that usually precedes overt shifts of gaze. The time taken for the brain to achieve an explicit representation of the location of a target varies predictably according to how distinct the target appears in relation to nontarget elements.

Coordinated with this visual processing is activation in a network including frontal eye field and superior colliculus that is responsible for producing the eye movement. A saccade is produced when the activation at one location within the motor map reaches a critical threshold. One job

of visual processing influenced by memory and goals is to ensure that only one site—the best site—within the map of movements becomes activated. This is done when the neurons signaling the location of the desired target develop enhanced activation while the neurons responding to other locations are attenuated. When confronted with ambiguous images having multiple potential targets, partial activation can occur in parts of the motor map representing saccades to nontarget elements that resemble the target. Saccade target selection converts an initially ambiguous pattern of neural activation into a pattern that reliably signals one target location in a winner-take-all fashion. However, the representation of likely targets for orienting does not automatically and unalterably produce a saccade. Sometimes potential targets are perceived without an overt gaze shift or gaze can shift to locations not occupied by salient stimuli. The explanation of this flexible coupling between target selection and saccade production requires separate stages or modules, one to select a target for orienting and another to produce gaze shifts. The flexible relationship between target selection and saccade production also affords the ability to emphasize speed or accuracy. Accuracy in fixating correctly can be emphasized at the expense of speed by allowing the visual selection process to resolve alternatives before producing a saccade. On the other hand, accuracy can be sacrificed for speed, allowing the visuomotor system to produce a saccade that may be inaccurate because it is premature relative to the target selection process.

This summary should be regarded as a signpost along a path and not as a destination. Much has been learned, but many questions remain. Throughout all the investigation, we should not lose a sense of marvel at the nimble and flexible manner of movements of the eyes. Is it any wonder that these shiny globes of gristle are called the windows to the soul?

93 Visual Perception during Saccades

DAVID C. BURR AND M. CONCETTA MORRONE

WE FREQUENTLY REPOSITION our gaze by making rapid ballistic eye movements called *saccades* in order to focus the fovea on visual areas under scrutiny. While the strategy is highly efficient for the visual system, allowing it to analyze the whole visual field with the high resolution of the fovea, it poses several problems for perception. Saccades cause rapid large-field motion on the retina, potentially confusable with large-field motion in the external world. They also change the relationship between external space and retina position, confounding information about visual direction. Much effort has been made in recent years to attempt to understand the effects of saccades on visual function. Evidence suggests that saccades trigger two distinct neural processes: a suppression of visual sensitivity, specific to motion analysis, probably mediated by the magnocellular pathway, and a gross perceptual distortion of visual space just before the repositioning of gaze. While the evidence for these phenomena is strong, their functional role for perception is less clear, leaving several areas of inquiry still open.

Saccades are ballistic movements of the eyes made to reposition our gaze. They can be deliberate, but normally they are automatic and go unnoticed. Not only do the actual eye movements escape notice, but so does the image motion they cause and the fact that gaze itself has been repositioned. The first to document this problem was probably the Persian scholar Alhazen: "For if the eye moves in front of visible objects while they are being contemplated, the form of every one of the objects facing the eye . . . will move on the eye as the latter moves. But sight has become accustomed to the motion of the objects' forms on its surface when the objects are stationary, and therefore does not judge the object to be in motion" (Alhazen, 1083, p. 194; see Howard, 1996). Much later, Helmholtz (1866) argued that image motion caused by eye movements is *sensed* but not perceived. He further claimed that, together with "the effort of will involved in trying to alter the adjustment of the eyes," eye movement-induced retinal motion is used to maintain constancy of visual direction during and after saccades. Sperry (1950) and Von Holst and Mittelstädt (1954) expanded on Helmholtz's ideas in the 1950s with two closely related theories. They suggested that saccades were accompanied by a *corollary discharge* (Sperry, 1950) or an *effference copy* (Von Holst and Mittelstädt, 1954) of the motor signal and that this information was used to cancel image motion caused by saccades. This idea was popular, but it has become less

plausible with the realization that motion is probably analyzed by specialized mechanisms distinct from those signaling spatial position, and can therefore not simply be annulled by a contrary displacement signal (Burr and Ross, 1986).

An alternative potential source of extraretinal information about the eye position is proprioceptive signals from extraocular muscles: Sherrington's (1918) *inflow* theory. However, this theory has serious difficulty explaining perceptual effects that precede eye movement, given the latencies involved. Nevertheless, recent evidence suggests that proprioceptive feedback might contribute to stability, although the feedback loop has a high threshold and low gain (Bridgeman and Stark, 1991; Gauthier et al., 1988) and is certainly not sufficient to annul completely the effects of saccadic image motion. Historical accounts of early work and the debate between inflow and outflow theories are to be found elsewhere (e.g., Bridgeman et al., 1994; Carpenter, 1977).

Saccadic suppression

Another idea to emerge early in the twentieth century was that visual sensitivity is actively reduced during saccades. Holt (1903) concluded that saccades "condition a momentary visual central anaesthesia," a loss of sensitivity. However, evidence for suppression by saccades is contradictory. Many researchers (Krauskopf et al., 1966; Latour, 1962; Zuber and Stark, 1966) have reported weak threshold elevation for detecting spots of light flashed briefly during saccades (two- to threefold), and Krauskopf et al. (1966) found no threshold elevation at all. By contrast, Bridgeman et al. (1975) reported a strong reduction in sensitivity for detecting displacement during saccades when the displacement occurred at about the same time as the start of a saccade.

Dodge (1900) and Woodworth (1906) concluded that there was no requirement for a central change in visual functions, arguing that image motion during saccades was too rapid to be seen and caused what Campbell and Wurtz (1978) later termed a *grayout*. However, measurements of contrast sensitivity (during normal vision) show that this idea cannot be generally true. Although stimuli of high spatial frequency become unresolvable at saccadic speeds, stimuli of low spatial frequency can be seen only in motion but become considerably more visible at saccadic speeds (Burr and Ross,

FIGURE 93.1. *A–C*, Contrast sensitivity for detecting a horizontal grating briefly displayed either at the beginning of a large (30 degrees) horizontal saccade (*filled circles*) or during free viewing (*open circles*). Measurements were made for 2500 trolands, 1 troland, and 0.014 troland. Sensitivity is greater during normal than saccadic viewing at low spatial frequencies, but the two curves converge at high frequencies; the point of convergence decreases steadily with retinal illuminance. Note that at the higher spatial frequencies of the lowest illuminance (*C*), contrast sensitivity was actually higher during saccades than during normal vision (see also Fig. 93.2). Measurements were not made above 3 c/deg, as the large

saccade would cause smearing of the grating. *D–F*, Contrast sensitivity for continuously displaced horizontal gratings, either stationary (*filled squares*) or drifting at 10 Hz (*open squares*). There is an advantage for drifting gratings at low spatial frequencies. The spatial frequency at which the motion curve peels away from the stationary curve changes with illuminance and corresponds very closely to the point at which the sensitivity during saccades (*above*) diverge from normal sensitivity, strongly suggesting that motion mechanisms are selectively suppressed during saccades. (Data reproduced with permission from Burr et al., 1982.)

1982). Thus, during saccades, the normally invisible low spatial frequencies that predominate in natural scenes (Field, 1987) should become abruptly salient, posing a potential problem for vision.

It seems that at least part of the reason motion is not seen during saccades is that the low spatial frequencies that would normally be so conspicuous are suppressed during saccades (Burr et al., 1982, 1994; Volkman et al., 1978). An example of this frequency-dependent suppression is shown in Figure 93.1*A–C*, which compares contrast sensitivity for detecting briefly flashed horizontal gratings during saccades (*filled symbols*) with that for fixation (*open symbols*). Sensitivity is very similar at the higher spatial frequencies, but at low spatial frequencies sensitivity during saccades is reduced sharply, reaching a tenfold reduction of sensitivity at 0.02 c/deg; these are the very frequencies that would otherwise be visible and highly conspicuous during saccades. The selectivity for spatial frequency might explain some of the conflicting data from earlier studies. Loss of sensitivity should depend on the spatial frequency content of the experimental stimuli, typically high (e.g., small spots of light) in the luminance threshold studies (Krauskopf et al., 1966;

Latour, 1962; Zuber and Stark, 1966) but low (large targets) in displacement studies (Bridgeman et al., 1975).

Burr et al. (1982) also reported qualitative changes in motion perception during saccades. Observers viewed at close distance a high-contrast scene back-projected through a deflectable mirror. Displacing the scene abruptly at saccadic speeds and amplitudes caused a strong sensation of motion that instantly commanded attention. However, if the displacements of the scene were the result of a saccade, the motion was sensed, but lacked the salience and the alarming sensation that usually accompany fast motion in normal viewing: subjects observed that the image had been displaced, but they did not report feeling startled. This qualitative impression, together with Bridgeman et al. (1975) demonstrations of large desensitization to displacement during saccades, suggested that the frequency selectivity of the suppression may reflect desensitization of motion mechanisms.

A good deal of evidence points to motion desensitization during saccades. However, it should be pointed out that it is difficult to test motion directly during saccades, for several important technical reasons. One is that, by definition,

motion requires moderately long stimulus durations, necessarily exceeding the duration of maximal saccadic suppression. Another is that the movement of the eyes will introduce image motion, which is difficult to take into account accurately in calculating the real retinal velocity of external motion. However, it is possible to infer the action of motion mechanisms using brief stimuli that contain a wide range of temporal frequencies and hence will excite motion mechanisms (tuned to all directions) as well as mechanisms that respond best to stationary stimuli.

An attempt to do this is shown in Figure 93.1. As mentioned earlier, sensitivity during saccades becomes progressively compromised at low spatial frequencies, while at higher spatial frequencies, above 3 c/deg, there is virtually no suppression at all. Figure 93.1D–F shows steady-state sensitivity measurements for stationary and drifting (10 Hz) gratings measured under comparable conditions. As had been well documented previously (Burr and Ross, 1982), gratings in motion are more conspicuous at low spatial frequencies. Importantly, the spatial frequency at which sensitivity for drifting gratings begins to exceed that of stationary gratings is very similar to the spatial frequency at which saccadic suppression begins (illustrated by the vertical dashed lines). As brief stimuli comprise a wide range of temporal frequencies, the similarity in frequency ranges suggests that it is the motion mechanism that is selectively impaired during saccades. To be certain that the correspondence in spatial frequency was not merely a coincidence, the measurements were repeated at two lower levels of illumination. At all three levels of illuminance, both sets of curves—sen-

sitivity to brief displays in normal and saccadic viewing and sensitivity to continuously drifting or stationary stimuli—peeled apart at about the same spatial frequency, consistent with the suggestion that the mechanisms suppressed during saccades are those responsible for the higher sensitivity to motion in normal viewing.

Despite the problems in examining motion perception directly during saccades, there have been several attempts to do so. For example, thresholds for detecting an abrupt change in the speed of a drifting grating are far poorer during saccades than during normal vision (Burr et al., 1982). The discrimination of motion of random-dot patterns is also severely impaired during saccades (Ilg and Hoffmann, 1993; Shiori and Cavanagh, 1989). And discrimination of two-frame motion sequences is severely impaired when one frame is presented near saccadic onset (Burr et al., 1999).

What may be the mechanism whereby motion sensitivity is reduced? Recent anatomical and physiological advances have shown that vision, at least in the early stages of visual analysis, is processed through two largely independent streams: the magno- and parvocellular systems (see Chapter 30). Although these two systems are not completely separate, parvocellular function can be probed by using equiluminant stimuli, which are modulated in color but not in luminance. The magno system there may respond spuriously to some equiluminant stimuli, but it is known to be incapable of color discriminations (Merigan, 1989). Figure 93.2 shows forced-choice discriminations of either the color of equiluminant red-green stimuli or the luminance of equichromatic yellow-

FIGURE 93.2. Contrast sensitivity for discriminating the color or the luminance of a broad horizontal bar briefly presented at a given time after the onset of a saccade (abscissa) for two subjects. Bars were modulated either in color (equiluminant red-green: *square symbols*) or in luminance (yellow-black: *circle symbols*). Sensitivity is expressed as the inverse of rms cone contrast. The dotted line

shows the chromatic sensitivity in free viewing, the dashed line the luminance sensitivity. Note that not only is there no desensitisation for chromatic discrimination just after the saccade, there is actually a marked increase in sensitivity for a period of up to 200 msec after the saccade. (Data reproduced with permission from Burr et al., 1994.)

black stimuli (both of very low spatial frequency) as a function of time after saccadic onset. Luminance discrimination (*filled circles*) was severely impaired just after saccadic onset, by one log unit, steadily improving to normal levels over a 200 msec period. Chromatic sensitivity (*filled squares*), on the other hand, was not at all impaired at around the time of the saccade, and actually improved over the period following the saccade, by approximately a factor of 2. This is an example of saccadic enhancement of contrast sensitivity, similar to that previously observed by Burr et al. (1982) for relatively high frequencies of luminance modulation (see Figure 93.1C) that presumably stimulate the same P-pathways.

These results, showing that equiluminant stimuli (irrespective of the spatial frequency) are not suppressed during saccades and can actually be enhanced, imply that saccadic suppression is specific to the magnocellular pathway. The parvocellular pathway, essential for chromatic discrimination, is left unimpaired. Using a different technique, Uchikawa and Sato (1995) arrived at a similar conclusion. They measured incremental spectral sensitivity for detecting monochromatic discs displayed against a white background during normal viewing and saccades. They showed that during saccades, the spectral sensitivity curve showed a marked decrease at ~570 nm (known as *Sloan's notch*), a clear signature of the spectrally opposed mechanisms of the parvocellular system. In normal viewing, this decrease was absent (for brief stimuli), suggestive of magnocellular function. Their results are replotted in Figure 93.3, together with representative measurements of responses of P and M retinal ganglion cells of macaque monkey. The psychophysical detection thresholds during normal viewing follow closely the responses of M cells, while during saccades they are more like those of P cells.

A fundamental question provoked by these studies was whether saccadic suppression results from a central signal, such as the corollary discharge proposed by Sperry (1950) and Von Holst and Mittelstädt (1954), or whether the visual motion caused by the eye movement itself masks vision during saccades (Campbell and Wurtz, 1978; Castet et al., 2001; MacKay, 1970, 1973). There is good evidence that image motion of the kind caused by saccades can mask brief stimuli (Campbell and Wurtz, 1978; Derrington, 1984; MacKay, 1973), but is this the only, or indeed the principal, mechanism at work? Diamond et al. (2000) simulated visual saccades by optically deflecting the display at suitable speed, amplitude, and acceleration, and measured contrast sensitivity to briefly displayed gratings. When the target gratings were displayed on an otherwise blank screen, simulated saccades had little effect on thresholds compared with real saccades. However, when a high-contrast random pattern was added to the display to provide a strong spurious visual motion signal, the simulated saccade produced a suppression

FIGURE 93.3. Sensitivity (in relative units) for detecting a monochromatic bar briefly presented on a white background in normal viewing (*open circles*) or at the onset of a 6 degree saccade. In normal viewing, the curve has a broad peak around 550 nm and closely follows the sensitivity of a sample of retinal M cells in the macaque monkey (taken from Zrenner, 1983). During saccades, however, the form of the curves changes dramatically to reveal Sloan's notch, a sharp dip in sensitivity at around 570 nm. The dashed lines show the average response of a population of P cells. While not following the human sensitivity data exactly, they show the same characteristic dip for middle wavelengths. This is very strong evidence for suppression of magnocellular activity during saccades. (Adapted with permission from Uchikawa and Sato, 1995, and Zrenner, 1983.)

that was comparable in magnitude to and lasted longer than that produced by the real saccade. This result suggests that visual masking can be important for vision at around the time of saccades but that it is not the only mechanism. There must also be a signal of nonvisual origin that accompanies each real saccade to decrease sensitivity to low-frequency, luminance-modulated stimuli. Other evidence for a non-visual suppression signal is that visual phosphenes generated by applying weak electrical signals to the eye in darkness are suppressed during saccades by a comparable amount to real light images (Riggs et al., 1974).

The similarity between the time course of saccadic suppression and visual masking observed by Diamond et al. (2000) could indicate that these two phenomena have a common site of action. This seems reasonable, given the evidence that saccadic suppression occurs early, preceding the site of contrast masking (Burr et al., 1994) and motion analysis (Burr et al., 1999). One interesting possibility is that both saccadic suppression and masking act on *contrast gain mechanisms* of cortical and/or geniculate cells. This idea predicts that saccades should not only decrease sensitivity, as shown in Figures 93.1 and 93.2, but should also cause the system to respond more rapidly. This is what occurs. During saccades, the temporal impulse response function

becomes more rapid (Burr and Morrone, 1996), as many models of contrast gain (e.g., Shapley and Victor, 1981) would predict.

The fact that the impulse response accelerates rather than decelerates during saccades suggests that although strongly attenuated, the magno system remains active during saccades (a parvo-dominated response should be slower). This is consistent with experiments demonstrating that under certain conditions, saccades in the direction of a rapidly moving, high-contrast grating can improve direction discrimination of that stimulus (Castet and Masson, 2000; Garcia-Perez and Peli, 2001). While these demonstrations clearly do not refute the existence of a centrally driven suppression mechanism, they do highlight the important point that centrally driven saccadic suppression only attenuates motion detection, not eliminating it completely, leaving an important role for other mechanisms, such as masking, in natural (usually visually rich) viewing conditions (Campbell and Wurtz, 1978; Derrington, 1984; Diamond et al., 2000; MacKay, 1973).

The studies discussed above all refer to moderate to large saccades and might not be applicable to the microsaccades that are normally made, together with slow drifts, around the fixation point. Most evidence suggests that small saccades cause little or no threshold elevation (Krauskopf et al., 1966; Sperling, 1990), indicating that the effects of the image tremor may be controlled by other means. Murakami and Cavanagh (1998, 2001) recently proposed that the retinal motion generated by microsaccades is eliminated by subtracting a baseline speed, estimated from the minimal retinal *jitter*, from the velocity signals of local-motion detectors. Evidence favoring this model is derived from the observation that if a region of the retina is adapted to jittering motion and a static pattern is subsequently inspected, the unadapted (but not the adapted) region appears to jitter. Murakami and Cavanagh claim that the reduction in motion sensitivity caused by adaptation reduces the estimate of the baseline jitter so that the motion caused by eye jitter becomes superthreshold in the unadapted region and hence visible. This idea is particularly interesting in the context of older theories that suggested that stabilization is achieved by subtraction of extraretinal signals. In such cases, there is subtraction of a speed scalar (not a spatial displacement vector) from velocity estimates that have been extracted by specialized motion detectors.

In conclusion, human psychophysical data clearly suggest an extraretinal suppression of early visual activity during saccades. There is also much neurophysiological evidence pointing to the underlying neural mechanisms of suppression, but there is no clear consensus on this: some studies show clear evidence of suppression, but others do not. Still others point to more complicated effects, such as an inversion of directional selectivity of MT cells during saccades

(Thiele et al., 2002). For a recent review of some of this literature, readers are referred to Ross et al. (2001).

Perceived position

Retinal motion is not the only problem introduced by saccades. A related problem is how the visual system manages to maintain a stable sense of visual direction while the retinal input is constantly changing. Helmholtz (1866) believed that the constancy of perceived position was maintained during and after saccades, because both extraretinal information (the *effort of will*) and retinal information (sensed but not perceived image motion) were used to recalibrate the direction of gaze.

Leonard Matin and colleagues (Matin, 1972; Matin and Pearce, 1965; Matin et al., 1969, 1970) and Bischof and Kramer (1968) were among the first to find errors in localization at the time of eye movements. Figure 93.4A replots data from Bischof and Kramer showing the perceived position of a stimulus briefly flashed at a variable interval after observers initiated a 16 degree saccade. There is a strong mislocalization immediately after the saccade onset in the direction of the saccade, about half of its amplitude. Halfway through the saccade, the direction of the misperception inverts before returning to veridical. This experiment has since been replicated by many observers, including Honda (1989, 1991, 1993), Schlag and Schlag-Rey (1995), and Dassonville et al. (1992). The curve in Figure 93.4 was replotted in a more recent study by Ross et al. (1997) that measured the perceived position of a bar briefly flashed at various times over a period preceding and following the saccade. The results are quite similar to those of Bischof and Kramer (except for the rebound after the saccade in this instance, although it has been observed under other conditions). They also show that the mislocalizations precede the saccade, before the eye has begun to move, reaching a maximum at around saccadic onset. The maximum shift is again about half the size of the saccade, suggesting a relative gain of 0.5, as observed by others (Bridgeman, 1995).

If the errors in localization are to compensate for eye movements, they should be in the same direction as the saccade. However, this is not always the case, as first observed by Bischof and Kramer (1968) and studied systematically by Ross et al. (1997). Figure 93.5A shows reports of perceived positions of visual targets presented just before a saccade as a function of the actual position of the bar. The small symbols show data on when the bars were flashed during control fixation conditions: localization was veridical and accurate. However, when the same bar was flashed to the stationary eye just prior to a saccade, it was seen to be displaced, but the direction of the displacement depended critically on its position. Bars flashed to the left of the

FIGURE 93.4. Perceived positions for stimuli briefly presented at various times relative to the onset of a rightward horizontal saccade (shown by the dotted lines). The dashed line shows the veridical position of the target. The upper curve shows data reproduced from Figure 3 of Bischof and Kramer (1968), the lower curves from Figure 1 of Ross et al. (1997). Both data show a strong mislocalization of maximal strength near the onset of the saccade.

saccadic target were displaced rightward, in the direction of the saccade. However, bars flashed beyond the saccadic target were displaced leftward, against the direction of the saccade, resulting in a general compression. This compression is powerful enough to remove vernier offsets for line targets that are flashed at about the time of saccade onset and can create offsets for collinear line targets flashed at different times (75 msec apart). Compression can even cause four bars, flashed to straddle the saccadic target, to merge into a single bar and severely distorts natural scenes. Because the relative distance between objects does not depend on retinal coordinates in these conditions, this emphasizes how large the perceptual compression can be.

Compression does not always accompany saccades. For example, Cai et al. (1997) reported no compression occurring under the conditions of their experiment. The issue was at least partially resolved by Lappe et al. (2000), who reported compression only in conditions where visual referents were perceived after the saccade. Another major difference is that in order to remove visual referents, Lappe et al. performed their experiments at very low levels of illumination, near darkness, as did many of the previous investigations that report no compression (Cai et al., 1997).

As with saccadic suppression, it is important to understand if the apparent shifts and compression are caused by the visual events associated with the saccade or if they have a central origin. As before, simulating saccades by rapid

FIGURE 93.5. Perceived positions of bars briefly flashed to stationary eyes in the 40 msec before observers made a 20 degree saccade. The large filled circles in A show results for verbal reports in which subjects called out a number from a remembered scale. In this example (taken from Burr et al., 2001), the subject closed her eyes immediately after making the saccade. The curve follow-

ing the data is the output of a model for the shift and compression effects (Morrone et al., 1997). The small circles show control data taken under identical conditions during fixation (from Ross et al., 1997). The filled squares in B show results for blind pointing to the remembered positions, again with the eyes shut. (Adapted with permission from Burr et al., 2001.)

rotation of a mirror provides crucial information. Mislocalizations can occur during simulated saccades, but they have a very different time course and magnitude than those during real saccades (Morrone et al., 1997). More significantly, no compression occurs with simulated saccades: all stimuli are displaced in the same direction and to the same extent, irrespective of their position in the visual field (Morrone et al., 1997).

There exists a good deal of evidence for the involvement of extraretinal eye position information in judging apparent visual direction, although some of it is contradictory. Helmholtz (1866) noted that causing the eye to move by applying pressure with the finger (creating an eye movement without an “intention to move” signal) caused an apparent displacement on the visual world. However, the inverse experiment, attempting to move the eyes under conditions of total paralysis, did not create a sense of apparent motion of the visual scene (Brindley et al., 1976; Stevens et al., 1976), even though there should have been a mismatch between the extraretinal signal and the retinal movement (or lack thereof). The issue has been readdressed by Matin et al. (1981), who showed that with partial systemic paralysis, observers make enormous errors in visual localization, on the order of 20 degrees. In darkness, partially paralyzed (but not normal) observers misperceive completely the median plane and make gross errors in pointing to visual targets. Most significantly, when using an auditory tone to localize a visual target, partially paralyzed observers grossly overestimate the eccentricity (Fig. 93.6). With full room illumination, the perception of the median plane and the pointing performance to visual targets return to normal, but the auditory-to-visual matches remain as distorted as they are in darkness (Fig. 93.6). This experiment provides clear evidence for the role of extraretinal eye position information in judging apparent visual direction. When the muscular response is weakened through partial paralysis, the motor command for a given response must be increased. The fact that the increase in gain of the motor command produces a commensurable increase in perceived eccentricity suggests that the extraretinal signal combines with retinal information in determining visual location. It seems that when present, visual information can dominate in determining the medial plane (possibly explaining the previous null results of Brindley et al., 1976, and Stevens et al., 1976); but the visual illumination is not sufficient to override the erroneous eccentricity estimates in the auditory-to-visual matches.

Motor responses during saccades

Although there is overwhelming evidence for perceptual mislocalizations during saccades, there is also good evidence that subjects maintain a veridical spatial map, and that this map can be used to guide motor activity such as second sac-

FIGURE 93.6. Error in auditory localizations of fixed visual targets in observers that have been partially paralyzed by curare (filled squares) compared with control measurements in the same observers (open circles). During paralysis, observers overestimated the distance of the light from the median by more than a factor of 2. These results suggest that extraretinal information used to control eye position is used in estimating eccentricity. These results were the same in darkness as in normal lighting conditions. (From Matin et al., 1981, with permission.)

cades and hammering (Hallett and Lightstone, 1976a, 1976b; Hansen and Skavenski, 1977, 1985). Bridgeman et al. (1975) also reported that subjects can point accurately to targets that were displaced perisaccadically, even though the subject did not perceive the change in target position. These results are intriguing because they imply that two visual representations exist: one that remains veridical during saccades and another that becomes transiently distorted. This is consistent with the long-standing (Trevarthen, 1968) and recently revived (Goodale and Milner, 1992) idea that separate systems are responsible for conscious perception and for direct interactions with our environment.

While the early evidence was clear, some recent experiments on pointing and secondary saccades have failed to replicate the original dissociation between motor accuracy and perceptual mislocalization during saccades, reporting localization errors for both tasks (Bockisch and Miller, 1999; Dassonville et al., 1992, 1995; Honda, 1991; Miller, 1996; Schlag and Schlag-Rey, 1995). However, it should be pointed out that localization errors for motor responses vary considerably both in size and in dynamics in different laboratories: some show errors as large as the perceptual errors, starting well in advance of saccadic eye movements (Dassonville et al., 1992, 1995; Schlag and Schlag-Rey, 1995); others show very small errors (4 to 5 degrees for 15 degree saccades), mainly for targets presented at the completion of the saccade (Bockisch and Miller, 1999; Miller, 1996). The errors have been reported to be similar for finger indication and for secondary saccades. Unfortunately, all these studies used different experimental paradigms, with various levels of dark adaptation, visual references from the eye recording systems,

and possible visual cues introduced from diffuse or reflected light from the apparatus (Bockisch and Miller, 1999; Dassonville et al., 1992; Miller, 1996).

We have recently revisited the problem to see whether the compression of visual space that occurs with verbal reports also occurs with blind pointing under matched conditions (Burr et al., 2001; see also Husain and Jackson, 2001). When asked to report verbally the position of a bar flashed just before a saccade, subjects made strong compression errors, as mentioned before and plotted in Figure 93.5A. This occurred even when all visual references were removed by obscuring the screen at the time of the report. However, when subjects were asked to point ballistically to the location where a bar had been seen (again with transient darkness caused by eye shutting), the pattern of pointing was virtually veridical (Fig. 93.5B). This supports the idea that there are two separate visual representations with separate remapping during saccades. Importantly, when subjects were asked to point with visual cues available (but the hands obscured from view), the pattern of errors was like that for verbal reports. This suggests that, when available, the perceptual representation can override the motor representation of visual space. It is also possible that this result explains the conflicting results in the literature. Hansen and Skavenski (1977, 1985) used the technique of transient darkness (with a light-adapted eye) to remove visual cues, and they reported accurate motor response, similar to those in Figure 93.5B. On the other hand, fully dark-adapted subjects, viewing stimuli through eye sensors that provided clear visual references (Schlag and Schlag-Rey, 1995), made substantial errors on secondary saccades in the direction of the primary saccade.

Other lines of evidence also suggest that veridical information might be available at the time of saccades and can be used under certain conditions. For example, Deubel et al. (1996) repeated Bridgeman et al.'s (1975) measurements of sensitivity to line displacements at the time of saccades. The saccade typically raises thresholds by more than a factor of 3. However, if a line is briefly blanked at the time of the saccade and reappears ~100 msec later, subjects can detect displacements with unimpaired accuracy. This suggests that information about position is not lost during the saccade and that mechanisms exist to maintain continuity between fixations. Interestingly, even under conditions where observers are unable to report correctly the direction of the displacement, they frequently make an accurate second saccade toward the displaced target (Deubel et al., 1998).

In conclusion, the bulk of the evidence suggests that veridical pointing and second saccades can occur with perisaccadic targets under conditions where perception is severely distorted. However, in order to demonstrate veridical motor responses, care must be taken to render the visual signals unreliable (that does not only entail removal of visual

references), or else vision will dominate. The results suggest the existence of separate representations for perception and action that are affected differently during saccades. However, there is clearly considerable interaction between the representations, and when there is conflict, the perceptual system seems to dominate.

Physiological mechanisms

In an important paper, Duhamel et al. (1992) showed that the receptive fields of some neurons in the lateral intraparietal area (LIP) of monkeys change position before each saccadic eye movement, effectively anticipating its consequences. Up to 80 msec before the onset of a saccade, LIP neurons start to respond to stimuli that will fall within their receptive field after the saccade is completed. This predictive effect might represent a mechanism by which the visual and oculomotor systems combine and calculate a spatially accurate image of the world in spite of the eye movement. This could enable neurons to respond immediately at the end of a saccade to stable stimuli that enter the receptive field by virtue of the saccade without having to “wait” for retinal reafference (Gottlieb et al., 1998).

Perisaccadic receptive field shifts are not unique to the LIP but have been found in other eye movement-related areas—for example, the superior colliculus (Walker et al., 1995) and the frontal eye field (Umeno and Goldberg, 1997), a medial parietal area that is associated with reaching (Batista et al., 1999)—and even in earlier stages in the cortical visual system, V4, V3a, and V2 (Nakamura and Colby, 2002). The remapping of receptive fields in all these areas is consistent with visual mislocalization in the direction of the saccade. It is not, however, obvious how it may explain the observed compression: compression requires a shift that is dependent on the position of the stimuli.

One possibility is that during the perisaccadic interval, not all LIP neurons (and other neurons in the parietal stream) show the predictive shift of receptive field in the direction of the saccade. Other neurons continue to respond to the pre-saccadic position, and some respond to stimuli in both positions (Kusunoki et al., 1997; Nakamura and Colby, 2000). Areas that receive input from the LIP (including the frontal eye field and the superior colliculus) might thus interpret stimuli arising over a large area (comprising pre- and post-saccadic receptive fields) as being in the same position, resulting in compression, particularly of the positions of stimuli that are flashed briefly during psychophysical experiments. The fact that many areas show anticipatory shifts in receptive fields, to a greater or lesser extent, could mean that multiple representations in all these areas in some way contribute to the observed compression.

Neural correlates of perisaccadic mislocalization have also been observed in MT and MST neurons. Using a

FIGURE 93.7. Perisaccadic compression of space in areas MT and MST. The curves of various widths and line types indicate the predictions of the perceived stimulus position of a population of MT and MST neurons, as a function of time relative to saccadic onset, for bars stimulated at various positions (actual positions are indicated at the left and right of the graph). The animal made 20 degree leftward saccades, as indicated by the faint dashed black curves. Well before and well after saccadic onset, the model prediction from the cell population is very close to veridical. However, at times near saccadic onset, the population code tends to converge near the saccadic target, implying compression. (From Krekelberg et al., 2003, with permission.)

Bayesian analysis, Krekelberg et al. (2003) show that a population of MT and MST cells can encode veridically the position of briefly flashed bars. However, analysis of the same neurons just prior to a saccade (using the weights derived from free viewing) shows a gross mislocalization in the population response, shown in Figure 93.7. The mislocalization is in the direction of compression, as observed with human observers. Interestingly, both the magnitude of the compression and the time course are very similar to those observed with human observers (Morrone et al., 1997; Ross et al., 1997).

While the work is new and very much in progress, it is fair to say that strong neural correlates exist between the psychophysical and electrophysiological single-unit findings, to account for both the systematic shift in the direction of the saccade and the compression toward the saccadic target. The areas involved include V3, LIP, VIP, MT, MST, and superior colliculus.

Future directions

At the time of saccades, vision is profoundly modified. There is a transient desensitisation of low-frequency stimuli modulated in luminance together with gross distortions of perceptual (but not motor) space. The time course of perceptual compression is very similar to that for loss of sensitivity: both begin more than 50 msec before saccades start, are maximal

at or shortly before the start of saccades, diminish during saccades, and disappear only after saccades have ended. These psychophysical findings, summarized in this chapter, have been confirmed in many laboratories and have spurred the successful search for neural correlates in the single neurons of nonhuman primates.

What is the functional role of these perisaccadic changes? How do they enable the visual system to perceive a steady world from input arriving from such unsteady sensory platforms? As discussed earlier, the transient suppression of low spatial frequency luminance information probably serves to dampen the motion system (or one part of the motion system), blunting the otherwise disturbing sensation of movement the rapid displacement should cause. But as we have seen, the suppression is very brief, lasting for only about 50 msec, and by no means total, 1 log unit at most. How can this brief, partial suppression obliterate the extended motion that occurs with each eye movement? Indeed, we know that motion is not totally suppressed in some cases (Castet and Masson, 2000) and that part of the magnocellular system remains operative at reduced gain (Burr and Morrone, 1996). One fruitful line for future research will be to simulate saccadic vision by large-field motion and spatial blur to investigate whether this transient partial attenuation of luminance, but not color, is sufficient to blunt the motion sensation or whether other factors are involved.

The perceptual distortions are even more perplexing: a shift in the direction of the saccade combined with gross compression of perceptual space toward the saccadic target. There is clear neural activity in the parietal pathway correlated with these two processes. But what is their function? Do the shift and compression facilitate directly the perceptual transitions from one fixation to another or is it an epiphenomenon of some more subtle, still not understood process?

Finally, there is now very good evidence that at the time of these gross perceptual distortions, veridical information remains available during saccades, information that can be used to guide ballistic motor acts and secondary saccades. What is the nature of the spatial representation used in this case? Why is this information normally unavailable to perception? Which visual pathway mediates the spatial map used by the action system? How can the retention of this ability be reconciled with the psychophysical and physiological demonstrations of massive suppression of the magno (dorsal) pathway's activity during saccade?

While much progress has been made in documenting the psychophysical and electrophysiological events that accompany saccades, many of the important questions about visual stability remain unsolved and will provide a fertile terrain for research for the next few decades.

94 Smooth Pursuit Eye Movements: Recent Advances

STEPHEN J. HEINEN AND EDWARD L. KELLER

MOST OF THE WORK covered in previous reviews of the pursuit system (Eckmiller, 1987; Keller and Heinen, 1991; Leigh and Zee, 1999; Lisberger et al., 1987; Pola and Wyatt, 1991) describes the physiology and behavior of pursuit to a single small spot stimulus. The theoretical framework that guided this work was that the pursuit system used negative feedback to minimize the retinal-image motion introduced when an object moves (Krauzlis and Lisberger, 1989; Robinson et al., 1986). Much of current pursuit research involves functions that either modulate or override the negative feedback process in situations more closely aligned with object motion in the natural environment. The purpose of this review is to discuss how signals related to cognitive aspects of pursuit interact with signals arising in the visuomotor processing stream, and to summarize recent literature on a common neural substrate for pursuit and saccades that might support the more naturalistic cooperative response of these ocular subsystems. The outline of the chapter is as follows.

The first section discusses research on how pursuit operates under experimental conditions that more closely approximate natural scenes. Here we cover work on target selection, that is, how a single moving object is selected from among several objects. Literature on gain control in the pursuit system that occurs in these situations is also reviewed here. Next, work on the predictive mechanism that governs anticipatory pursuit is discussed. Finally, we address how the pursuit system responds to stimuli that are larger and more complex than a single spot. The second section speaks to the important emerging issue in pursuit research of how cognitive signals interact with signals in areas of the brain that process visual motion for pursuit. In this section, new developments in the cortical control of pursuit are discussed, including evidence that areas in the frontal lobe generate cognitive aspects of pursuit behavior. The cortical visual-motion processing areas in the superior temporal sulcus and parietal lobe, although not covered in detail, will be referenced here as components in a pathway that might be complementary to the frontal pathway. Also in this section, new developments in brainstem and cerebellar pursuit research will be discussed, including the exciting possibility that cognitive and visual-motion signals are processed in different regions at this level. In the third and final section, we sum-

marize recent evidence that the pathways subserving smooth pursuit and saccades overlap to a greater degree than was thought previously. Finally, we suggest that the reader refer to reviews by Leigh and Zee (1999) on pursuit deficits in the clinic and by Krauzlis (1994) on cortical visual-motion processing areas for pursuit, as these important topics are not covered in detail here.

Pursuit in the natural scene

The purpose of early smooth pursuit studies was to characterize the motor limb of the system without contamination by signals introduced by complex visual processing and cognition. To this end, most studies employed a single small spot to minimize the visual complexity of the stimulus and random-motion patterns to minimize target predictability. To understand fully how the pursuit system operates in a natural scene, recent research has been devoted to studying pursuit of visual stimuli that are more complex than the single spot and cognitive factors that contribute to pursuit control. This section will discuss recent research on target selection, gain control, and prediction, as well as work addressing how the pursuit system follows stimuli that are larger and visually more complex than the spot.

GAIN CONTROL AND TARGET SELECTION FOR PURSUIT It has been suggested that when the pursuit system is confronted with multiple objects, selective attention biases the observer to select a single one in a winner-take-all fashion (Kowler, 1990). Other work supports this contention for certain spatial and temporal target separations (Ferrera and Lisberger, 1997; Recanzone and Wurtz, 1999). Interestingly, during pursuit initiation, a weighted vector average of the speed and direction of both targets appears to describe the data better than does winner-take-all selection (Lisberger and Ferrera, 1997). Vector averaging during pursuit initiation occurs even when an animal is cued to track one of the targets before they move (Ferrera, 2000). In this study, the pre-motion cueing biased the subsequent pursuit response toward the cued target, yet the response remained influenced by the nonrewarded target motion. The results of microstimulation in area MT are consistent with the idea that

velocity signals that are read out from this structure are vector averaged for use by the pursuit system (Groh et al., 1997).

An increase in pursuit gain can occur after pursuit is engaged and the observer has selected an object to follow. Modulation of gain was first demonstrated in experiments where brief sinusoidal perturbations were superimposed upon step-ramp target motions (Goldreich and Lisberger, 1987). In this study, higher gain was observed when the perturbation occurred during pursuit than during fixation. Based on these data, the authors suggested that there is a neural “switch” that activates the pursuit system. Later work showed that the gain of the pursuit system with superimposed sinusoidal perturbations varied as a function of target speed (Keating and Pierre, 1996; Schwartz and Lisberger, 1994). Therefore, it appeared that a variable gain element, and not a switch, modified the pursuit system’s level of activation.

Normally, smooth pursuit to step-ramp target motion is initiated with a smooth eye acceleration followed by a saccade that places the fovea close to or on the target (Keller and Johnsen, 1990). Lisberger (1998) used the step-ramp paradigm to investigate the interaction between the smooth and saccadic components of pursuit initiation and found that eye velocity just after the saccade was greater than before it. He argued that this “postsaccadic enhancement” resulted from a boost of the gain in the visuomotor pathways. Specifically, the oculomotor system anticipates that the selected target will be near the fovea following the catchup saccade, and the system boosts pursuit gain to ensure that eye speed closely matches target speed at this time. The finding that when two targets are present, heightened eye velocity after the catchup saccade to the foveated target supports the idea that gain control is used during target selection (Gardner and Lisberger, 2001). These data are also evidence that postsaccadic enhancement of pursuit is spatially selective.

Recently, the frontal eye fields (FEF) have been implicated in pursuit gain control (Tanaka and Lisberger, 2001). These authors found that the magnitude of eye velocity induced by electrical stimulation here was greater during pursuit than during fixation. This difference was seen both with and without the sinusoidal perturbations used in earlier studies (e.g., Schwartz and Lisberger, 1994). Stimulation of the supplementary eye field (SEF) also facilitates eye velocity during pursuit (Missal and Heinen, 2001). In this study, stimulated eye velocity increased as a multiplicative function of initial eye velocity, suggesting that, as in the FEF, the current was interacting with a gain element. While the stimulation results in FEF and SEF are evidence that both of these areas are involved in a gain control process, a key difference in the results suggests that these regions have different specific roles in pursuit control. Stimulation in the FEF produces smooth eye movements even during fixation (Gottlieb et al., 1993;

Tanaka and Lisberger, 2001), but stimulation of the SEF does not (Missal and Heinen, 2001). This implies that the FEF is in the direct pathway for pursuit movement generation, while the SEF has a more general executive function, controlling the gain of intentional processes.

PURSUIT TO LARGER AND MORE COMPLEX VISUAL STIMULI
A stimulus larger than a spot will activate a population of motion detectors that tiles a spatially extended region. Since the pursuit system can generate only a single eye velocity vector, the outputs of multiple motion detectors must be combined in this situation to produce one signal. The motion perception system integrates signals that stimulate multiple motion detectors to eliminate noise and to better detect and discriminate spatially extended stimuli (Watamaniuk and Sekuler, 1992). When presented with a random-dot cinematogram (RDC) composed of multiple coherent-motion dots, the pursuit system also appears to integrate motion signals, since pursuit gain is higher, and there is less variability in the response than when a single-spot stimulus is pursued (Heinen and Watamaniuk, 1998) (Fig. 94.1). This finding suggests that the same motion processing substrate limits smooth pursuit and motion perception. The same conclusion was reached when psychophysical judgments and smooth pursuit responses were compared in motion direction discrimination tasks (Beutter and Stone, 1997; Krauzlis and Adler, 2001; Watamaniuk and Heinen, 1999). In all of these experiments, perceptual and motor performances were similar when directional noise was added to moving stimuli. Other work has demonstrated that human observers can integrate the local motion of line-figure objects to derive a global motion signal (Beutter and Stone, 2000). Global information was used similarly to both perceive and pursue these objects, even when partial occlusion made the resulting image motion vastly different from the underlying object motion.

An unresolved issue that surfaces when larger stimuli are used to study pursuit is the degree to which the function and the underlying neural architecture of the pursuit system are distinct from those that subserve other smooth eye movements. One system in question is the one that generates the optokinetic reflex (OKN). The OKN is a response to full-field motion that supplements the vestibulo-ocular reflex (VOR), a nonvisual reflex originating in the semicircular canals. The VOR serves to rotate the eyes to counter head rotation. The distinction between smooth pursuit and OKN is not clear in the literature. Typically, pursuit is studied with a small-spot stimulus and OKN with a large, textured field. However, pursuing a spot can produce eye movement behavior similar to that seen when large fields are used, that is, a recurring pattern of slow and fast phase responses (van den Berg and Collewyn, 1986). Conversely, stimuli larger than a spot can produce eye movements that look like smooth

FIGURE 94.1. Eye speed during pursuit of single spots and random-dot cinematograms (RDCs) moving at different speeds. The left column (*A* and *C*) shows average eye speed during pursuit of 200 dot RDCs (dot size = 0.1 degree) that moved at 4, 5, 6, 7, and 8 deg/sec for one observer at the top (*A*) and for a second observer at the bottom (*C*); the right column (*B* and *D*) shows pursuit of a 0.1 degree spot moving at the same five speeds for each

of the two observers. Each trace is an average of approximately 10 trials. Traces are aligned on pursuit onset (*small vertical arrows*). Note that during pursuit of RDCs, observers showed higher gain as well as better speed discrimination, as evidenced by greater separation between the traces. (Modified from Heinen and Watamaniuk, 1998.)

pursuit (Beutter and Stone, 1997; Krauzlis and Adler, 2001; van den Berg and Collewyn, 1986; Watamaniuk and Heinen, 1999). Furthermore, the initial rapid OKN response to visual motion onset is thought to be controlled by the pursuit system (e.g., Cohen et al., 1977; Robinson, 1981), although this notion remains controversial (for a discussion, see Fuchs and Mustari, 1993).

A possible difference between OKN and pursuit is that OKN gain increases with stimulus size up to full field (e.g.,

Cheng and Outerbridge, 1975; Dubois and Collewyn, 1979; van Die and Collewyn, 1982), which does not appear to be the case for pursuit. In a preliminary study investigating the benefit that larger stimuli provide the pursuit system, it was found that increasing the size of a stimulus to ~12 degrees increased pursuit gain, but with further increases gain dropped (Watamaniuk and Heinen, 2000). Consistent with this, stimulating the retina beyond the ~12 degree central region with oppositely directed motion boosted the gain

again. These results implied that the receptive field for pursuit, that is, the *pursuit field*, has a center-surround architecture with an excitatory center and an inhibitory surround. Center-surround receptive fields are common in neurons throughout visual cortex, and neurons with similarly organized motion receptive fields have been found in area MT (Born and Tootell, 1992; Raiguel et al., 1995; Xiao et al., 1995) and could facilitate pursuit when an object moves in the world across a background.

Another type of smooth eye movement response that seems to overlap pursuit (and OKN) to a degree is ocular following. This response has been documented relatively recently and is present in both monkeys (Miles et al., 1986) and humans (Gellman et al., 1990). Ocular following is characterized by smooth eye movements that occur shortly after a large-field visual stimulus begins to move (latency of ~50 msec in monkeys). That a large stimulus is *required* to evoke ocular following suggests that it may be more similar to OKN than is pursuit, as pursuit movements can be made to a small spot stimulus. Nevertheless, the optimal retinal stimulation for ocular following appears to have a center-surround organization similar to that of the pursuit field but on a larger spatial scale, with a central excitatory region of ~20 degrees (Miles et al., 1986). Ocular following also has several properties that distinguish it from OKN as well as from smooth pursuit. First, ocular following is more pronounced when the stimulus is presented just after a saccadic eye movement (Kawano and Miles, 1986). Second, its gain is higher when the central field motion appears in the depth plane where the subject is attending and the motion in the periphery is presented with crossed disparity (Kawano et al., 1994a). This laboratory situation mimics the natural one that occurs when a moving observer attends to a central object and ignores the motion parallax induced by more distant ones.

Despite the differences in the optimal stimuli and responses for pursuit, OKN, and ocular following, the majority of neurons studied in cortical area MST (Kawano et al., 1994b), dorsolateral pontine nucleus (DLPN) (Kawano et al., 1992), and the cerebellum (Gomi et al., 1998) respond to all three types of eye movements. This observation suggests that these eye movement systems may share to a degree a common neural substrate.

PREDICTING OBJECT MOTION It is well established that the pursuit system can override reflexive behavior and predict target motion when it is periodic and continuous (Deno et al., 1995; Dodge et al., 1930; Stark et al., 1962; Westheimer, 1954; Winterson and Steinman, 1978). After an observer learns the periodicity of such a target, it can be pursued with zero phase lag or even phase lead. However, when that target first moves, the eyes lag behind initially because the first motion is unpredictable, and the pursuit system must rely on

a delayed signal arising from the retinal-image motion of the target. Pursuit in the step-ramp paradigm involves multiple discrete trials and can simulate the onset of multiple periodic target motions. Therefore, the step-ramp paradigm might be ideal for isolating signals related to retinal-image motion in the pursuit system. However, data obtained with the step-ramp paradigm must be interpreted carefully, because anticipatory pursuit can precede step-ramp motion even when motion parameters are randomized from trial to trial. Next we discuss some of the forces that guide anticipatory pursuit.

Anticipatory eye velocity is a function of target motion onset timing (Barnes and Asselman, 1991; Barnes and Grealy, 1992; Barnes et al., 1987) and target velocity (Kao and Morrow, 1994; Kowler and McKee, 1987; Kowler et al., 1984; Wells and Barnes, 1998), and can be enhanced by briefly blanking the fixation point (*gap paradigm*) before the target moves (Boman and Hotson, 1988; Heinen and Liu, 1997). Randomization does not necessarily eliminate anticipatory eye velocity, because the direction or speed of the target in trials that precede the one being studied are stored in short-term memory and can bias the pursuit response (Kowler and McKee, 1987; Kowler et al., 1984). There is also evidence that the timing of target motion onset is remembered from preceding trials and that this memory modifies anticipatory pursuit onset (Heinen et al., 2001). A cognitive expectation about the direction in which a target will move can override short-term memory and guide anticipatory pursuit (Kowler, 1989). As it does during continuous periodic motion, during step-ramp trials the predictive mechanism modulates eye velocity even while the target is moving (Kao and Morrow, 1994; Kowler and McKee, 1987; Kowler et al., 1984), including during the *open-loop period* which has been studied to understand visual-motion signals that drive pursuit.

There are other examples of cognitive influences on open-loop pursuit. In humans, pursuit speed declines when the subject's attention is directed away from the moving target (Khurana and Kowler, 1987). Also, initial eye acceleration is systematically higher for lower-speed trials inserted in a block of high-speed trials or lower for high-speed trials inserted in a block of lower-speed trials (Carl and Gellman, 1987; Kowler and McKee, 1987; Lisberger and Westbrook, 1985). This phenomenon might be related to short-term memory of previous target motion but, alternatively, could be due to a cognitive expectation about what the speed of the target will be if the observer determines that all the targets in the block have been set to move at the same speed.

Although previously thought to be a special property of the human oculomotor system (Fuchs, 1967), anticipatory pursuit occurs in monkeys as well (Fig. 94.2). Furthermore, as in humans, the predictive mechanism can modulate

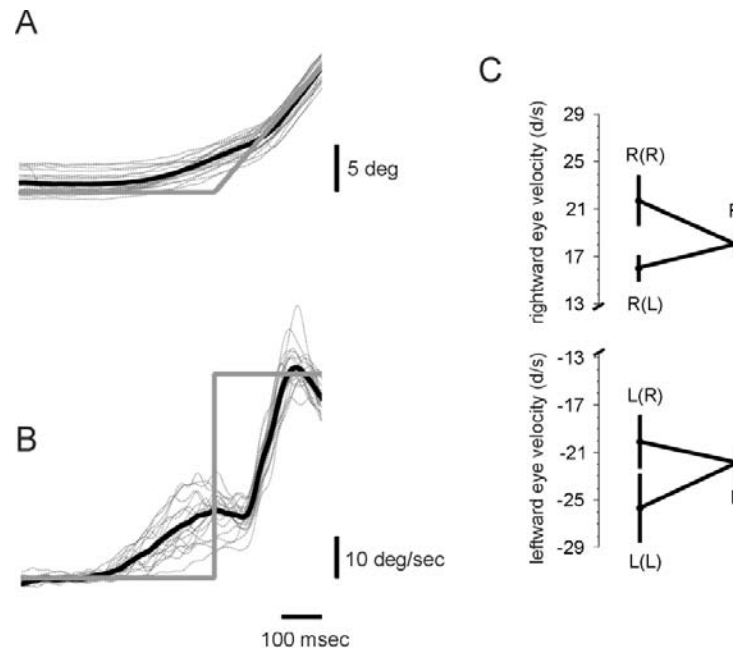

FIGURE 94.2. Predictive influences on monkey smooth pursuit. Eye and target position traces (*A*) and eye and target velocity traces (*B*) from a block of trials where the monkey tracked a target that always had the same constant velocity motion (50 deg/sec to the right). The target is shown as a solid gray line, individual eye traces as dashed gray lines, and mean eye traces as a solid dark line. Note that the anticipatory eye velocity began to build up before the target moved. Note also the sharp transition to rapid eye acceleration that occurs 100 msec after the target begins to move, consistent with activation by a retinal-image motion signal. *C*, The effect of target motion history on monkey open-loop pursuit. Data were taken during pursuit of a target that moved at a rate of 50 deg/sec, with

open-loop pursuit in monkeys when target velocity is randomized (Fig. 94.2*C*). Since anticipatory and open-loop pursuit behave similarly during target randomization (Heinen et al., 2001), visual-motion processing and short-term memory might use the same neural substrate. This could occur if the activity of neurons in the motion pathway were altered by pursuit experience so that it biased the population response when new motion appeared. However, the visual stimulus can apparently generate a smooth response with different dynamics than anticipatory pursuit. It is often possible to identify two phases in the response, the first of which accompanies the onset of anticipation (Fig. 94.2*B*). Usually, an abrupt deflection of the eye velocity traces at ~80 to 100 msec after the target starts to move marks the onset of the second phase, which is characterized by higher acceleration than anticipation onset. That the onset of this second phase is time-locked to the onset of target motion suggests that it reflects the contribution of the visual signal to the pursuit response. In addition, eye acceleration during this second phase depends on retinal-image motion (e.g., Keller and Kahn, 1986; Lisberger and Westbrook, 1985).

the direction randomly chosen on each trial as either left or right. The rightmost node of each plot indicates mean eye velocity for all trials where the target moved right (R) or left (L). The nodes on the left indicate the mean eye velocity of all trials with a given direction that are preceded by a trial with the same or opposite direction. For example, the point designated “R(L)” indicates the eye velocity of all trials where the target moved to the right, given that in the preceding trial target motion was to the left. Note that overall eye velocity was more rightward when the preceding target motion was to the right and more leftward when the preceding motion was to the left. The velocity of the eye was characterized at the end of the open-loop period.

Therefore, even if the visual-motion pathway is used to generate anticipatory pursuit, it might be possible to determine the relative contribution that the visual signal makes with the proper experimental design. A more detailed discussion of the interactions between processing streams for signals related to visual motion and cognition follows.

Extraretinal and retinal image motion substrates for smooth pursuit control

ARE VISUOMOTOR AND COGNITIVE PROCESSING SUBSERVED BY SEPARATE NEURAL PATHWAYS? Smooth pursuit eye movements usually cannot be generated without a moving target, suggesting that these eye movements are a sensorimotor reflex. This notion is supported by work in humans and monkeys demonstrating that pursuit depends on the visual properties of the stimulus—for example, its location with respect to the fovea and the direction and speed of its motion (Lisberger and Westbrook, 1985; Tychsen and Lisberger, 1986). These authors introduced the idea that the characteristics of eye acceleration during the open-loop period of pursuit to step-ramp target motion are determined by

retinal-image motion. However, a number of observations have raised doubts that the response of the pursuit system can be so simply explained.

Kowler (1990) has argued that visual-motion influences on pursuit cannot be studied in isolation from cognitive processes, because cognition is pervasive and affects every level of the system. Since physiological studies of the cognitive control of pursuit are relatively new, the question of whether cognition and visual motion are processed by separate neural subsystems is still largely open. Two alternative ways in which the pathways that carry these signals could be organized are presented in Figure 94.3. In the model shown at the top, cognitive and retinal-image signals are processed in the same pathway, and in the model shown at the bottom, they are processed independently. In the next several sections, we review recent studies that lay the groundwork for determining pathways that support the cognitive control of pursuit, and discuss how signals arising in these pathways interact with those generated by retinal-image motion.

AN ALTERNATIVE CORTICAL PATHWAY FOR SMOOTH PURSUIT

At the time we wrote our last review of the neurophysiology of the pursuit system (Keller and Heinen, 1991), a major pathway for pursuit from cortical motion processing areas in the superior temporal sulcus (STS), middle temporal (MT) area, and medial superior temporal (MST) area was well established. This pathway followed a classical cortico-ponto-cerebellar nexus with its relay in the DLPN. Since then, the FEF has been implicated in pursuit control with single-unit recordings (Fukushima et al., 2000; Gottlieb et al., 1994; MacAvoy et al., 1991), with imaging studies (Berman et al., 1999; O'Driscoll et al., 2000; Petit and Haxby, 1999; Petit et al., 1997), with electrical microstimulation (Gottlieb et al., 1993; Tian and Lynch, 1996), and with lesions (Keating, 1991; Lynch, 1987; MacAvoy et al., 1991; Shi et al., 1998). Single cells located in the floor and posterior bank of the arcuate sulcus discharge before pursuit onset and have directional tuning that, over the population, is rather uniformly distributed (Gottlieb et al., 1994). In contrast to the speed tuning of most MT cells, the response of FEF cells increases as a function of pursuit speed (Gottlieb et al., 1994). Electrical stimulation here produces a short-latency smooth eye movement, even when the animal is attempting to fixate a stationary target (Gottlieb et al., 1993). This is in contrast to what is observed in the STS, where stimulation fails to evoke significant smooth movements during fixation (Komatsu and Wurtz, 1989). Muscimol injections in the FEF suppress smooth pursuit in the same direction as that coded by cells recorded at the same sites (MacAvoy et al., 1991). The deficits these investigators observed were more severe and more lasting than the deficits produced by chemical lesions placed in isolated regions of the STS (Dürsteler and Wurtz,

FIGURE 94.3. Functional organization schematics that hypothesize how retinal-image motion signals may be combined with a signal resulting from the memory of previous target motion to yield the pursuit eye movement drive signal. *A*, Short-term memory and retinal-image motion signals are processed in the same neural structures. The resulting signal is then passed through a variable gain element whose level is set by cognitive functions such as predictability of target motion and certainty of the target to be pursued. *B*, Signals resulting from short-term memory are processed separately from those resulting from direct retinal-image motion and are combined at a subsequent stage. Gain control is then exercised as in *A*.

1988; Dürsteler et al., 1987; Newsome et al., 1985) but comparable to those produced by larger injections that disrupted most of the motion processing cortex in the STS (Yamasaki and Wurtz, 1991). Ablations of the FEF that included the fundus of the arcuate sulcus produced milder deficits than those resulting from muscimol injections (Keating, 1993), perhaps because of neural adaptation that might have occurred given the longer recovery time that typically accompanies ablation studies.

Control of smooth pursuit by the frontal lobe is probably not limited to the FEF. The SEF, which had been implicated previously in saccade generation (Schlag and Schlag-Rey, 1987), also has neurons active during pursuit that are tuned for direction and speed (Heinen, 1995). The SEF receives projections from area MST (Huerta and Kaas, 1990), a structure that participates in visually guided pursuit (Newsome et al., 1988). The SEF also has strong reciprocal connections with the FEF (Huerta and Kaas, 1990). The SEF, in turn, projects to the nucleus reticularis tegmenti pontis (NRTP) (Shook et al., 1990), a brainstem region involved in the generation of pursuit movement commands (see below). Smooth eye movements have been evoked from the SEF in anesthetized cebus monkeys (Tian and Lynch, 1995) and more recently in behaving macaques (Missal and Heinen, 2001). Functional imaging studies suggest that activity in the SEF during pursuit is equal to or even greater than that which accompanies saccades (Berman et al., 1999; O'Driscoll et al., 2000; Petit and Haxby, 1999; Petit et al., 1997). In some respects, the pursuit eye movement-related physiology of the SEF appears similar to that of the FEF. However, neurons in the SEF have activity that rises to a peak which occurs close to the time when predictable target motion begins, stops, or reverses direction, implicating this structure in controlling the timing of predictive and anticipatory smooth pursuit (Heinen and Liu, 1997). Preliminary data suggest that stimulation of the SEF can also facilitate anticipatory eye velocity (Heinen et al., 2001). Furthermore, microstimulation experiments have implicated both the FEF (Tanaka and Lisberger, 2000) and the SEF (Missal and Heinen, 2001) in gain control for smooth pursuit, as was discussed earlier in this chapter.

NEW INSIGHTS INTO THE ROLES OF BRAINSTEM AND CEREBELLUM IN PURSUIT CONTROL Both the FEF and the SEF make stronger projections to the NRTP and the medial portion of the pontine nuclei than to the DLPN (Huerta and Kaas, 1990; Stanton et al., 1988). This suggests that these frontal cortical areas together form a cortico-reticular-cerebellar smooth pursuit pathway parallel to the cortico-ponto-cerebellar pathway that originates in the STS and courses mainly through the DLPN. Neurons in the NRTP are active during pursuit (Keller and Crandall, 1981; Suzuki et al., 1991), and stimulation here evokes smooth eye movements when the eyes are stationary, but without an active fixation target (Yamada et al., 1996). This behavior is more similar to that reported for stimulation of the FEF (Gottlieb et al., 1993) than that for stimulation of the STS or the DLPN (Komatsu and Wurtz, 1989; May et al., 1985). Deficits in pursuit also accompany reversible (lidocaine) or permanent (ibotenic acid) lesions of the NRTP (Suzuki et al., 1999). These authors suggested that the

NRTP is divided into a rostral region that is associated with pursuit eye movements and a caudal region that is involved in saccade control.

In our previous review, we discussed evidence that a posterior vermis to fastigial nucleus to vestibular nucleus pathway and a flocculus to ventral paraflocculus to vestibular nucleus pathway form parallel cerebellar pathways for pursuit. More recent single-unit recording studies support the role of the flocculus/ventral paraflocculus in smooth pursuit generation (Fukushima et al., 1999; Gomi et al., 1998; Suh and Kettner, 2000). Additional support has also accumulated for a parallel smooth pursuit pathway through the posterior vermis. Ablation of the cortex in lobules VI and VII significantly impairs pursuit function (Takagi et al., 2000). A recent paper suggested that most pursuit-related Purkinje cells in the posterior vermis are located in lobule VIII (Sato and Noda, 1992), and not in lobules VI and VII, as was previously reported (Suzuki and Keller, 1988a). This discrepancy has not been resolved. Lobules VI and VII project to the fastigial oculomotor region (FOR) (Yamada and Noda, 1987). Although the FOR was originally believed to be a saccade control region, more recently it has been shown to also participate in pursuit generation, the evidence being that single neurons here are active during pursuit (Büttner et al., 1991; Fuchs et al., 1994), and muscimol injections here lead to mild pursuit deficits (Robinson et al., 1997).

The output pathways for these putative parallel cerebellar pursuit pathways are different. The flocculus and paraflocculus have direct connections to the vestibular nuclei (VN) and the nucleus prepositus hypoglossi (PH), which are both established pursuit areas in the brainstem (Langer et al., 1985). In the only study with localized injections in the FOR using anterograde tracers (Noda et al., 1990), the caudal fastigial nucleus did not appear to project to the oculomotor region in the VN or to the PH; rather, these projections mostly terminated in the excitatory burst neuron (EBN), inhibitory burst neuron (IBN), and omnipause neuron (OPN) regions, which are thought to be involved in saccade control. However, some neurons located in the medial reticular formation near the abducens nuclei are modulated during pursuit (Eckmiller and Mackeben, 1980). More recently, saccadic burst neurons that are also modulated during pursuit have been identified in the EBN area (Missal and Keller, 2001).

Is there functional support for the anatomical evidence that two pursuit pathways course through the cerebellum? Some work suggests that these pathways differentially control predictive and visuomotor pursuit. One study used visual stimuli that allowed the authors to study activity accompanying pursuit responses to predictable target motion or to targets that made sudden, random changes in

motion direction and therefore could be followed better by relying on visual-motion signals (Suh and Kettner, 2000). They concluded that the floccular pathway is more concerned with predictive aspects of maintained pursuit than with the visually generated initiation of the randomly evoked pursuit. The pursuit pathway that courses through the posterior vermis to fastigial nucleus seems more concerned with direct visuomotor-driven pursuit (Takagi et al., 2000). These authors found that vermal lesions affected to a greater degree pursuit of random step-ramp motion during the open-loop period than during pursuit of a predictable target (triangle wave tracking). However, this point is controversial, because another study reached the conclusion that the flocculus was equally involved in predictive and visually guided pursuit (Stone and Lisberger, 1990).

In summary, the studies to date suggest that signals relating to retinal-image motion and cognition together determine the smooth pursuit response. However, only limited physiological data exist that address where these signals are processed and how they are combined to produce the pursuit movement.

Shared neural pathways for pursuit and saccades

The saccadic system reduces the retinal error between the image of an object and the fovea (Robinson, 1964). The pursuit system is thought to reduce retinal-image velocity that is produced by a moving object (Krauzlis and Lisberger, 1989; Robinson et al., 1986). Saccadic and smooth pursuit eye movements also have different temporal characteristics (Robinson, 1964, 1965). For the above reasons, it was thought that these eye movements are generated by separate neural systems, and neuroanatomical studies in the past supported this view (Leigh and Zee, 1999). However, evidence suggests that the pursuit and saccadic systems are not segregated absolutely. The saccadic system is sensitive to motion (de Brouwer et al., 2002; Keller and Johnsen, 1990), and the pursuit system can respond to positional error cues (Pola and Wyatt, 1980). Pursuit and saccades are coordinated in that the saccadic system appears to compensate for pursuit eye velocity (de Brouwer et al., 2002; Kim et al., 1998). This last section will cover research investigating neural substrates that may be shared by saccadic and pursuit ocular subsystems and that might support their cooperative behavior.

When an object moves in the natural scene, saccades and pursuit work together to foveate and track features of that object and to shift gaze to different objects. Recent evidence suggests that there is considerable overlap in the pursuit and saccade pathways. The superior colliculus (SC) was considered previously as involved exclusively in saccade control (see Guitton, 1991; Sparks and Hartwich-Young, 1989, for

reviews). In addition, rostral portions of the SC contain fixation neurons that are active during intersaccadic periods of fixation (Munoz and Guitton, 1991; Munoz and Wurtz, 1993; Peck, 1989). Recently, it was demonstrated that the rostral SC also contains neurons active during pursuit (Krauzlis et al., 1997, 2000). These same neurons are also active for small target displacements during fixation and for small saccades, and in both cases are more active for contralateral target displacements than for ipsilateral ones. Based on these results, it was suggested that neurons in the rostral colliculus code small motor errors, that is, mismatches between target and eye position that could be used to produce either corrective pursuit or corrective saccades (Krauzlis et al., 2000). This interpretation was supported by electrical stimulation and by similar effects on both types of eye movements following muscimol injections in the rostral SC (Basso et al., 2000).

Evidence for shared circuitry in the saccadic and pursuit systems has been reported in several other premotor structures that lie downstream from the SC. The posterior cerebellar vermis is one such structure. Early work showed that many Purkinje cells recorded in lobules VI and VII had both pursuit- and saccade-related activity, but the functional significance of this overlap was unclear (Suzuki and Keller, 1988b). This dual function of the vermis has been clarified recently by microstimulation experiments showing that the type of movement evoked depends on stimulation frequency and the behavioral state of the monkey, that is, whether it was engaged in a pursuit or saccade task (Krauzlis and Miles, 1998). Signals from lobules VI and VII reach the brainstem via projections to the caudal region of the fastigial nucleus (FN) (Noda et al., 1990). Some neurons in the caudal FN are active during saccades and some during pursuit, but none seem to be active for both types of eye movement (Fuchs et al., 1994).

OPNs lie in an anatomically distinct region of the raphe nucleus just rostral to the abducens nucleus, and receive projections from the FN and the region of the medial reticular formation where saccadic burst neurons are located (Langer and Kaneko, 1990; Noda et al., 1990). OPNs have been considered previously to gate exclusively the saccadic system by inhibiting these eye movements in the face of neural noise (see Keller, 1991, for a review). These neurons discharge at a high tonic rate during fixation but quiesce before and during all saccades. To prevent saccades from occurring, OPNs inhibit directionally selective burst neurons that in turn project directly to the ocular motoneurons. Recent evidence suggests that the activity of OPNs also decreases during smooth pursuit (Missal and Keller, 2002), and electrical stimulation in the OPN region slows ongoing pursuit movements (Missal and Keller, 2002). These findings suggest that OPNs inhibit the motor output signal for both pursuit

and saccades. Interestingly, EBNs do not seem to discharge at all during pursuit movements even when the inhibitory input from OPNs that project directly to them is reduced (Missal and Keller, 2001). Instead, a population of long-lead burst neurons (LLBNs) in the paramedian pontine reticular formation (PPRF) that fire for ipsilateral saccades also fire during ipsilateral pursuit (Missal and Keller, 2001). These authors hypothesized that LLBNs might be “latch” neurons that completely or partially silence OPNs during saccades or pursuit, respectively. In support of this, direct inhibitory projections from the PPRF to the OPNs have been demonstrated (Kamogawa et al., 1996). Pursuit/saccade cells which respond similarly for vertical movements have been reported in the interstitial nucleus of Cajal (Missal et al., 2000).

Two regions in the frontal cortex, the FEF and the SEF, are also involved in smooth pursuit and saccades. The FEF is an area where the distinction between pursuit and saccade control still appears to hold. This structure has nonoverlapping regions which contain either pursuit or saccade cells (Gottlieb et al., 1989) and in which only one of the two types of eye movement is evoked by electrical stimulation (Bruce et al., 1985; Gottlieb et al., 1993; Tian and Lynch, 1996). However, the anatomical projections of the pursuit and saccade areas in FEF appear to overlap in the brainstem reticular formation (Yan et al., 2001). The SEF also has neurons that are active during pursuit (Heinen, 1995; Heinen and Liu, 1997) and during saccades (Schall, 1991; Schlag and Schlag-Rey, 1987). Microstimulation here evokes saccades (Russo and Bruce, 2000; Schlag and Schlag-Rey, 1987; Tehovnik et al., 1994) and facilitates smooth pursuit (Missal and Heinen, 2001; Tian and Lynch, 1995). While the initial microstimulation experiments found saccade sites to be fairly equally distributed across the SEF (Schlag and Schlag-Rey, 1987), more recent work suggests that they lie in lateral subregions and that saccades cannot be evoked close to the midline (Russo and Bruce, 2000). Smooth pursuit sites appear to be distributed uniformly within the SEF and overlap to a degree the regions where saccades are evoked (Missal and Heinen, 2001).

Summary and future directions

Past research on the pursuit system using single-spot stimuli and linear systems analysis was essential in laying the groundwork to understand basic sensorimotor processing for pursuit and to determine the structures in the brain where this processing occurred. However, behavioral studies suggest that pursuit behavior has a complexity greater than that of a sensorimotor reflex and that cognitive factors are intrinsic to the pursuit response. Since the basic building blocks are now in place, it is timely to advance the level of stimulus complexity used in pursuit experiments and study

the neurophysiology of cognitive signals that modulate pursuit behavior in the natural scene. It is also important to consider that the pursuit and saccadic systems often operate together and therefore might use common signals that are processed in shared neural substrates. In conclusion, some of the challenging issues facing eye movement researchers in the future are how visual and cognitive signals interact and how ocular subsystems coordinate to view objects in the natural scene.

95 Neural Control of Vergence

Eye Movements

LAWRENCE E. MAYS

EYE MOVEMENT CONTROL subsystems have evolved to serve different functions. For example, the vestibulo-ocular reflex mechanisms help stabilize images on the retina in the face of head motion, and the saccadic subsystem allows for very rapid changes in the direction of gaze. Binocular vision requires that the two eyes be aligned on an object of interest to within about 15 minutes of arc. A vergence subsystem has evolved to achieve this goal.

Vergence commands are those that rotate the two eyes simultaneously in the opposite direction. They are distinguished from *versional* commands, such as saccades and smooth pursuit, where the eyes move in the same direction. Often, the terms *disjunctive* and *conjugate* are used to refer to vergence and versional movements, respectively. Some authors (Ono, 1983) use *version* and *vergence* to refer to the underlying mechanisms, while using *disjunctive* and *conjugate* to refer to the actual eye movements. Vergence movements may be horizontal, vertical, or torsional (i.e., rotation around the line of sight). Vertical and torsional vergence are small, generally reflexive eye movements, and while they are important for aligning the two eyes upon a target, relatively little is known about these types of movements (Kertesz, 1983). Horizontal vergence movements can be reflexive or voluntary and are needed when gaze is shifted between targets at differing distances from the observer. *Convergence* refers to lines of sight moving toward each other; *divergence* to the reverse. Unless stated otherwise, *vergence* as used here will refer to *horizontal* vergence movements. The control of horizontal vergence movements by the extraocular motoneurons and their premotor inputs will be reviewed.

Horizontal vergence is part of what has been called the *near triad* or *near response* (Myers and Stark, 1990). The other components of the near response are pupillary constriction (*miosis*) and *accommodation* of the crystalline lens, which changes the focal length of the eye. The miosis associated with convergence is somewhat questionable (Stakenburg, 1991), but the relationship between accommodation and convergence is quite robust. Indeed, accommodation of the eye, as when switching from a far to a near target, invariably induces convergence, even if the target is viewed monocularly. This linkage is termed *accommodative convergence* and is measured clinically as the accommodative convergence/

accommodation (AC/A) ratio. Moreover, convergence of the eyes induces accommodation, and this effect, termed *convergence accommodation*, is equally robust. The strength of this relationship is the CA/C (convergence accommodation/convergence) ratio. Considering the linkage between accommodation and vergence, it may not be surprising that the premotor neurons that control vergence appear to control accommodation as well.

Hering (1868) observed that the two eyes act as if yoked, that is, they move either the same amplitude in the same direction (*version*) or the same amplitude in the opposite direction (*vergence*). *Hering's Law of Equal Innervation* implies that all eye movements should be generated by a linear combination of largely independent versional (*conjugate*) commands and vergence (*disconjugate*) commands. In this view, conjugate commands operate on a *cyclopean eye*, an imaginary eye located between the two actual eyes. Many, but not all, studies of vergence control have used symmetrical vergence movements, in which the subject looks between targets at different distances aligned with the cyclopean eye in order to eliminate versional demands. An alternative view to Hering's Law states that the brain has independent control of each eye. This has been debated for over a century, and the debate continues (Enright, 1984; Zhou and King, 1998). The focus is on how to interpret what appear to be unequal saccades in the two eyes when vergence movements are combined with saccades.

Finally, considerable attention has been directed to the analysis of higher-order brain mechanisms for vergence control. Recent evidence suggests roles for the parietal cortex (Gnadt and Mays, 1995), frontal eye fields (Gamlin and Yoon, 2000), and superior colliculus (Chaturvedi and Van Gisbergen, 1999). Since these areas are involved in other types of eye movements, they may help coordinate vergence movements with saccades or perhaps smooth pursuit.

Extraocular motoneurons

Medial and lateral rectus muscles, which are innervated by motoneurons in the oculomotor and abducens nuclei, respectively, are primarily responsible for convergence and divergence. Figure 95.1 is a schematic diagram of these

FIGURE 95.2. Distributions of static vergence and versional gains for neurons in the oculomotor nucleus displaying a burst-tonic firing pattern for conjugate adduction. Data are from Gamlin and Mays (1992). *Vergence gain* refers to the change in firing rate for each degree of adduction of the eye during symmetrical vergence movements. *Version gain* refers to the change in firing rate for each degree of adduction during conjugate saccades between distant targets. Positive values indicate increased activity for adduction. Open circles indicate oculomotor internuclear (OI) neurons, identified by antidromic stimulation from the contralateral abducens nucleus. Closed circles indicate cells with activity consistent with that of medial rectus (MR*) motoneurons but not positively identified as such. Data points falling along the dashed line labeled “Version only” represent cells that did not show any change in activity for symmetrical vergence movements. Data points on the “Ipsi eye” line showed the same change in activity for conjugate adduction as for symmetrical convergence. Any data points associated with the “Contra eye” line would have shown an increase in activity for conjugate adduction but a decrease for convergence, a pattern consistent with the innervation pattern for the contralateral eye. The overall activity pattern of OI neurons was very similar to that of putative MR* motoneurons. OI neurons did not have a Contra eye activity pattern, even though they project to the contralateral abducens nucleus. This suggests that OI neurons are used to coordinate horizontal conjugate movements and not vergence.

only for version would coincide with the “Version only” line, and those that fall along the “Contra eye” line would behave like contralateral MR motoneurons. Two important observations can be drawn from Figure 95.3. The first is that AIs (including MLF fibers) show the same pattern of responses as the overall population of abducens neurons, which presumably includes many lateral rectus (LR) motoneurons. The conclusion is that most LR motoneurons and AIs decrease their firing rate for convergence as well as for versional adduction. This is a critical observation since AIs provide powerful excitatory input to contralateral MR motoneurons. Since AIs decrease their activity for convergence, this means that they send an *inappropriate* signal to MR motoneurons during vergence movements. This implies that the AIs, like the OIs, coordinate conjugate horizontal eye movements and not vergence movements. The second observation is that, on average, abducens neurons do not reduce their firing rate as much for vergence adduction as for versional adduction. Indeed, most neurons in Figure 95.3 fall below the “Ipsi eye” line, which indicates equal firing rate change for version and vergence. This would suggest some degree of co-contraction of MR and LR muscles during convergence. However, recent measurements of LR and MR forces during convergence show no evidence of co-contraction (Miller et al., 2002). One possible reason for this apparent contradiction between muscle force measurements and motoneuron activity is that not all subsets of motor units develop equivalent forces for a given firing rate. Motoneurons responsible for larger decreases in muscle force during convergence may have been undersampled. Other explanations may involve the role of the trochlear motoneurons and muscle pulleys.

NEURONS IN THE TROCHLEAR NUCLEUS Although LR and MR muscles are primarily responsible for vergence eye movements, there is a well-known excyclotorsion of the eyes associated with convergence (Allen and Carter, 1967). The magnitude of this torsion depends on elevation of the eyes as well as the vergence angle, with greater excyclotorsion seen with ocular depression. A study of trochlear motoneurons (Mays et al., 1991) showed a systematic decrease in activity associated with convergence that was far larger than that expected from the values associated with conjugate abduction of the innervated eye. Moreover, the magnitude of the decrease in firing rate increased with ocular depression. These findings are consistent with the behavioral observation of excyclotorsion with convergence and with the lateral tilt of Listing’s plane during convergence (van Rijn and Van der Berg, 1993). The decreased superior oblique tension could aid adduction during convergence (Mays et al., 1991), but a recent analysis (Miller et al., 2002) of all muscle forces indicates that this cannot explain the discrepancy between the motoneuron and muscle force data.

FIGURE 95.3. Distributions of static vergence and versional gains for neurons in the abducens nucleus displaying a burst-tonic firing pattern for conjugate abduction. *Vergence gain* refers to the change in firing rate for each degree of abduction of the eye for symmetrical vergence movements. *Version gain* refers to the change in firing rate for each degree of abduction during conjugate saccades between distant targets. Positive values indicate increased activity for abduction. Closed circles and triangles indicate cells with activity consistent with that of lateral rectus (LR) motoneurons but not positively identified as such. The closed circles (Abd^1), which are from Mays and Porter (1984) and Gamlin et al. (1989a), largely overlap the closed triangles (Abd^2) that were recorded by Maxwell (1991). Open circles indicate abducens internuclear (AI) neurons identified by antidromic stimulation of the medial longitudinal fasciculus (MLF) between the oculomotor and abducens nuclei. Open triangles are horizontal burst-tonic fibers recorded from the MLF, which are presumably axons of AI neurons. Data points falling along the dashed line labeled “Version only” represent cells that did not show any change in activity for symmetrical vergence movements. Data points on the “Ipsi eye” line showed the same change in activity for conjugate abduction as for symmetrical divergence. Most abducens neurons fell between the “Ipsi eye” and “Version only” lines, indicating that most decreased their activity for convergence and conjugate adduction, although the decrease for convergence was somewhat less. Any data points associated with the “Contra eye” line would have shown a decrease in activity for conjugate adduction but an increase for convergence, a pattern consistent with the innervation pattern for the contralateral eye. The overall activity pattern of AI neurons was very similar to that of the overall population of abducens neurons, which presumably included many LR motoneurons. Thus, most AI neurons decreased their firing rate for convergence, even though they project to the contralateral medial rectus (MR) motoneurons. This indicates that AI neurons send appropriate signals to the MR motoneurons to coordinate horizontal conjugate movements, but they do not provide the appropriate signals for vergence.

MUSCLE PULLEYS Recent evidence has shown that the effective origin of some eye muscles is altered by passing through slings or pulleys associated with Tenon’s capsule (Demer et al., 1995). These pulleys are shown schematically in Figure 95.1 as rings labeled “P.” It has been hypothesized that these pulleys provide a mechanical means for the eyes to obey Listing’s Law. Indeed, it appears that the LR pulleys are moved posteriorly during convergence, while the MR pulleys shift anteriorly in such a way as to produce the lateral tilt of Listing’s plane (Clark et al., 2000). Recent work (Demer et al., 2000) indicates that the orbital fiber layers of the LR and MR muscles insert on muscle pulleys and not on the globe itself. This implies that the activity of the motoneurons innervating orbital fibers in the pulley muscles (LR_O and MR_O in Fig. 95.1) may have very different activity patterns than the motoneurons innervating the global muscle fibers (LR_G and MR_G). Thus, the discrepancy between the LR motoneuron data and the absence of co-contraction may be due to recording a mixture of unidentified LR_O and LR_G motoneurons. To date, it has not been possible to distinguish between these motoneuron types with single-unit recording alone. The added biomechanical complexity of movable muscle pulleys makes it difficult to estimate muscle forces indirectly during convergence by observing the motoneuron firing rate from a combined motoneuron pool.

Premotor commands

NEAR RESPONSE CELLS AIs are a primary input to MR motoneurons for versional eye movements but not for vergence movements. This is implied by recording studies (Gamlin et al., 1989a) and convincingly demonstrated by clinical and experimental lesion studies (Gamlin et al., 1989b). Damage to the MLF, which carries AI axons, causes the clinical syndrome of internuclear ophthalmoplegia (Cogan, 1970), in which conjugate adduction is weakened or lost but convergence is preserved. This indicates that the MR motoneurons receive their vergence input from another source. Several studies (Judge and Cumming, 1986; Mays, 1984; Zhang et al., 1992) have conclusively demonstrated the presence of *near response* (“NR” in Fig. 95.1) cells in the midbrain reticular formation, just dorsal or lateral to the oculomotor nucleus, which carry signals related to vergence and accommodation but not version. Figure 95.4 shows the firing pattern of a near response cell for a symmetrical convergence movement. Most near response cells increase their activity for convergence (convergence cells). A smaller number of intermixed cells show the opposite response (divergence cells). For both types of cells, there is a nearly linear relationship between tonic firing rate and vergence angle and ocular accommodation. Many near response cells, including the one shown in Figure 95.4, also have a phasic

FIGURE 95.4. Activity pattern of a midbrain near response cell for symmetrical convergence. HR, horizontal right eye position; HL, horizontal left eye position; VL, vertical left eye position; VA, vergence angle, which is HL-HR. The firing rate is displayed as an instantaneous frequency histogram in spikes per second, which is the reciprocal of interspike interval. This neuron shows a linear tonic increase in activity for increasing convergence as well as a phasic increase related to convergence velocity. There is no change in firing rate for changes in conjugate eye position (not shown). Calibration bar = 5 degrees.

component to their activity that is related to vergence velocity. Some cells have *only* this phasic component for convergence (convergence burst cells) or divergence (divergence burst cells). For both types of burst cells, there is a nearly linear relationship between the number of spikes in the burst and the size of the vergence movement (Mays et al., 1986). Interestingly, this suggests that the vergence system, like the conjugate eye movement control systems, may be based on velocity commands and incorporates a vergence integrator to produce vergence position. Moreover, most MR motoneurons have both vergence position and vergence velocity signals (Gamlin and Mays, 1992). It has been possible to activate near response cells antidromically from the MR subdivisions of the ipsilateral oculomotor nucleus (Zhang et al., 1992). Based on the signals carried by these near response cells and the stimulation studies (Zhang et al., 1992), it seems very likely that the midbrain near response cells provide the needed vergence signals to the MR motoneurons.

Although the divergence and divergence burst cells have the signals needed by LR motoneurons, it has not yet been possible to determine if they project to the abducens nucleus. The most straightforward interpretation of Hering's Law would presume that conjugate (i.e., cyclopean) eye movement commands are provided to the abducens nucleus by one input (e.g., I_1 in Fig. 95.1), while a near response command, with the appropriate sign, is provided by a second input (I_2 in Fig. 95.1). This is in addition to the known near response input to MR motoneurons.

VERGENCE-ACCOMMODATION LINKAGE In order to understand the signals carried by the near response cells, the rela-

tionship between vergence and ocular accommodation has to be taken into account (Hung and Semmlow, 1980). Disparity-driven vergence can be considered as being under the control of a negative feedback servomechanism (Fig. 95.5). Referring to the top half of Figure 95.5, target distance determines convergence demand. The difference between the convergence demand and the convergence response is binocular disparity, which is the input to the vergence controller. The output of this controller goes eventually to the extraocular muscles (EOMs) to produce the convergence response. The goal of the vergence controller is to reduce disparity to an acceptably low level. A similar servomechanism is presumed to exist for the minimization of blur by an accommodation controller (lower half of Fig. 95.5). There is cross-coupling between these two control systems. In the absence of disparity, the accommodation system induces convergence with increases in accommodation. Similarly, increases in disparity-driven convergence result in increased accommodation. In normal viewing conditions, the two control systems function in a synergistic manner to provide the (covariant) appropriate amounts of accommodation and vergence.

An obvious question is whether the activity of midbrain near response cells (such as the one shown in Fig. 95.4) is related to accommodation or vergence. In terms of the model in Figure 95.5, a vergence-related near response cell would be located at the upper summing point (the small dashed ellipse labeled "VNR"), while an accommodation-related near response cell would be located at the lower summing point (the small dashed ellipse labeled "ANR"). For this analysis, it is necessary to dissociate the accommodative from the convergence responses. This can be done by attempting to vary accommodation while holding convergence constant or by varying convergence while holding accommodation constant. Although the two control systems are tightly coupled, some degree of dissociation of responses is possible. An early analysis of the activity of near response cells indicated that while a few cells could be classified as related to accommodation only, and another group appeared to be related to convergence only, the majority of near response cells were related to both (Judge and Cumming, 1986). A subsequent study of near response cells, including some that were activated by antidromic stimulation of the oculomotor nucleus and therefore in control of the vergence angle (Zhang et al., 1992), provided a model of how vergence (VNR) and accommodation (ANR) near response cells could be related both to accommodation and vergence.

Figure 95.6 shows the vergence and accommodation gains of 72 near response cells from the study by Zhang et al. (1992). Near response cells antidromically activated from the ipsilateral MR subdivisions of the oculomotor nucleus are shown as open circles; unidentified near response cells are

FIGURE 95.5. Dual interaction model of accommodation and vergence. Vergence and accommodation are controlled by their own negative feedback loops. In addition, part of the output of the accommodation controller is sent to the vergence subsystem. The gain of this cross-link is the AC/A ratio, and vergence near response (VNR) cells carry the summed signals. Part of the output of the vergence controller, with a gain corresponding to the CA/C ratio, is sent to the accommodation subsystem. The steady-state outputs of the accommodation and vergence controllers, and that of the cross-link components, can be calculated for any combina-

tion of convergence and accommodative demands as long as the CA/C and AC/A ratios are known. Accommodation near response (ANR) cells signal the sum of the output of the accommodation controller and the convergence accommodation signal. The large dashed ellipses represent a large number of near response cells, which receive direct and cross-link signals with different weights. The behavior of all recorded near response (N1 to N6) cells can be explained by assuming that different near response cells vary in the relative weights of their direct and cross-link inputs. EOMs, extraocular muscles.

shown as filled circles. The accommodation gain of a cell is the estimated change in firing rate for each diopter of accommodation if the vergence angle is held constant. The vergence gain is the estimated change in firing rate for each meter angle of convergence, if accommodation is held constant. The meter angle is a unit of angular measure that is comparable to the diopter (i.e., 1 M.A. is the angle between the eyes when viewing a target at 1 m). For the macaques used in this study, 1 M.A. is approximately 1.5 degrees. Any near response cell with activity related only to vergence angle, regardless of accommodation, would fall along the horizontal dashed line marked "Vergence Cell (N2)." Cells related exclusively to accommodation would fall along the vertical line marked "Accommodation Cell (N5)." Figure 95.6 shows that the majority of cells, whether identified as projecting to the oculomotor nucleus or not, are not uniquely related to accommodation or vergence alone but are related to both.

The model in Figure 95.5, at first glance, is incompatible with the distribution of the data in Figure 95.6. The ver-

gence near cells at the summing junction projecting to the oculomotor plant (dotted ellipse labeled "VNR") have exclusive control of the vergence angle. Similarly, the accommodation near cells at the summing junction projecting to the lens (dotted ellipse labeled "ANR") have exclusive control of the accommodation. Furthermore, there is no mixing of the outputs, implying that these signals are not shared between the extraocular muscles and the ciliary muscle. The critical point associated with the results illustrated in Figure 95.6 is that both groups receive inputs from both the vergence and accommodation controllers, directly or through the cross-links. Consider the behavior of the model if one attempts to measure the accommodation gain of one of those cells by maintaining a constant level of convergence demand while increasing accommodation demand. Increasing accommodation demand will, accordingly, increase the accommodation level of the subject through the direct link between the accommodative controller and the accommodation near cells. At the same time, the increased accommodative signal will be sent to the vergence near cells

FIGURE 95.6. Relationship between vergence gain and accommodation gain for 72 near response cells. Data are from Zhang et al. (1992). Open circles represent a subset of these cells which were antidromically activated from the ipsilateral oculomotor nucleus and are presumed to be vergence near response (VNR) cells (see Fig. 95.5). *Accommodation gain* refers to the change in firing rate for each diopter of accommodation if the vergence angle remains constant. *Vergence gain* refers to the change in firing rate for each meter angle of convergence if accommodation remains constant. Note that, unlike Figures 95.2 and 95.3, vergence gain is calculated for total vergence angle in meter angles, which are comparable to diopters. Near response cells that have an accommodation gain of zero, and so have activity related exclusively to vergence angle, fall along the horizontal dashed line (Vergence Cell) and correspond to the vergence near response cells represented by N2 in Figure 95.5. Near response cells with activity related exclusively to accommodation (i.e., a vergence gain of zero) fall along the vertical dashed line and are represented in Figure 95.5 as N5 cells. Near response cells with a positive accommodation and vergence gain increase their activity for increases in either accommodation or convergence and are located in the upper right quadrant (N3 and N6 cells in Fig. 95.5). Near response cells with a negative accommodation gain and a positive vergence gain are located in the lower right quadrant. These cells *decrease* their activity with *increases* in accommodation, even though they otherwise increase their activity when accommodative and vergence demands increase appropriately (i.e., normal viewing conditions). This paradoxical behavior is due to the balance of direct and cross-link inputs as shown for N1 in Figure 95.5. Similarly, the cells in the upper left quadrant of Figure 95.6 have negative vergence gains, and so will decrease their activity for convergence if accommodation is held constant. These cells are represented by N4 in Figure 95.5.

through the AC/A cross-link to generate a covarying vergence change. This strategy is appropriate for what is normally needed in a natural environment, where vergence and accommodation are geometrically linked. However, in the situation where the vergence demand is left artificially unchanged, increasing accommodation will lead to over-convergence. This (negative) disparity error will engage the (di)vergence controller to reduce the vergence level of the subject to compensate for the unneeded vergence activation through the AC/A cross-link. This correction will also affect the accommodation level through the CA/C cross-link with additional (erroneous) changes in the accommodation level, and so on, but after a transitory period the subject will reach a steady-state condition. A similar sequence of events, starting with an increase in vergence demand, occurs when maintaining a constant level of accommodation demand while increasing vergence demand. How does this process affect the (steady-state) vergence and accommodation gains of a near response cell?

When the new steady state is reached, the vergence controller and the accommodation controller will have their output levels adjusted in such a way as to have the vergence and the accommodation levels matching the visual (dissociated) requirements in terms of vergence and accommodation. These adjustments at the controller level depend on the global AC/A and the CA/C ratios of the subject, but the important issue here is that these corrections are proportional to the variation imposed on the visual stimulus (i.e., the change in vergence demand for a fixed accommodation demand and vice versa). For example, keeping the vergence demand constant, larger changes in accommodation demands require larger changes in the output of the accommodation controller and proportional, but with a fixed ratio, negative changes in the output of the vergence controller to maintain an unchanged vergence level. The accommodative and vergence gains of each cell are determined by the relative amount of signal reaching the cell from the direct and cross-link inputs. These ratios will be determined by the global ratios of the subject, as well as by the individual weights of the direct and cross-link inputs to the cell. Depending on the resulting overall weights of the cell, we have three typical cases: (1) the ratio between the signal coming from the direct link and the cross-link is greater than 1; (2) it is exactly 1; (3) it is less than 1.

A vergence near cell with a ratio of exactly 1 (N2 in Fig. 95.5) will always receive equal and opposite signals from the direct and cross-link inputs during changes in accommodation only. The cell will appear insensitive to accommodation changes if they are not accompanied by vergence changes and so would be classified as a pure vergence cell. A cell with a ratio greater than 1 (i.e., a stronger direct link) will, under the same conditions, have a negative accommodation gain. This is because the negative direct corrective signal from the

vergence controller overcomes the positive accommodation signal from the cross-link (N1 in Fig. 95.5). A cell with a ratio less than 1 (i.e., stronger cross-link) will, in the same conditions, have a positive accommodation gain. The positive accommodation signal from the cross-link will overcome the negative direct corrective signal from the vergence controller (N3 in Fig. 95.5). The remarkable result is that all of these cells are, in terms of output, vergence cells, but depending on their weights, they can behave, at least partially, as “accommodation-related” cells. The same logic applies to the accommodation near cells (N5, N4, and N6, respectively) during changes in vergence with accommodation held constant, with, as a consequence, more or less “vergence-related” behavior. The overall schema does not change for vergence near cells during vergence changes with fixed accommodation demand or for accommodation near cells during accommodation changes with fixed vergence demand. The global AC/A and CA/C ratios of the subject are normally less than 1, when measured in comparable units (i.e., diopters and meter angles).

These theoretical considerations result in predictions that match the data in Figure 95.6 very closely. The two cells in the upper left quadrant of Figure 95.6 were not antidromically activated from the oculomotor nucleus. This is consistent with the model, since the N4 type cells would have to be in the accommodation output path. Vergence near response cells represented by N3 would show a positive vergence gain and a positive accommodation gain, but so would cells represented by N6 in the accommodation output path. Using plausible values for the AC/A and CA/C ratios, no near response cells that increase their activity for covariant convergence and accommodation should be seen in the lower left quadrant of Figure 95.6 using dissociated stimuli. Indeed, no cells were found with a negative accommodation gain and a negative vergence gain using the dissociated stimuli. This analysis shows that a biologically plausible distribution of differing direct and cross-link inputs to near response cells can account for the wide variety of vergence and accommodation gains, including negative gain values.

Saccade-vergence interactions

UNEQUAL HORIZONTAL SACCADES Although the analysis of near response cells clearly demonstrates the presence of vergence-related signals, Hering’s Law suggests that we should also see premotor signals related exclusively to conjugate commands, that is, to movements of the cyclopean eye. Saccadic eye movements are assumed to be intrinsically conjugate. In other words, both eyes execute identical rotations of an amount related to the needs of the cyclopean eye. This assumption has been challenged by observations that horizontal saccades may be markedly unequal in amplitude if they are executed together with a vergence move-

ment. Figure 95.7A shows a smooth symmetrical convergence movement approximately 10 degrees in size made by a macaque. This movement was made between far and near targets aligned with the cyclopean eye and contained no saccades. The vergence velocity (VV) trace shows that the peak velocity of this movement was approximately 50 degrees. This is about an order of magnitude slower than the peak velocity of a conjugate saccade of similar size. Figure 95.7B shows a similar size convergence movement combined with a rightward saccade, indicated by an arrow. The rightward saccade made by the right eye appears to be two to three times smaller than the saccade made by the left eye. Careful analysis of saccades during vergence in both the human (Ono et al., 1978) and the macaque (Maxwell and King, 1992) has shown that the differences in saccade size between the two eyes cannot be attributed to the ongoing smooth vergence movement. That is, the difference in saccade size is larger than the one expected by the linear combination of the version and smooth vergence. This is more clearly shown by an inspection of the vergence velocity trace of Figure 95.7B, which shows an abrupt doubling of vergence velocity associated with the saccade. Hering’s Law would predict that the vergence velocity profile in Figure 95.7B would be the same as for smooth vergence in Figure 95.7A.

DO UNEQUAL SACCADES IMPLY MONOCULAR CONTROL?

Markedly unequal horizontal saccades during vergence have been interpreted by some investigators (Enright, 1992) as a clear violation of Hering’s Law. Enright (1984) and others (Dell’Osso, 1994; Zhou and King, 1998) have suggested that the control mechanisms for the two eyes may be intrinsically independent. In this view, although many eye movements are conjugate, the underlying circuitry allows for independent control of the two eyes for smooth pursuit eye movements (King and Zhou, 1995) and for saccades (Enright, 1984). Any difference in the monocular commands to the two eyes would generate changes in the vergence profile that are not associated with the vergence system proper. Zee and colleagues (1992) have suggested alternative eye movement models that can produce unequal saccades without invoking monocular control. The critical observation for these models is that vertical saccades can also cause vergence to be speeded. An example of this can be seen in Figure 95.7C, which shows a small (2.5 degree) downward saccade which occurs during a 10 degree convergence movement. An examination of the vergence velocity trace in Figure 95.7C shows that its peak is more than doubled by the occurrence of the saccade (i.e., compare to VV in Fig. 95.7A). This indicates that the speeding of vergence depends on the occurrence of a saccade in any direction rather than the generation of unequal *horizontal* saccades.

Zee et al. (1992) have evaluated several models of saccade-vergence interactions, where vertical saccades can

FIGURE 95.7. Saccade-vergence interactions. Convergence in the absence of a saccade (*A*), similar convergence with a horizontal (rightward) saccade (*B*), and similar convergence with a vertical (downward) saccade (*C*). The arrows in *B* and *C* indicate the occurrence of a saccade. The calibration bar corresponds to 5 degrees for eye position traces and 50 deg/sec for the vergence velocity (VV) trace. Eye position trace abbreviations are as in Figure 95.4. The occurrence of a saccade during the early phase of a vergence movement (either convergence or divergence) results in an immediate increase in vergence velocity, even if the saccade is purely vertical (*C*). This indicates that the mechanism by which vergence is speeded by a saccade does not depend on unequal horizontal saccadic rotations.

also speed vergence. Two related models, which are alternatives to the independent eye control hypothesis, allow for vergence-related neural activity to be gated by pontine omnipause neurons (OPNs) (Keller, 1974). Both models simulate saccade-vergence interactions reasonably well. One of these models, the OPN model, is consistent with two critical observations: (1) the enhancement of vergence velocity by vertical saccades (Enright, 1984; Zee et al., 1992), which could implicate the pontine OPNs (which are omnidirectional) in this interaction, and (2) the existence of midbrain vergence burst neurons which carry vergence velocity signals (Mays et al., 1986). These observations suggest that a vergence velocity signal could be modulated by saccade-related (i.e., OPN) activity.

The inputs to the OPN model are pure symmetric vergence and pure conjugate saccadic commands. Consider a convergence-saccade combination with a horizontal saccade that occurs near the beginning of the convergence. This situation typically produces markedly unequal horizontal saccades. In the absence of a saccade, a slow vergence command is relayed to convergence burst (CB) cells that are tonically, but weakly, inhibited by OPNs. Consequently, only slow vergence movements can occur in the absence of a saccade (Fig. 95.7*A*). The occurrence of a saccade is associated with the cessation of activity in the OPNs, which results in a release of the inhibition of the CB cells. The disinhibited CB cells produce an additional pulse of vergence activity that is processed through the vergence neural integrator, and the resulting position signal is combined with the vergence velocity signal at the CB-tonic cells. The output of these cells is added to the ongoing saccadic horizontal pulse and step commands communicated to the MR motoneurons by the AI neurons. The simple linear addition of these commands produces an accentuated pulse-step command for one eye and a diminished pulse-step command for the other eye, resulting in markedly unequal horizontal saccades in the two eyes (Fig. 95.7*B*). Since this depends on the omnidirectional OPN cells, saccades in all directions, including vertical saccades (Fig. 95.7*C*), will be equally effective in speeding vergence. Although this model requires more rigorous testing, it demonstrates that unequal horizontal saccades do not necessarily imply monocular saccadic control mechanisms for each eye.

Conjugate versus monocular commands

EXCITATORY BURST NEURONS The monocular control hypothesis suggested by Enright (1984) and the saccadic facilitation of vergence hypothesis described by Zee et al. (1992) imply very different ways of generating saccades and vergence eye movements. One way of resolving this issue would be to record premotor signals during these unequal horizontal saccades to determine if they are related to the

movement of the cyclopean eye (Hering's Law) or to the separate movements of the two eyes. This experiment has been reported by Zhou and King (1998), who recorded from putative excitatory burst neurons (EBNs), located in the pons near the abducens nucleus. EBNs project to the ipsilateral abducens nucleus and show a burst of activity that is related to the horizontal component of ipsilateral saccades. Specifically, the number of spikes in each burst is believed to be linearly proportional to the horizontal size of the saccade (Keller, 1974). Taking advantage of this relationship, Zhou and King counted the number of spikes recorded from EBNs during unequal-amplitude horizontal saccades. By comparing the number of spikes in the burst during unequal saccades with the number of spikes for conjugate saccades, Zhou and King determined if the burst was associated with the amplitude of the rotation of the ipsilateral eye, the contralateral eye, or the cyclopean eye. Although the activity of a few EBNs was associated with the cyclopean eye during unequal saccades, as expected by Hering's Law, the activity of the majority of EBNs was more closely associated with the rotation of either the ipsilateral or the contralateral eye.

OTHER MONOCULAR SIGNALS Zhou and King (1998) also reported that the majority of cells recorded in the nucleus prepositus hypoglossi, an area thought to produce horizontal eye position signals, were also monocular. McConville et al. (1994) recorded position-vestibular-pause cells in the vestibular nuclei of macaques during conjugate and vergence eye movements. They found that 18 out of 20 cells had monocular eye position signals.

HOW ARE MONOCULAR EYE COMMANDS USED? The results of Zhou and King are inconsistent with the idea that neurons in the abducens nucleus are provided with separate conjugate and vergence inputs, as required by Hering's Law. Instead, they strongly suggest that the inputs I_1 and I_2 in Figure 95.1 do not reflect conjugate and vergence inputs, but instead represent ipsilateral and contralateral eye commands. This new conjecture raises a puzzling question: how are these monocular commands used? A number of studies (Gamlin et al., 1989a; Maxwell, 1991; Mays and Porter, 1984), including data from Zhou and King, show that even if the inputs to the abducens nucleus represent monocular signals, the activity of the vast majority of abducens neurons is not monocularly coded. This can be seen in Figure 95.3. Abducens neurons with activity reflecting an ipsilateral monocular input would fall along the "Ipsi eye" dashed line, while those with activity related to the other eye would fall along the "Contra eye" line. While there are a number of cells with activity corresponding to a monocular ipsilateral eye input, there are very few with activity related to the contralateral eye. Indeed, most abducens neurons show an

activity pattern that is between the ipsi and contra eye lines. This indicates that if ipsilateral and contralateral eye movement signals are provided to neurons in the abducens nucleus, these signals are commingled and individual eye position information is lost on the abducens neurons. This finding is consistent with the AI and MLF recording data, as well as lesion studies (cited above), which demonstrate that neurons in the abducens nucleus do not provide an appropriate vergence signal to the MR motoneurons. Furthermore, monocular eye position and velocity signals do not appear to be used for the generation of vergence eye movements, at least via the abducens nucleus. This strongly implies that the vergence angle changes brought about by unequal horizontal saccades are not due to activity differences between abducens motoneurons and internuclear neurons.

It is possible that in primates these premotor monocular signals have lost their original function. From an evolutionary point of view, a fully developed vergence system with depth perception (stereopsis) is present only in primates. Primitive lateral-eye animals do not have a vergence system. In these animals, each eye is controlled independently; therefore, there is a need for appropriate monocular commands to be sent to each eye. This raises the possibility that the migration of the eyes from a lateral position to a frontal one with the development of an independent precise vergence system able to maintain the accurate binocular alignment needed by stereopsis was accompanied by the fusion of the original monocular signals into a single cyclopean structure. Disjunctive signals, generated independently by the vergence system, were simultaneously added to the motoneurons to allow precise disjunctive eye movements to be guided by disparity errors. These are also binocular from a sensory point of view. It should be noted that the precision required by the vergence system for stereopsis is much higher than that required by the versional systems (or the monocular ones in the evolutionarily primitive animals). This is even true in foveate animals, where the object of interest has to be projected over a small area of the retina for the best spatial resolution. Perhaps the inherent lack of precision achievable by a monocular arrangement pressed evolution toward a versional/vergence solution. The need for a positional vergence signal is also important in frontal-eye animals to estimate the viewing distance of the object of interest to program, accordingly, the gain of the vestibulo-ocular reflexes. For a review of this issue, see Miles (1995). An alternative possibility is that these monocular premotor signals were initially generated as versional signals, from which vergence signals were subtracted later on, perhaps to improve dynamic performance. At present, there is no way to distinguish between these alternatives.

Higher-order control

CEREBELLUM AND PONTINE AREAS There is some evidence that the cerebellum is involved in the near response. Westheimer and Blair (1973) reported transient vergence deficits after cerebellectomy in primates. Zhang and Gamlin (1998) found cells in the posterior interposed nucleus of the cerebellum related to vergence and accommodation. All of these cells increased their activity for divergence and so were described as *far response* cells. Gamlin and Clarke (1995) reported cells related to either near or far responses in the medial zone of the nucleus reticularis tegmenti pontis (NRTP), a precerebellar nucleus. Although these cells were often found near cells with saccade-related activity, the vergence-related cells did not change their activity in association with saccades or conjugate pursuit. The NRTP has reciprocal connections with the midbrain area containing the near response cells that, in turn, project to the oculomotor nucleus (May et al., 1992). Moreover, the NRTP is an area that receives cortical inputs and also has reciprocal connections with the cerebellum. It may be an important link providing vergence and accommodation signals to both the cerebellum and the midbrain near response areas.

SUPERIOR COLLICULUS The superior colliculus (SC) has long been implicated in the initiation of saccades and, more recently, in the control of gaze saccades (Freedman and Sparks, 1997) (i.e., combined rapid movements of the head and eyes). In the head-fixed animal, stimulation of most of the SC induces stereotyped conjugate contralateral saccades (Robinson, 1972). Stimulation of the rostral pole of the SC, which can inhibit saccades (Munoz and Wurtz, 1993), also partially inhibits convergence (Chaturvedi and Van Gisbergen, 2000), and stimulation of more caudal areas of the SC perturbs both ongoing saccades and vergence. Many neurons in the SC produce a burst of activity before specific contralateral saccades, but there have been no published reports of SC neurons firing for vergence in the absence of saccades. Preliminary data from our laboratory indicate that many saccade-related SC burst neurons fire less vigorously for saccades during both convergence and divergence than for conjugate saccades. This decrease in activity may be related to the report that saccades executed during vergence may be slower and longer than saccades of similar size without vergence (Collewijn et al., 1995). While there are some indications that the SC may be involved in saccade-vergence interactions, the significance of these observations remains unclear.

FRONTAL EYE FIELD The frontal eye field (FEF) area in macaques is located in the region of the arcuate sulcus. FEF cells fire in response to visual stimuli and also in relation to

saccades to visual stimuli (Bruce and Goldberg, 1985). Some neurons in the floor and posterior bank of the arcuate sulcus also discharge for smooth pursuit eye movements (Gottlieb et al., 1994). Recently, Gamlin and Yoon (2000) reported finding vergence- and accommodation-related cells just anterior to the arcuate sulcus. Most cells increased their activity for convergence, but some far response cells were observed as well. The activity of these cells appeared to be closely related to motor output, although several cells were responsive to the visual stimulus eliciting the near response. A small minority of cells were modulated during versional eye movements as well as during vergence. Microstimulation of an area anterior to the arcuate sulcus resulted in accommodation and convergence. The FEF projects to the NRTP, to the SC, and to brainstem oculomotor areas (Leichnetz, 1981; Leichnetz et al., 1984), and so may provide vergence and accommodation commands to these areas, as well as pursuit and saccadic commands.

PARIETAL CORTEX Many neurons in parietal cortex show a complex relationship between their activity and saccades, smooth pursuit, and fixation. A substantial number of neurons in the lateral intraparietal sulcus (LIP) discharge for saccades. A majority of these saccade-related neurons also show a modulation in activity associated with the vergence component when a saccade is combined with vergence (Gnadt and Mays, 1995). It appears that many cells are tuned for gaze shifts in three-dimensional space. More recently, Gnadt and Beyer (1998) antidromically activated a subset of LIP neurons with three-dimensional movement fields from the SC. This suggests a way in which vergence information, as well as saccadic signals, could be sent to the SC.

OTHER CORTICAL AREAS A number of other cortical areas have neurons that could provide information about the distance of an object from the viewer. Some neurons in ventral intraparietal cortex (VIP) (Colby et al., 1993) discharge most vigorously for visual stimuli near the face. Others fired for visual stimuli moving toward the animal. Areas MT (middle temporal) and MST (medial superior temporal) in the superior temporal sulcus have neurons that encode disparity and so may be important for tracking objects in three-dimensional space (Kawano et al., 2000). Other visual cortical areas, such as V1, contain neurons sensitive to binocular stimulation. Some of these neurons are particularly sensitive to targets near the plane of fixation (tuned-zero neurons), while others respond best to targets closer to (near cells) or beyond (far cells) the plane of fixation (Poggio, 1995). In short, there are many cortical areas with signals that could be used to control vergence movement. Whether or not signals in a particular area are, in fact, used for this purpose is unknown.

Summary

The activity patterns of extraocular motoneurons during versional and vergence eye movements have been well characterized. The biomechanical complexity of the oculomotor plant, especially with the recent discovery of movable muscle pulleys, has made the task of relating motoneuron activity to muscle forces quite difficult, as Miller et al. (2002) have pointed out. A better assessment of the role of the muscle pulleys, and of the mechanical coupling between the orbital and global muscle layers, is needed to resolve the discrepancy between muscle force data and motoneuron activity for vergence movements. This should be accompanied by recordings from motoneurons identified as innervating global or orbital muscle fibers.

There has been significant progress in understanding premotor near response commands and the role of near response cells in coordinating accommodation and vergence. Surprisingly, the nature of the commands used for conjugate eye movements needs further clarification. Recent work indicates that these premotor commands may be monocular, but it appears that these “monocular” signals are commingled to construct what is essentially a conjugate (cyclopean) signal at the level of the motoneurons. The evolutionary history of eye movement circuits may provide an explanation of why such a scheme should exist.

The debate as to whether the premotor commands are monocular or represent a combination of cyclopean and vergence signals has often centered on the nature of saccade-vergence interactions. The observation of horizontal saccades of different amplitudes does not, in itself, indicate that the control of the saccades is inherently monocular. A better understanding of the mechanism by which vergence speed is increased during saccades is needed.

The route by which vergence commands are generated and sent to near response neurons is unknown. Recent studies of the NRTP, the cerebellar interposed nucleus, and the FEF suggest several possibilities, but the details need to be provided. Visual cortical areas have an embarrassingly large number of disparity- and spatial frequency (blur)-sensitive neurons, but no direct linkage between the activity of these cells and the near response has been demonstrated.

Acknowledgment

I thank Dr. Claudio Busetini for his helpful comments on the manuscript and for his assistance in preparing the figures.

96 The Primate Frontal Eye Field

CHARLES J. BRUCE, HARRIET R. FRIEDMAN, MICHAEL S. KRAUS,
AND GREGORY B. STANTON

IN PRIMATES, A PARTICULAR region of frontal lobe neocortex, the frontal eye field (FEF), is prominently involved in the control of voluntary eye movements. FEF is principally concerned with eye movements that serve to image important aspects of the visual world on the most sensitive part of the retina, the fovea. Foveation is particularly important in primates because visual acuity at the primate fovea is far better than peripheral acuity. Because voluntary saccades are the most important and conspicuous eye movements of the foveation system, and because FEF has been most extensively studied in relation to saccades, the saccadic aspects of FEF will be emphasized in this chapter. However, smooth pursuit, fixation, and vergence eye movements also serve foveation, and FEF has a distinct subregion for smooth pursuit and is involved in vergence movements and fixation as well.

FEF and saccadic eye movements

DISCOVERY OF FEF AND OTHER CORTICAL EYE FIELDS David Ferrier (1876) was the first to discover that electrical stimulation of the frontal lobe neocortex deviated the eyes toward the contralateral side. It was subsequently found that all primates, including the great apes (Leyton and Sherrington, 1917) and humans (Penfield and Boldrey, 1937), possessed such an FEF. The top part of Figure 96.1 shows Ferrier's experimental mappings in a macaque monkey.

As also shown in Figure 96.1, FEF is not the only neocortical area involved in eye movements. In the macaque, there also is a parietal eye field (PEF), located in the lateral bank of the intraparietal sulcus (e.g., Shibutani et al., 1984), and a supplementary eye field (SEF), located in the dorsal frontal lobe near the midline (e.g., Mott and Schäfer, 1890; Schlag and Schlag-Rey, 1987). The FEF, PEF, and SEF are reciprocally interconnected (e.g., Huerta et al., 1987; Stanton et al., 1993, 1995). The FEF, however, seems to be the principal cortical eye field: FEF has the lowest thresholds for electrically elicited saccades (Russo and Bruce, 1993, 2000; Shibutani et al., 1984), oculomotor behavior is generally more impaired by FEF lesions than by lesions in the other eye fields (e.g., Schiller and Chou, 1998, 2000a, 2000b), and FEF is indispensable for visually guided saccades if the superior colliculus (SC) is damaged (Keating and Gooley, 1988; Schiller et al., 1980).

NATURE OF EYE MOVEMENTS ELECTRICALLY ELICITED FROM FEF Early FEF studies did not determine which type of eye movement caused the contralateral deviations produced by electrical stimulation. Nearly a century after Ferrier, Robinson and Fuchs (1969), using alert macaque monkeys as subjects and their search coil technique of transducing eye movements, unequivocally demonstrated that these electrically elicited eye movements were saccadic eye movements indistinguishable from naturally occurring saccades. When tested with the head unrestrained, FEF stimulation results in a combined eye-head movement (as does head-free stimulation in the SC as well as SEF and PEF). Thus, the elicited movement is actually a saccadic gaze shift, with the magnitude of the head component depending on circumstances including the size of the elicited movements at the FEF site (Tu and Keating, 2000; see also Sparks et al., 2001).

Still, the specific role of FEF remained unclear because FEF lesions do not abolish saccadic eye movements, nor do they produce oculomotor paralysis analogous to the skeletal paralysis following lesions of the upper motor neuron in area 4. Moreover, FEF neurons do not project directly to the oculomotor nuclei (Künzle and Akert, 1977), as was originally thought to be the case. However, extensive neurophysiological, anatomical, and behavioral evidence now establishes FEF as the principal cerebral cortex for voluntary movements of the eyes (Bruce, 1990; Bruce and Goldberg, 1984). Except for its smooth pursuit and vergence zones, each site in FEF yields saccades of a characteristic direction and amplitude, and the set of all possible contralaterally directed saccades is represented by each hemisphere's FEF (Bruce et al., 1985; Crosby et al., 1952; Robinson and Fuchs, 1969; Wagman et al., 1961). Figure 96.2 shows some of this topography, as well as examples of ipsiversive elicited smooth eye movements found in the depths of the arcuate sulcus; this smooth pursuit region of FEF is discussed near the end of this chapter.

Basic properties of saccadic eye movements. Thus, FEF provides a major efferent pathway from the neocortex for commanding voluntary saccadic eye movements, and so understanding this highly specialized aspect of the foveation system is key to understanding FEF function. Saccades are brief (usually <75 msec) and fast (usually >500 deg/sec) eye movements. Humans average about two saccades per second

FIGURE 96.1. Cortex for eye movements in the human and the monkey. *Top*: left hemisphere of a macaque monkey mapped by Ferrier (1876). *Electrical irritation* at 12, 13, and 13' produced contralateral eye movements. The 12 region represents the FEF, although contemporary studies indicate that FEF is located principally in the anterior lip and anterior wall of the arcuate sulcus, and thus slightly posterior and lateral to Ferrier's location. Similarly, movements at 13 may be the PEF, but contemporary studies locate PEF in the LIP. Eye movements at 13' may reflect the seldom mentioned occipital eye field, also called the *posterior eye field*. *Bottom*:

Cortical regions important for saccade and smooth pursuit eye movements are highlighted on the monkey brain and the human brain. In both monkey and human, FEF is in front of premotor cortex for the hand and neck, and mostly lies within the sulcus marking the anterior limit of the precentral gyrus. In both species, the smooth pursuit region of FEF is just posterior to the saccadic region of FEF (particularly if the cortex was flattened). The monkey brain is shown from a dorsolateral viewpoint to minimize distortion of the arcuate sulcus.

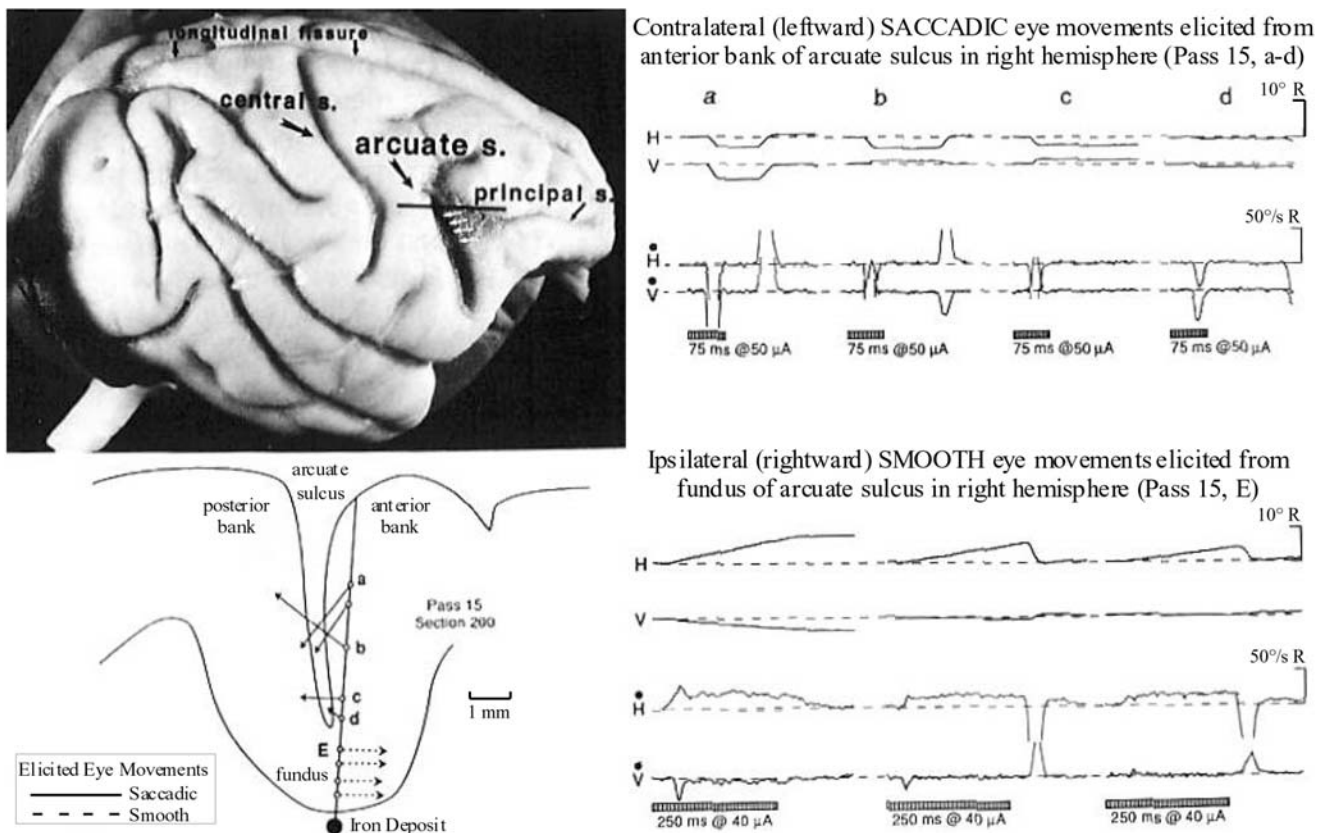

FIGURE 96.2. Reconstructed electrode pass down the anterior bank of arcuate through the saccadic FEF and encountering the smooth pursuit region of FEF. *Top left*: dorsolateral views of the right hemisphere. The small white arrows on the right hemisphere indicate additional locations where smooth eye movements were elicited. *Bottom left*: cross section of the arcuate sulcus showing reconstructions of electrode penetration down the anterior bank; sites that yielded saccadic and smooth eye movements are indicated. Note that contralaterally directed saccadic eye movements

were elicited first, whereas ipsilaterally directed smooth eye movements were elicited in the arcuate fundus. *Right*: representative eye movements at four saccadic sites (*a-d*) and three examples from a smooth movement site. In all cases, the electrical stimulation was applied while the monkey was attentively fixating a small stationary spot of light, and usually the monkey made a voluntary saccade back toward that spot after the electrical stimulation ceased. (Adapted from Figure 2 of MacAvoy et al., 1991.)

while awake, and so our day is spent in brief fixations of different small parts of the visual world, constantly, but only briefly, interrupted by saccades. This unremitting procession, the processing of foveal visual information during a fixation, as well as the planning of the next saccade, engages much of the human brain, as exemplified by brain-imaging studies of humans doing both simple and complex visuomotor tasks (e.g., Luna et al., 2001; O'Driscoll et al., 2000).

Saccades are open-loop (i.e., ballistic, preprogrammed) movements. In fact, less than 50 to 100 msec prior to its start, a saccade generally cannot be canceled or redirected on the basis of new sensory information. The saccadic waveform and its main parameters (duration, peak velocity, etc.) are largely determined by the dimensions of the movement being accomplished, and thus one cannot simply choose to make faster or slower saccades.¹ The saccadic objective is to effect the desired ocular displacement as quickly as possible and immediately return the eye to stationary fixation in the

new direction. In fact, vision during the saccade is poor or absent (*saccadic suppression*), meaning that the subject is nearly blind during saccades—more reason for their high speed and brief duration.

Saccadic launch is under voluntary control, and saccades have relatively long latencies (i.e., reaction times). For example, saccade latency, as measured from the time of the appearance of a visual target until the start of the saccadic movement to foveate the target, is usually 100 to 400 msec, with 200 msec being typical. By contrast, the vestibulo-ocular reflex has a 10 msec latency. Although saccades to quickly foveate suddenly appearing visual stimuli are somewhat reflexive; one can readily forgo making saccades to even highly salient stimuli. Furthermore, one can instead

¹ For example, saccade duration is roughly a linear function of the saccade size ($\sim 21 \text{ msec} + 2.2 \times \text{size}$; Carpenter, 1988).

make accurate and advantageous “predictive” or “anticipatory” saccades to the location where a stimulus is likely to appear in the future or even antisaccades in the opposite direction as a stimulus.

Thus, saccades are guided by our experience, guesses, objectives, and strategies,² as well as by overt visual stimulation, even though their motoric details are largely independent of their purpose. Overall, the saccadic plan is to consider judiciously whether to disengage the current foveated stimulus, select a new stimulus of interest, plan a movement based on the retinal locus that will foveate that new stimulus, execute the plan in a ballistic fashion, and then process the new foveal image for at least a few hundred milliseconds before considering a subsequent saccade.³ Reading is the prime example of the saccadic system fully engaged under voluntary control.

Neural basis of saccadic eye movements. Figure 96.3 summarizes the brain’s distributed network for triggering and carrying out voluntary saccades. All saccades are ultimately fashioned by a dedicated neural circuit in the brainstem called the *saccade generator* (e.g., Scudder et al., 2002). This network of several distinctive types of neurons in the pontine and mesencephalic reticular formation originally evolved to produce the quick-phase movements of vestibulo-optokinetic nystagmus that reflexively stabilize images on the retina. In primates, however, it serves as the final common pathway for all rapid eye movements, and so if the saccade generator is damaged, then all rapid eye movements, reflexive and voluntary, are disabled. Thus, the voluntary saccades of primates involve triggering a part of the phylogenetically older image stabilization circuitry for the purpose of foveation.

The output of the saccade generator is a displacement vector of the current direction of gaze and a *neural integrator* downstream of the saccade generator computes the tonic eye position signal needed to hold the eye steady in its new position following each saccade. Because it serves all eye movement commands, smooth/slow eye movements as well as rapid/saccadic movements, it is called the *common* neural integrator. Figure 96.3 details the brainstem locale of the saccade generator and neural integrator and illustrates how all saccadic eye movements rely on these two vital brainstem circuits.

Thus, FEF does not directly control the extraocular musculature, but instead achieves its purposes by triggering and

modulating the brainstem circuitry of the much older image stabilization system, that is, the circuits underlying the reflexive eye movements that serve to hold the whole visual world stationary on the retina. Without oculomotor stabilization during movements of the head or body, the retinal image is smeared and all vision, foveal and peripheral, is severely compromised. The stabilization system generally functions reflexively in parallel with the more voluntary foveation system (for a review, see Bruce and Friedman, 2002).

The superior colliculus and the visual-grasp response. The SC is the vertebrate brain’s prototype sensorimotor structure and occupies a key position in the saccade circuitry of Figure 96.3 above the saccade generator. The primate SC receives topographic visual projections from corresponding parts of both retinas that portray a precise map of the contralateral hemifield on each hemisphere’s SC. This visual map is found in the superficial layer of the SC and is in register with the map of the movement vectors for saccade-related neurons in the intermediate layer. This remarkable alignment of the sensory and motor maps underscores the principal role of the primate SC, which is to move the eyes so as to foveate quickly a stimulus seen anywhere in the visual periphery by commanding the saccade generator to fashion a rapid eye movement of the appropriate size and direction. This prepotent visually guided saccade has been called the *visual grasp reflex* and is the basic building block of the foveation system.

Probably the most important output from FEF for effecting saccades is its massive topographic projection to the intermediate layers of the SC (Huerta et al., 1986b; Stanton et al., 1988). Hanes and Wurtz (2001) found that FEF-elicited saccades were eliminated or distorted by temporary inactivation of parts of the SC map. Nevertheless, visually guided saccades and FEF-elicited saccades survive complete ablation of SC in primates because the primate also has a substantial neocortical network for saccades with access to the saccade generator independent of SC. Figure 96.3 also shows these cortical pathways and clarifies some effects of such lesions. For example, the sparing of visually guided saccades following SC lesions is mediated by FEF projections to the brainstem saccade generator that bypass the SC. The SC, however, normally provides a faster and more accurate pathway for visually guided saccades via its direct retinal projections and accurate retinotopic map, which explains why an increase in the latency of visually guided saccades is a lasting deficit of SC damage. Likewise, FEF lesions alone generally spare visually guided saccades; however, FEF lesions combined with SC lesions eliminate most visually guided saccades (Schiller et al., 1980). Thus, the primate SC and FEF provide both serial and parallel pathways for visual triggering of the brainstem saccade generator for the purpose of foveating saccades.

² Including social purposes for avoiding or making eye contact with others.

³ Saccades also have a refractory period; it is relatively difficult to initiate a saccade sooner than 100 to 200 msec after the previous saccadic movement ends.

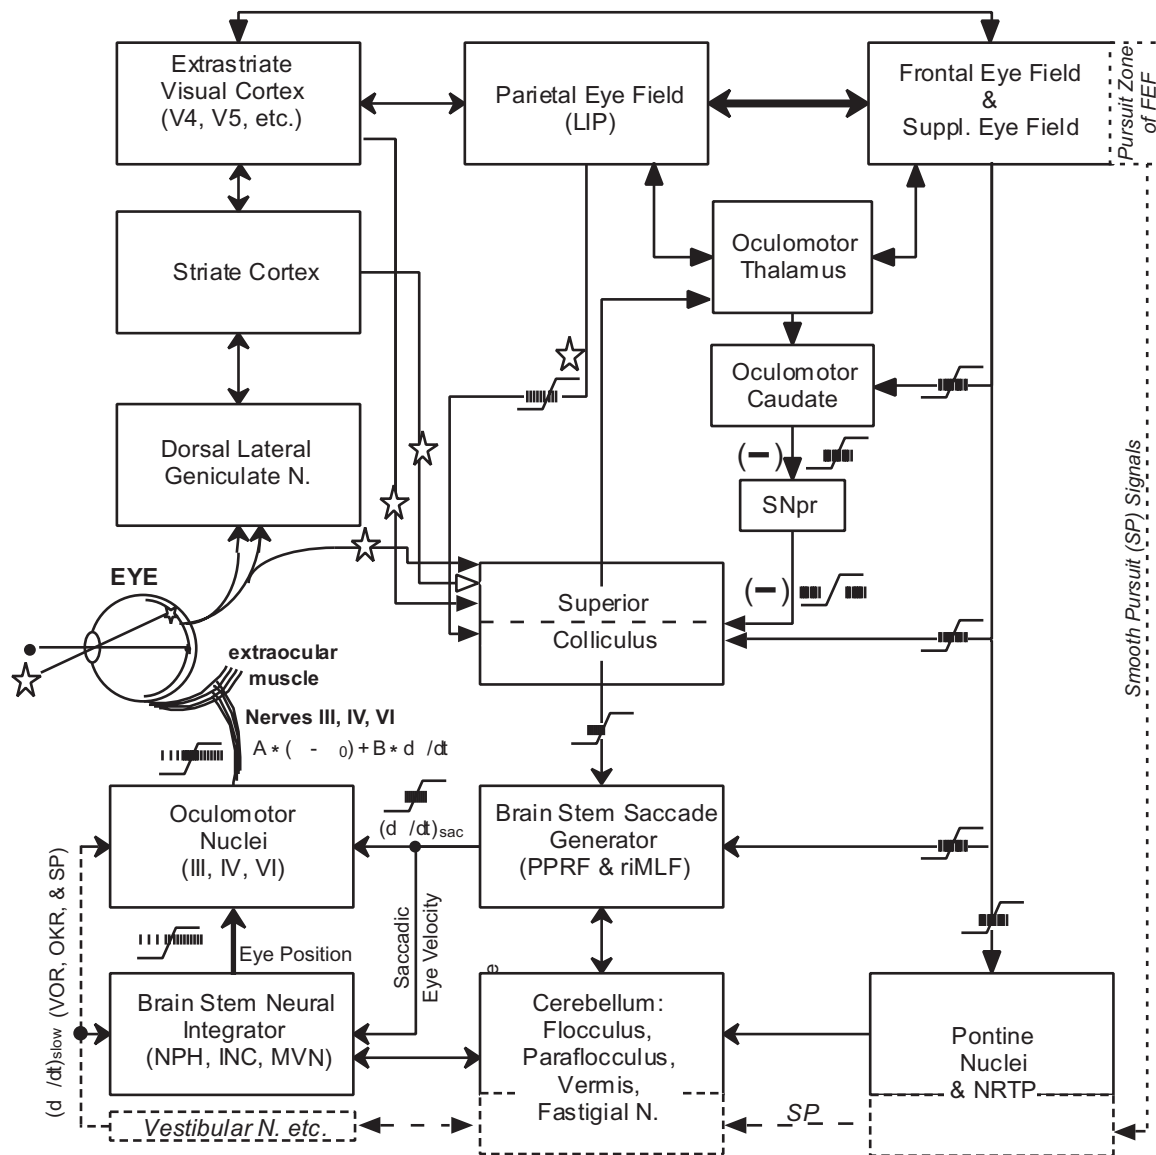

FIGURE 96.3. Pathways for voluntary and visually guided saccades and smooth pursuit. This diagram shows anatomical connections between cortical and subcortical structures involved in the control and generation of saccadic eye movements. The FEF receives visual information via pathways originating in the striate cortex, as do the PEF and the SEF. Note that all visual cortical areas project to the SC, with FEF, PEF, and SEF projecting primarily to its intermediate layers. By contrast, the superficial layers of SC receive direct visual projections from the retina and indirect visual projections from the striate and extrastriate cortices. Connections to locations marked with a star principally carry visual signals, whereas those marked by a saccade and burst are principally motoric.

The brainstem saccade generator is located in the paramedian pontine reticular formation (PPRF) and in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF). The brainstem neural integrator is located in the medial vestibular nucleus (MVN), the adjacent nucleus prepositus hypoglossi (NPH), and the interstitial nucleus of Cajal (INC). The cerebellum controls the

gains of both the saccade generator and the common integrator, in addition to being a critical link in the pursuit pathway. The smooth pursuit pathways shown with dashed boxes, dashed lines, and italicized text is very basic; for example, V5 and other temporal and parietal areas, as well as the pursuit zone of FEF, project to the pursuit-related pontine nuclei. SNpr, substantia nigra pars reticulata; NRTP, nucleus reticularis tegmenti pontis; LIP, lateral intraparietal sulcus; Suppl, Supplementary; θ , eye position; $d\theta/dt$, eye velocity; $(d\theta/dt)_{\text{sac}}$, saccadic eye velocity; $(d\theta/dt)_{\text{slow}}$, slow (or smooth) eye velocity; VOR, vestibulo-ocular reflex; OKR, optokinetic reflex; SP, smooth pursuit; (-), inhibitory synapse; $A * (\theta - \theta_0) + B * d\theta/dt$, equation for spike rate of the general oculomotor neuron as a function of eye position and velocity; A and B, constants; θ , eye coordinate along the pulling direction of the extraocular muscle that is innervated; $d\theta/dt$, eye velocity along the same direction; θ_0 , eye position at which the oculomotor neuron is recruited.

EFFECTS OF FEF LESIONS ON SACCADIC EYE MOVEMENTS
Whereas FEF lesions spare most visually guided saccadic eye movements (unless combined with SC damage, as discussed above), there is a cluster of deficits indicating that FEF is important for many types of *purposive* saccades, particularly when no overt visual target is available. Gordon Holmes (1938) found that patients with frontal lesions had difficulty moving their eyes in response to verbal commands (“look right”), even though they could follow visual objects and understood the verbal commands. He concluded, “The frontal centers make possible the turning of gaze in any desired direction and the exploration of space, but they also keep under control, or inhibit, reflexes that are not appropriate.” Guitton et al. (1985) used the antisaccade paradigm to demonstrate just that, namely, that “Frontal lobe lesions in man cause difficulties in suppressing reflexive glances and in generating goal-directed saccades.” In other words, their subjects could not launch saccades in the direction opposite the visual target (antisaccades), even though they understood that to be the task. Instead, they often made inappropriate saccades toward the visual targets (prosaccades), exactly what they were instructed not to do. Humans with FEF lesions also have difficulty executing memory-guided saccades (Ploner et al., 1999). Similarly, monkeys have difficulty making memory saccades after FEF inactivation (Dias and Segraves, 1999; Dias et al., 1995; Sommer and Tehovnik, 1997). Monkeys with FEF lesions fail to generate predictive saccades during square-wave target motion (Bruce and Borden, 1986), as do humans with FEF lesions (Gaymard et al., 1999).

NEUROPHYSIOLOGY OF FEF IN RELATION TO SACCADIC EYE MOVEMENTS

Low-threshold FEF and presaccadic burst activity. Bruce et al. (1985) define FEF as cortex where saccades are elicited by microstimulation at 50 μ A or less with the electrode tip in gray matter. In the macaque monkey, this low-threshold (saccadic) FEF lies primarily in the anterior bank and anterior lip of the arcuate sulcus (see Figs. 96.1 and 96.2) and has a distinctive cytoarchitecture (see also Stanton et al., 1989).

When recording is restricted to the saccadic FEF, the vast majority of neurons have robust task-related changes in their discharge rate when a monkey performs almost any purposive saccadic eye movement task, such as a visually guided saccade task (see below), and a full range of saccade sizes and directions are tested for each cell. With appropriate control experiments, these functional activities can be parsed into several types, such as visual responses, auditory responses, presaccadic movement responses, postsaccadic responses, tonic gaze-direction responses, predictive movement activity, mnemonic visual activity, and so on (see below;

also see Bruce and Goldberg, 1985; Schall, 1991; Sommer and Wurtz, 2001).

Incidence and significance of presaccadic burst activity in FEF. One particular activity, a burst of increased spiking that starts immediately prior to saccades into a cell’s movement field, is the signature activity of the FEF. Approximately one-third of FEF neurons have this presaccadic burst (PSB) activity.⁴ A representative PSB from an individual FEF neuron is shown in Figure 96.4. PSB activity begins just prior to saccade initiation, usually ends approximately when the saccade is completed, and is always tuned, albeit fairly broadly, for a particular saccade vector (i.e., its movement field).

In many respects, FEF cells with PSB activity are remarkably similar to saccade-related bursters (SRBs), which are abundant in the intermediate layers of the SC (e.g., Glimcher and Sparks, 1993) and are even similar to vectorial *long-lead burst neurons* found in the rostral pontine reticular formation (e.g., Hepp and Henn, 1983). But there are significant differences in timing (Segraves and Park, 1993). Moreover, referring to the PSB activity in FEF as generic motor or movement activity (as in presaccadic movement responses, e.g., Bruce and Goldberg, 1985), although not incorrect, implies, by analogy with true motoneurons in the spinal cord and cranial nerve nuclei, a stronger relation between the FEF activity and the realized saccadic eye movements than is truly the case.

Most FEF neurons with PSB activity also have one or more other functional activities. Most conspicuously, approximately two-thirds of FEF cells with PSB also have significant visual activity in that they will respond to the appearance of simple visual stimuli, such as a spots of light, within a large peripheral receptive field (RF), even when no saccade is involved.⁵ Such was the case for the neuron of Figure 96.4. Conversely, a substantial fraction (~20%) of FEF cells have visual responses but lack PSB activity.

Relationship of PSB activity to electrically elicited saccades. PSB activity in the FEF correlates very strongly with the electrically elicited saccade phenomenon that has been used to discover, define, and map FEF. Bruce et al. (1985) found that thresholds for eliciting saccades were lowest at the sites of cells with PSB activity. When testing stimulation at the site of cells lacking PSB activity (usually these other cells were visually responsive, had postsaccadic activity, or both), far

⁴Bruce and Goldberg (1985) found 409 of 752 (54%) FEF cells to be presaccadic (their Table 1), and of a well-analyzed and classified subset of 115 presaccadic cells, 60% had presaccadic movement activity (Table 2) yielding ~33%, or approximately one-third.

⁵Bruce and Goldberg (1985) termed such cells *visuomovement* cells.

FIGURE 96.4. FEF neuron tested with the memory-saccade task. This neuron combined PSB with phasic-tonic visual activity and mnemonic continuation of the visual activity. *Top*: task events. Shortly after the monkey fixates a central light, a peripheral cue briefly appears. Then, after a delay period, the fixation light is extinguished and the monkey must saccade to the location where the peripheral cue had been shown earlier. The location was varied from trial to trial but was in the response field (RF), except for several trials in the middle of testing, when it was deliberately moved to locations outside the RF (see rasters and Gaussian-fit plots). *Top-middle*: rasters (by trial) and histograms of spike activity aligned on cue onset (*left*) show the burst of activity elicited by the

visual stimulus, and those aligned on the saccade onset (*right*) show the large burst of activity preceding the saccades. Note that the visual response has three components: a phasic high-rate burst to the initial appearance of the visual stimulus (latency ~50 msec), a robust tonic visual discharge while the cue remained on, and then, starting ~50 msec after the cue was extinguished, a medium-level tonic mnemonic response that was maintained above the cell's baseline level of activity throughout the delay interval. *Bottom-middle*: spike density histograms based on rasters. Blue and green indicate the intervals used for the Gaussian fits (*bottom*) of best direction for visual and PSB activity, respectively. (From M. S. Kraus et al., unpublished data.)

more electrical current was usually needed to elicit saccades. For example, low thresholds ($<50\mu\text{A}$) were found at the sites of 34 cells with both visual and PSB activity and 11 cells with PSB activity only, but only at the site of 3 cells with visual responses and no PSB activity. Conversely, high thresholds ($>150\mu\text{A}$) were found at the sites of 11 VIS + PSB cells and 2 PSB-only cells, but at the site of 21 visual-only

cells. Thus, recording PSB activity is highly indicative that electrically evoked saccades will be obtained with low currents.

Moreover, the dimensions of the evoked saccades at FEF sites are highly correlated, in both direction and amplitude, with the movement fields for PSB activity recorded from neurons at the same site (Bruce et al., 1985) (Figs. 96.3 and

96.4). Dimensions of both the PSB movement fields and the evoked saccades change together in a fairly systematic manner across the extent of the FEF (Bruce et al., 1985; Dias and Segraves, 1999).

Given this close relationship with the evoked saccades, it is not surprising that FEF cells with PSB activity are prevalent among those found to project to the SC and to the pontine reticular formation. Indeed, Segraves and Goldberg (1987) found that 59% of corticotectal neurons had presaccadic movement-related activity and that another 22% had foveal and fixation-related activity. The remaining 20% were miscellaneous FEF types. In fact, none of the 51 corticotectal cells in this study were primarily responsive to peripheral visual stimuli, even though this is an extremely common FEF cell type (~20%, as noted earlier; also see Fig. 96.6). A similar result was later found for FEF cells projecting to oculomotor regions of the pons (Segraves, 1992), with 48% of the corticopontine neurons firing in association with saccadic eye movements and 28% responsive to visual stimulation of the fovea combined with activity related to fixation.⁶

We infer from these data that the electrically evoked saccade phenomenon principally reflects the excitation of FEF cells with PSB activity that, in turn, activates the brainstem saccade generator via the corticotectal and corticopontine projections of FEF (Huerta et al., 1986; Stanton et al., 1988b). Thus, the functional involvement of the FEF in saccadic eye movements seems to involve naturally occurring PSB activity being sent to the saccade generator over the same FEF efferent pathways responsible for elicited saccades.

PSB activity is FEF's signature neuronal activity. In summary, the PSBs are a distinctive FEF activity. PSBs are manifest in ~33% of FEF neurons but are relatively rare in other neocortex, including the periprincipal prefrontal cortex anterior to the FEF/arcuate and the premotor cortex lying posterior to the arcuate/FEF. These two adjacent cortical regions both have abundant visual responses with large RFs fairly similar to those in FEF.⁷ Thus, although visual responses, both peripheral and central/foveal, are abundant in FEF, what truly distinguishes neural activity in FEF from activity in all other neocortical areas (except for the two other cortical eye fields, SEF and PEF) is FEF's abundance of neurons with robust PSBs. Moreover, the PSB activity is very strongly

associated with the low-threshold elicited saccade phenomenon used to discover, define, and map FEF.

An extremely strong line of evidence for the fundamental importance of the FEF's PSB activity for the production of saccadic eye movements comes from countermanding experiments. Hanes et al. (1998) find that FEF neurons with eye movement-related activity basically control the production of gaze shifts in this special paradigm where a signal to stop the saccade being prepared is sometimes given. Saccades were initiated if and only if the PSB activity of FEF neurons reached their threshold activation level, and not if their PSB activity decayed in response to the stop signal before reaching that level. In contrast, the spiking of FEF neurons with only visual activity was not critically related to the success of the stop signal.

PSB ACTIVITY IN FEF PRECEDES MOST TYPES OF PURPOSE SACCAD The PSB of FEF neurons occurs even in the absence of a visual target (e.g., in the learned-saccade and the memory-saccade paradigms); however, some FEF cells with PSBs in these tasks have little or no bursts in conjunction with "spontaneous" saccades made in the dark (Bruce and Goldberg, 1985; see their Figures 6 and 7). Moreover, as mentioned earlier, FEF lesions impair some categories of voluntary saccades but leave others (generally more reflexive) intact. Thus, it is an empirical question to know which of the many types of saccades (e.g., Table 3-1 in Leigh and Zee, 1999) that FEF PSB activity reliably precedes, and which types are not associated with PSB activity in FEF. Or, more quantitatively, how does the magnitude of PSBs in conjunction with different types of voluntary saccades, often made without a visual target, compare with the response magnitude on standard visually guided saccade tasks? Below we review data concerning the necessary and sufficient conditions for FEF's PSB activity, and, in conjunction with each type of saccade considered, we discuss which FEF activities and/or phenomena could underlie a target-appropriate PSB for that type of saccade.

FEF activity in conjunction with memory saccades. Single-cell examples of strong FEF activity in conjunction with memory saccades have been shown in many reports. Here we present the aggregate FEF response. Figure 96.5 shows the aggregate histograms from a primary database of 341 FEF cells that were (1) all deemed to have a significant presaccadic response and (2) all had their presaccadic responses parsed using the memory saccade task. The spike-density histogram on correctly performed trials in which the memory saccade was directed into its response field was computed for each neuron and then averaged across all 341 cells. Figure 96.6 shows the same data, but segregated into three basic FEF neuron types: 58 neurons with purely visual responses, 190 with both visual and PSB activity, and 93 with PSB activity but few or no visual responses.

⁶However, Sommer and Wurtz (2000, 2001) found FEF's corticotectal population to be more similar to the overall FEF (than did Segraves and Goldberg, 1987), and they emphasized that many corticotectal FEF cells were active during the delay period (on either a memory-saccade or a deferred-saccade task) as well as at the time of the saccade.

⁷Indeed, most macaque neocortex is visually responsive (e.g., Felleman and Van Essen, 1991).

FIGURE 96.5. Aggregate FEF response on the memory-saccade task. Average activity of 341 FEF neurons (from six monkeys) tested on the memory-saccade task. Histograms of spike activity aligned on the cue onset (*left*) show the burst of activity elicited by the visual stimulus. The histograms aligned on the saccade onset (*right*) show the large burst of activity preceding and during the saccades. This same PSB of activity is shown in relation to the signal to saccade

in the *middle* histogram. Note that the visual response has three components: a phasic high-rate burst to the initial appearance of the visual stimulus (latency ~50 msec), a robust tonic visual discharge while the cue remained on, and then, starting ~50 msec after the cue was extinguished, a low-level tonic mnemonic response that was maintained throughout the delay interval. (Data from Friedman et al., 1997.)

These aggregate histograms indicate that overall spiking rate in the FEF is largest in conjunction with saccades, not with the visual target's appearance. Specifically, Figure 96.5 shows that the population PSB in conjunction with memory saccades has over twice as many spikes as the aggregate phasic response to the visual cues. The aggregate histograms in Figure 96.6 further make the case that the PSB is the more intense FEF activity: for the VIS + PSB cells, the PSB is much larger than the phasic visual burst. Moreover, the PSB for memory saccades of the PSB-only cells is larger than the phasic visual cue response of the VIS-only cells.

Memory-saccade PSBs versus PSBs for visually guided saccades. We compared the memory saccade activity of a subset of the cells shown in Figures 96.5 and 96.6 with their activity on two visually guided saccade tasks, namely, the deferred-saccade and step-saccade tasks. The deferred-saccade paradigm⁸ is identical to the memory-saccade paradigm except that the peripheral cue remains on and is thus still available to guide the saccade when the fixation light is eventually extinguished (which is the signal to saccade in both tasks). In the step-saccade task, the appearance of the peripheral spot coincides with the extinction of the fixation point (as if the fixation point quickly moved or "stepped"). Hence, there is no imposed wait (or delay) period, and the monkey can saccade as quickly as desired after the saccade target light appears.

Figure 96.7 shows that the aggregate PSB magnitude for the memory saccade is nearly identical to the PSB magni-

tude for the deferred saccades and is only slightly smaller than the PSB on the step-saccade task. This equality is particularly unexpected in light of a similar comparison recently carried out in the SC by Edelman and Goldberg (2001). They found that many SC burster cells did not respond in conjunction with memory saccades or responded much less than on their version of the deferred-saccade task. Thus, it would seem that FEF PSB activity is more reliable than SRB activity in the SC in conjunction with purposive memory-guided saccades performed without a visual target, even though the SRB activity in the SC is thought to be significantly more reliable than the PSB activity in FEF for most saccades, especially spontaneous saccades.

⁸Note regarding task terminology: both the deferred-saccade and memory-saccade tasks prominently feature a delay period, and indeed, both have been called *delay tasks* or *delayed-saccade tasks* in recent papers (e.g., Edelman and Goldberg, 2001; Sommer and Wurtz, 2000, 2001). However, to avoid confusion we do not use the term *delay* or *delayed* for either. Originally, *delayed* denoted a mnemonic task (e.g., *delayed saccade*: Hikosaka et al., 1989; *oculomotor delayed-response task*: Funahashi et al., 1989), and historically, it refers to the *delayed-reaction* task that Jacobsen (1936) used to test the memory of monkeys with frontal lesions. However, the deferred-saccade task does not involve memory, only a wait, so it is misleading to call it delay task. It was originally termed the *stable target saccade task* by Bruce and Goldberg (1985); later, Russo and Bruce (2000) termed it the *deferred-saccade task*.

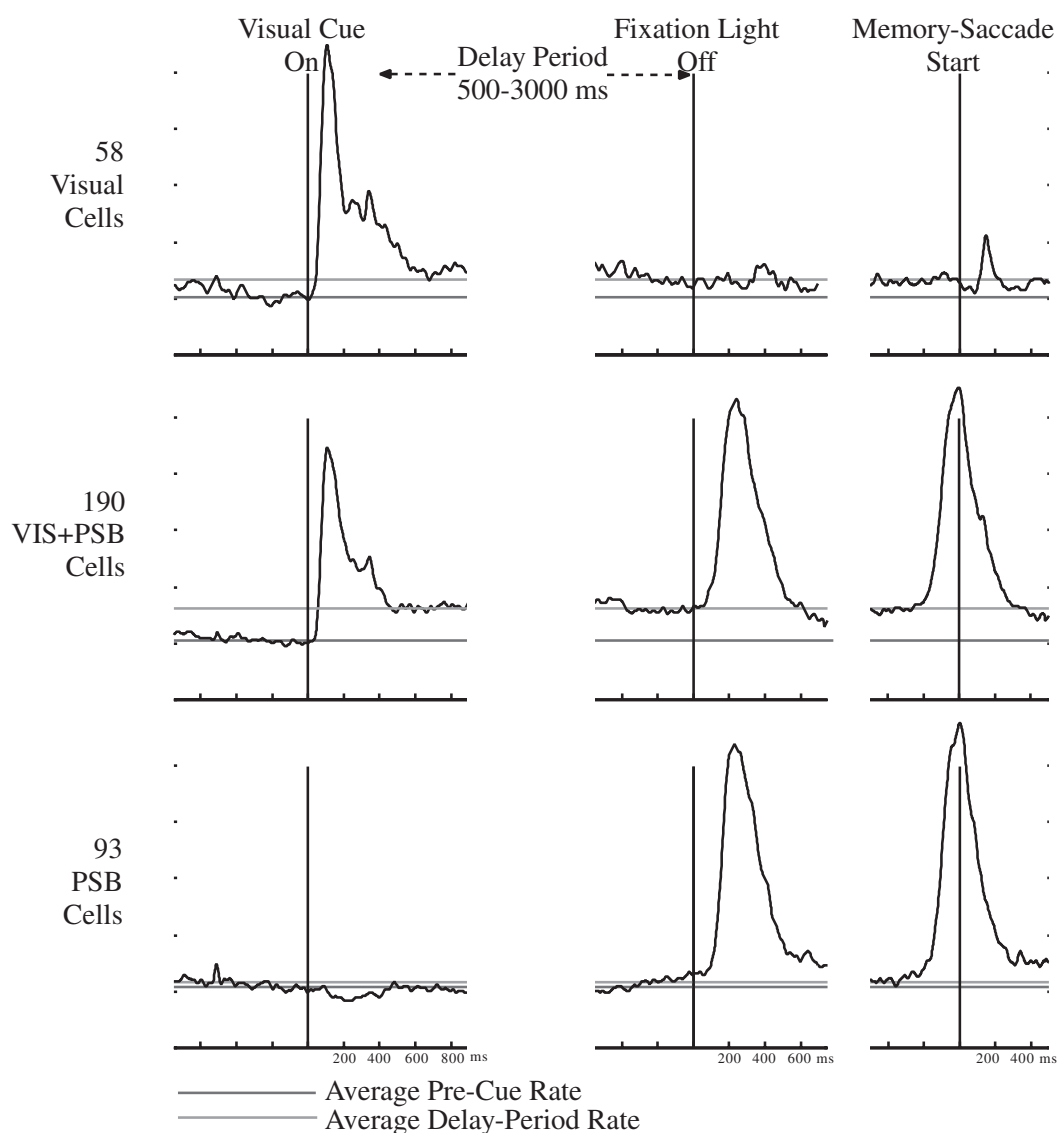

FIGURE 96.6. Aggregate FEF response on the memory-saccade task segregated by neuron type. This is the same experiment and data as in the previous figure, and presented in the same way except that the 341 neurons are separated into three categories: *Top*: neurons with only a visual response; *Middle*: neurons with both a visual (VIS) and a presaccadic burst (PSB); *Bottom*: neurons with a

PSB but no visual response. The red lines indicate the average baseline rate during fixation; the green lines are the average rate during the delay period after the cue is off. Note that PSB-only neurons do not have an elevated rate during the delay period and that VIS + PSB neurons have a higher elevation than VIS-only neurons. (Data from Friedman et al., 1997.)

BASIS OF PSBs FOR STEP, DEFERRED, AND MEMORY SACCADDES

FEF visual activity. As mentioned earlier, over half of the neurons in FEF are visually responsive. Typically, they have large RFs entirely or predominantly in the contralateral visual hemifield and respond promptly to the appearance of almost any visual stimulus within their RF, with little selectivity for color or form. FEF visual responses do not require overt attention to the stimulus or to the stimulus location, or that the visual stimulus have any functional significance. In general, the only requirement is that the stimulus be in the cell's RF.

Phasic, tonic, and mnemonic visual activities. The strongest visual responses in FEF are the short-lived phasic responses to the initial appearance of visual targets (e.g., Figs. 96.4 and 96.5). The intense phasic responses can serve as both target and trigger for FEF PSB activity in the step-saccade task. This reflects the fact that the initial appearance of a visual target sometimes immediately garners an unwelcome saccade in the deferred-saccade and memory-saccade tasks, and also the fact that saccades in the step-saccade task have significantly shorter latencies relative to tasks in which the trigger to saccade is given long after the initial visual response (e.g., a mean of 236 msec for the step saccades

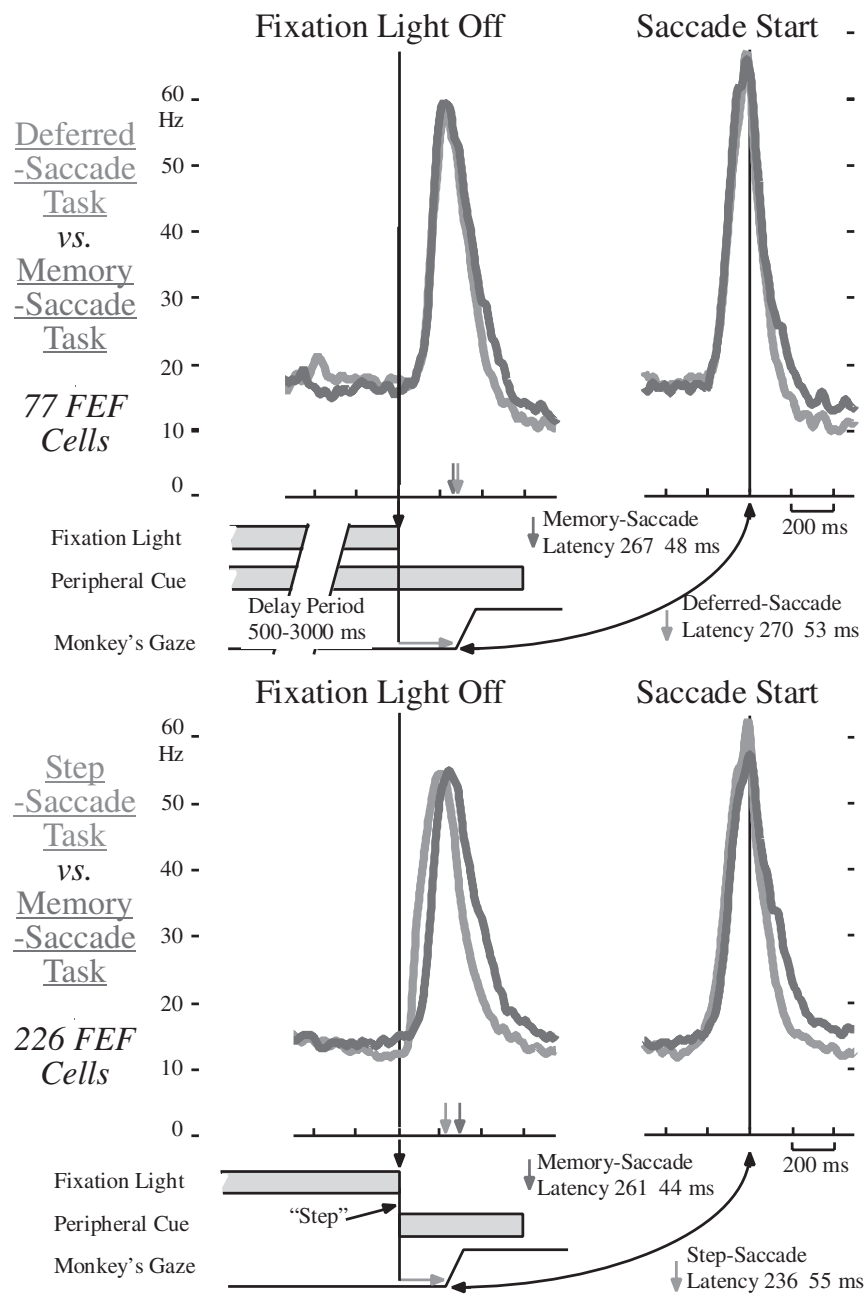

FIGURE 96.7. Comparison of PSB activity in FEF for visually guided saccades with PSB for memory-guided saccades. Histograms are aggregate activity of sets of FEF neurons recorded from six different monkeys during both tasks. *Top*: deferred-saccade task. Shortly after the monkey fixates a central light, a peripheral target appears in the neuron's response field. This target remains on for the remainder of the trial, but no saccade is permitted until the fixation light is extinguished at the end of the delay period. Thus, the target is an established presence at the time of the saccade. *Bottom*: standard step-saccade task. The fixation light is extinguished at the same time that the peripheral target appears. *Left*: histograms aligned on the fixation point's extinction. Note that the deferred-saccade PSB activity has the same latency as the memory-saccade PSB activity, but that the step-saccade response

slightly leads the memory-saccade response; however, the memory saccades themselves have a longer latency than the step saccades. *Right*: histograms aligned on the saccade start. Note that the deferred-saccade PSB has the same magnitude as the memory-saccade PSB activity, but that the step-saccade PSB activity is larger than the memory-saccade response; presumably this reflects the phasic visual response to the appearance of the peripheral target of the VIS + PSB cells in this sample. The number of neurons is smaller than that in the previous figures because (1) only a subset of the 341 cells were tested on both of these two visually guided saccade tasks, and (2) VIS-only cells were omitted from this comparison; only the PSB-only and the VIS + PSB cells were used. (Data from Friedman et al., 1997.)

vs. 270 msec for the deferred saccades for the behavior in Figure 96.5).

Some FEF cells respond phasically only to visual stimuli; however, assuming that a saccade to the stimulus's initial appearance does not occur, other visual cells then discharge tonically, usually at a relatively low rate, for as long as the stimulus remains in their RF (e.g., Fig. 96.4). This tonic FEF visual activity is available to target saccades to established visual targets on the deferred-saccade task when the signal to saccade is finally given.

After the visual cue is extinguished, many FEF cells still have significantly elevated activity during the delay period of the memory-saccade task (e.g., Figs. 96.4 and 96.5). This persistent mnemonic activity provides the targeting information that could underlie the spatially appropriate PSBs that materialize in FEF following the signal to saccade (usually extinction of the fixation light) at the end of the delay period. In Figure 96.6, note that the mnemonic/delay-period rate is most elevated for the combined visual-PSB cells, less elevated for the 58 visual-only cells, and nearly at the baseline level for the 93 PSB-only cells. Thus, FEF mnemonic activity is strongly associated with visual activity but is greatest in those visually responsive cells that also have PSB activity.

Alignment of visual and presaccadic movement fields. Visuomovement FEF cells have both visual and PSB activities, and their visual RF generally corresponds with the optimal saccade vector for their burst (i.e., movement field), as was shown for the cell of Figure 96.4. Moreover, the electrically elicited saccadic eye movement vector obtained at the cell's location generally matches its response fields as well. Thus, the FEF default is a foveating saccade. However, the PSB is independent of the location and/or presence of visual stimulation, particularly as shown by the antisaccade tasks and remapping experiments. Moreover, when carefully tested and fit as the cell in Figure 96.4, some visuomovement FEF cells turn out to be significantly discordant, with nonmatching, or even nonoverlapping, visual and movement fields (Friedman et al., 1998).

AURALLY GUIDED SACCADDES FEF activity also precedes saccades guided by sounds (aurally guided saccades). Russo and Bruce (1994) taught monkeys to make saccades directed to noise from one of eight speakers mounted along a horizontal hoop in front of the monkey. They then tested FEF cells in the dark after arranging the speaker hoop so that one of the speakers directed saccades into the cell's movement field. Figure 96.8 shows a representative FEF cell's response and a scatter plot of the data of all cells tested. In general, the magnitude of each cell's PSB for aurally guided saccades was comparable to its PSB for similar saccades directed to visual or visual-memory targets. Analogous

FIGURE 96.8. PSBs of FEF neurons in conjunction with aurally guided saccades. The rasters on the *right* show activity of an FEF neuron preceding visually guided saccades to an LED and preceding identical saccades guided to noise from a speaker at the LED location in the dark. The traces above the rasters show the waveform of representative visually and aurally guided saccades, and the raster lines are aligned on the saccade start. The scatter plot on the *left* shows, for all 22 FEF cells tested, PSB rates for aurally guided saccades versus those for visually guided saccades. (Adapted from Russo and Bruce, 1994.)

burst activity in the SC precedes aurally guided saccades (Jay and Sparks, 1987a).

Remapped FEF auditory activity. Although auditory responses in FEF are infrequent, some cells in and near the medial FEF do respond to sounds (Azuma and Suzuki, 1984; Bruce, 1990; Bruce and Goldberg, 1985; Russo and Bruce, 1989). However, the sound source location is initially given in head-centered coordinates, and it would seem inappropriate to generate PSBs in an oculocentric framework. Interestingly, these auditory RFs in frontal cortex are partially remapped from a craniocentric to an oculocentric framework (Russo and Bruce, 1993), similar to the remapping of SC auditory fields found by Jay and Sparks (1987b).

Such remapping should facilitate the production of appropriate PSB activity for aurally guided saccades. However, this production is complicated by the fact that the monkey's ears move substantially, and these pinna movements have a systematic relation to voluntary eye movements (Bruce et al., 1988). Since pinna orientation strongly affects the magnitude of the sounds reaching the inner ear, accurate remapping of the sound source location to oculocentric coordinates would have to take pinna position, as well as eye position, into account. Interestingly, the macaque has a small pinna movement region of cortex adjacent to the medial (large-saccade) region of the FEF (Burman et al., 1988).

ANTISACCADDES FEF neurons have robust PSBs in conjunction with antisaccades. For most FEF cells, the spiking rates are higher for prosaccades than for antisaccades (Everling and Munoz, 2000); however, a few FEF cells had significantly higher rates for antisaccades. Interestingly, several imaging studies have found that the human FEF is more active during antisaccades than in conjunction with prosac-

cares (e.g., O'Driscoll et al., 1995).⁹ As mentioned earlier, deficits in performing antisaccades are associated with FEF damage.

Everling and Munoz (2000) also found that saccade-related neurons in FEF had lower prestimulus and stimulus-related activity on antisaccade trials compared with prosaccade trials. This provides a plausible FEF mechanism for suppressing the prepotent prosaccade directly to the cue in the antisaccade situation. In fact, suppressing erroneous prosaccades is also a problem for patients with FEF damage (Guitton et al., 1985).

EXPRESS SACCADIC AND PREDICTIVE SACCADIC Dias and Bruce (1994) tested FEF neurons with the gap paradigm, which tends to trigger very short-latency *express* saccades. In the standard gap paradigm, the signal-to-saccade (e.g., fixation light off) precedes the peripheral target appearance by a 200 msec gap in time. It seemed possible that FEF cells might fail to burst *before* short-latency saccades on this paradigm, because Schiller et al. (1987) showed with experimental lesions that the SC is necessary for express saccades and that the FEF is not. However, Dias and Bruce found that all FEF cells with PSB activity still burst prior to short-latency saccades in the gap task. Moreover, approximately one-half of the FEF cells with PSB activity also responded to the gap event itself before the peripheral target came on. This *fixation-disengagement discharge* (FDD) is basically a prediction, as shown in Figure 96.9, because the target appeared in the cell's response field in only half of the trials. Thus, fixation-light extinction induces a moderate discharge of a large population of FEF cells representing a spectrum of possible saccades. This FDD could play a critical role in shortening saccade latency under the gap paradigm (the *gap effect*) by priming the SC (and the FEF) to respond more quickly and strongly upon the arrival of the peripheral visual signal informing which saccade to make. Moreover, these data indicate that FEF has a role in disengagement of fixation before saccades. It also indicates a powerful mechanism for quickly suppressing inappropriate FDD activity when a saccade outside the cell's movement field is called for, possibly the same mechanisms that terminate the buildup of PSB activity in order to stop a saccade from being made in the countermanding paradigm (Hanes et al., 1998).

The FDD is similar to the *anticipatory* discharge phenomenon: ~20% of FEF cells with PSB activity have an augmented discharge during fixation in a saccade task com-

pared to identical fixation in a nonsaccade task (Bruce and Goldberg, 1985). However, the FDD is a more robust response and is found on a much larger percentage of FEF cells. Furthermore, anticipatory activity is spatially selective in that it anticipates impending saccades into the cells' movement field, not just any impending saccade, whereas the FDD seems to involve disengagement of the current fixation prior to spatial specification of the saccade vector.

Fixation status signals (tonic foveation and eye position activity). The FEF cells that respond in relation to fixation or foveal stimulation could trigger both the FDD and PSB. One such type is excited by fixation (foveal) stimulation; these cells could play a role in suppressing activity in FEF and elsewhere in the interest of maintaining fixation. Another class has the inverse activity, being suppressed by foveal stimulation and spiking in response to extinction of the fixation light. Hanes et al. (1998) found that the discharge of FEF fixation neurons exhibited saccade-control properties in the countermanding situation. Moreover, fixation cells in FEF often project to the SC (Segraves and Goldberg, 1987), where their signals could play a role in triggering and suppressing SRB activity there.

Some of these fixation responses are modulated by the current eye position, and a few FEF cells simply respond tonically as a linear function of absolute eye position, for example, azimuth or elevation (Bruce and Goldberg, 1985). Both of these phenomena could be created by an efferent copy signal derived from the common neural integrator in the brainstem. This signal of current eye position may allow the FEF to be somewhat biased against calling for centrifugal saccades that move the eye to extreme orbital positions, and to be biased for centripetal saccades that move the eye closer to a central position in the orbit. An eye position signal could be used to remap sensory locations (see below).

REMAPPED SACCADIC (DOUBLE-STEP SACCADIC TASK) When peripheral lights at two separate locations are each briefly flashed in quick succession such that the second light is already extinguished before the eye has moved at all,¹⁰ primates naturally saccade to the physical location where the first light appeared and then, following a brief fixation period, make a second saccade to the physical location where the second light had appeared (Hallet and Lightstone,

⁹ However, a recent functional magnetic resonance imaging study (Connolly et al., 2000) located antisaccade activation in the human as being slightly anterior to the FEF, as identified by prosaccade activation.

¹⁰ Goldberg and Bruce (1990) typically used a 100 msec duration for the first light followed by a 50 msec duration for the second, as the latency of the first saccade was generally >150 msec.

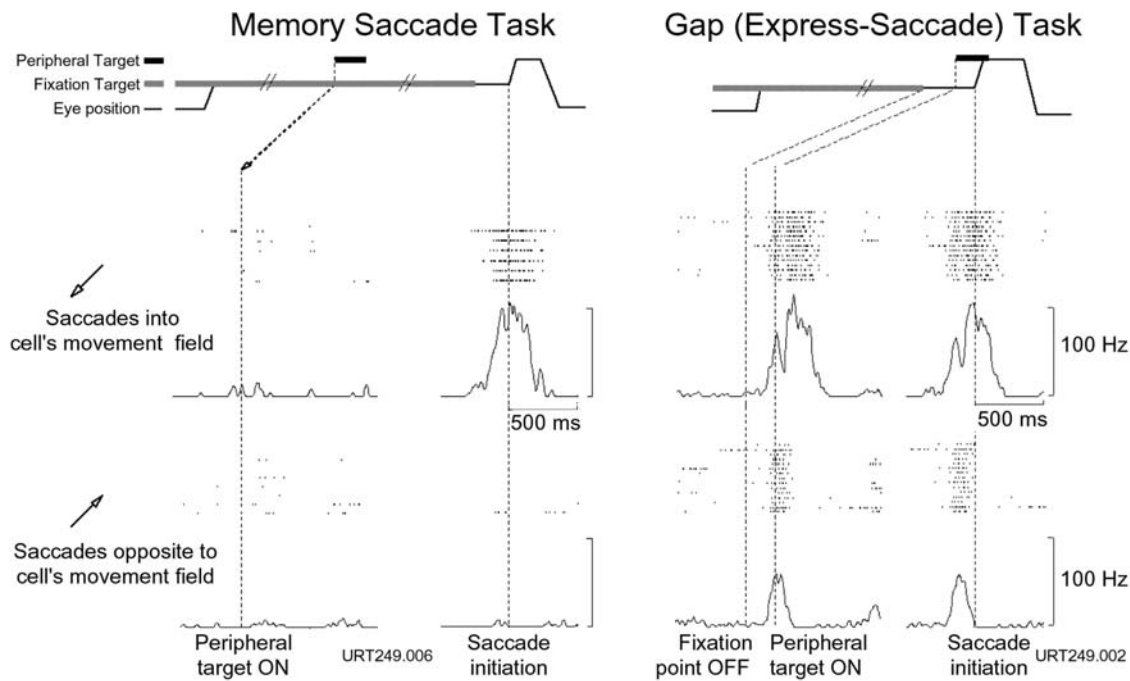

FIGURE 96.9. Activity of an FEF neuron with PSB activity on the memory-saccade task showing an FDD on the gap task. This neuron had no response to visual stimulation (PSB-only cell). *Left*: memory-saccade task. The paradigm is diagrammed at the top. The delay period is ~1 second, and two target locations were randomly interspersed: one in the center of the cell's response field—down and left—and the other opposite the cell's response field—up and right. Raster lines and spike density histograms on the left are aligned to the onset of the peripheral target. Those on the right are aligned to the beginning of the saccade; there is a strong PSB on all trials before saccades into the cell's movement field. *Right*: gap task. As diagrammed at the top, there is a 500-msec gap between the disappearance of the fixation target and the appearance of the peripheral saccadic target. Again, trials into and opposite to the cell's response field were randomly interspersed. The raster-histogram data on the left are aligned in relation to the task

events (disappearance of the fixation target and, 500msec later, appearance of the peripheral target). On the right, the same data are aligned on the saccade initiation. The median saccade latencies for this monkey in the gap task were ~80 msec quicker than for trials in a conventional step-saccade task without a gap (not shown) and over 100 msec quicker than its memory-saccade latency. In the gap task, the cell always had an FDD following the disappearance of the fixation target, but this FDD led into a PSB only when the saccade called for was into the cell's movement field and was sharply suppressed when the saccade was opposite to the cell's movement field. Note that there is no corresponding response to the disappearance of the fixation light in the memory-saccade task for trials opposite the cell's movement field, showing that the FDD is not simply a foveal off response. (Adapted from Dias and Bruce, 1994.)

1976).¹¹ This behavior is remarkable in that the vector of the second saccade is radically different from the vector from the fovea to the second light that the visual system registered. Mays and Sparks (1980) found that SC cells whose movement field matched the second saccade vector were usually very active in this situation, even though the visual cells in the superficial layers directly above them had not been visually activated. When FEF cells with PSB activity are tested (Goldberg and Bruce, 1990), a similar result obtains. Thus, PSBs in both FEF and SC "perform" the double-step saccade task.¹²

Remapped visual activity. Goldberg and Bruce (1990) hypothesized that a subtraction operation within FEF uses an efferent copy of the first saccade to remap FEF visual activity evoked by the second light to be suitable for guiding the second saccade (see also Bickle et al., 2000; Bruce, 1990;

Umeno and Goldberg, 1997, 2001). In other words, visual activity in FEF is initially given in retinal coordinates but is remapped by saccades to maintain its oculocentric validity. Similar remapping of visual activity is prominent in PEF (Colby and Goldberg, 1999), and PEF may be critical for the double-step situation (e.g., Duhmael et al., 1992).

¹¹ In early versions of the double-step saccade task, the second light appeared before the eye moved, but it remained on for the remainder of the trial. Westheimer, Wheelless, and others used this pulse-step version to study the ballistic nature of saccades. Hallet and Lightstone subsequently introduced the critical version wherein the second light flashes only briefly, and thereby completely disassociates the second visual vector from the second saccade vector.

¹² However, neither FEF nor SCs are critical for performing the double-step saccade task, and some reports indicate that PEF is the most important oculomotor structure for the remapping involved.

FEF postsaccadic activity codes the last saccade (efferent copy). Postsaccadic activity in FEF was first described by Bizzi (1967, 1968), and ~25% of FEF neurons are excited *after* particular saccadic eye movements (Bruce and Goldberg, 1985). This postsaccadic activity seems to represent an efferent copy of saccades actually executed, as it reliably follows all types of saccades made into the cell's postsaccadic movement field, even spontaneous saccades made in the dark or quick phases of nystagmus. An efferent copy of saccadic displacements, as coded by postsaccadic activity in FEF, is critical for several purposes. Interestingly, many FEF cells with presaccadic (visual, PSB, or both) activity often have postsaccadic activity for saccades directed opposite their presaccadic response fields. This reciprocity provides a mechanism for readily returning to the previous fixation (i.e., glances).

General suppression of presaccadic activities by saccade execution. A striking aspect of FEF presaccadic activity of all types (e.g., anticipatory, visual, mnemonic, and PSB) is that it quickly ends upon the execution of a saccade into the RF. Note in Figure 96.4 and in all the aggregate histogram figures that saccade execution actively ends the PSB shortly after the saccade, and often the postsaccadic rate goes well below baseline. Control experiments (Bruce, 1990) show postsaccadic suppression of both visual and mnemonic activities as well.

This suppression could come from the postsaccadic coding of prior saccades (efferent copy) just described. Such suppression is very important, because visual or mnemonic activity coding a peripheral cue location becomes misleading once the monkey foveates the peripheral location. Without prompt suppression, persistent activity could lead to multiple triggering of the same saccade, much like the "staircase" of saccades evoked by continued electrical stimulation in FEF. Bruce (1990) suggested that this suppression could be conceptualized as a single-step case of the efferent copy subtraction operation hypothesized to remap visual stimulus signals in FEF in the double-step paradigm, and thereby underlie double-step task behavior and physiology described earlier. Thus, the double-step behavior, the glance, and the virtue of not making multiple saccades in response to a single stimulus step may all reflect the same global transformation of FEF activity effected by the postsaccadic activity it receives following each saccade that is executed.

SACCADES TO MOVING TARGETS Saccades to rapidly moving targets are usually directed at a predicted target location, based on both the target's retinal position and its velocity as perceived 100 msec or so before the saccade starts. The PSBs of some FEF neurons evidence this velocity-predictive process, indicating that target motion information is being

utilized (Shi et al., 1995) and also that some visual activity in FEF was remapped by target velocity, which could provide targeting for the predictive PSB activity. Interestingly, the SC does not seem to provide such a predictive signal (Keller et al., 1996).

SACCADES BASED ON SELECTING FROM AMONG MULTIPLE TARGETS The paradigms discussed thus far show a single peripheral target at only one location (at a time), and therefore there is little ambiguity about the correct saccade vector. Testing FEF cells with paradigms that require a monkey to select the saccade target from among two or more concurrently seen peripheral targets shows profound effects of multiple targets and of target search and selection on visual activity in FEF (Schall and Hanes, 1993; Schall et al., 1995; Thompson et al., 1996, 1997). Nevertheless, FEF cells having PSBs respond reliably in relation to these complex volitional saccades matching the cell's movement field. Similarly, Shi et al. (1998b, 2000) found that FEF cells with PSB activity reliably burst before correctly performed saccades to targets in their response fields during a color match-to-sample memory task, even though the visual response to the RF target was far smaller whenever an alternative target simultaneously appeared in the opposite hemifield, as compared to control trials which presented only the correct target.

The oldest hypothesis is that FEF (and other structures) could select a stimulus to be a saccade target by somehow "enhancing" the intrinsic visual responses to that stimulus (e.g., Goldberg and Bushnell, 1991; Wurtz and Mohler, 1976). Moreover, when monkeys view a complex scene with natural scanning, enhanced visual responses effectively predict the next saccadic eye movement (Burman and Segraves, 1994). However, recent studies (Kodaka et al., 1997; Murthy et al., 2001) found that enhancement and selection of visual activity in FEF can be independent of eye movements and saccade programming. Similarly, Hanes et al. (1998) reported that FEF's visual activity did not predict or control the countermanding of saccades.

SUMMARY OF FEF SACCADE-RELATED ACTIVITIES AND PHENOMENON In conclusion, a diverse set of functional activities and cortical circuits underlie FEF's programming of purposive saccades in the monkey. These serve to facilitate the generation of appropriate PSBs in diverse situations and paradigms. In this respect, there is a more philosophical implication, beyond the realm of saccade latencies. Even though some FEF activity is firmly based on physical facts (visual stimuli, auditory stimuli, etc.), FEF PSB activity is neither a motor response nor a transformed or enhanced sensory response. It is more a motor prediction or guess based on the possibility and probability that a saccade into the cell's response field may or should soon happen

(Hasegawa et al., 2000). Human FEF is very active in conjunction with predictive saccades (O'Driscoll et al., 2000).

Bruce (1998) explored neural network models of FEF focusing on the generation of PSB activity. A small set of inputs represented FEF visual activity (eight peripheral and one foveal) in response to visual task events, and eight additional inputs provided postsaccadic corollary discharge input following saccadic events. These inputs went to a randomly connected two-layer Elman network with 32 hidden neurons. The network was trained using backpropagation, with the goal of having its eight output neurons learn to mimic PSB activity in FEF, each for a different optimal direction (0, 45, 90, 135, 180, etc.). The step-saccade, deferred-saccade, and memory-guided saccade paradigms were intermingled during training, with delays and target durations and locations varied over large ranges. This simple network learned to generate appropriate PSBs in the output neurons for all three paradigms. Hidden neurons had different combinations of visual, movement, and mnemonic activity with a variety of response fields. It is not known if such a simple network can learn to generate FEF-like PSBs for all the types of saccades reviewed earlier (e.g., express saccades, double-step saccades, antisaccades).

FEF and smooth pursuit eye movements

Smooth pursuit eye movements are the smooth, relatively slow (up to 100°/s) eye movements used to track moving targets. As was shown in Figure 96.2, the smooth pursuit zone of the macaque FEF (FEFsem) lies principally in the fundus of the arcuate sulcus. Microstimulation in FEFsem elicits smooth eye movements (usually ipsiversive) at fairly low thresholds. Discrete inactivation within FEFsem causes dramatic but reversible deficits in ipsiversive pursuit (Shi et al., 1998a), and unilateral FEF lesions that include the fundus cause profound and permanent pursuit deficits (Keating, 1991; Lynch, 1987; MacAvoy et al., 1991) even though the optokinetic reflex is not diminished by bilateral FEF ablation (Keating et al., 1996). Interestingly, schizophrenic patients show deficits in smooth pursuit (but normal optokinetic following); this deficit further implicates frontal lobe dysfunction as an underlying factor in schizophrenia (e.g., MacAvoy and Bruce, 1995; Sweeney et al., 1998).

As indicated in Figure 96.1, the smooth pursuit part of the human FEF is in the same relation to the saccadic FEF (Berman et al., 1999; Blanke et al., 2000; O'Driscoll et al., 2000; Petit et al., 1997; Rosano et al., 2002). Humans also show deficits in ipsiversive pursuit following damage to the FEF region.

SENSORY-TO-MOTOR TRANSFORMATION FOR SMOOTH PURSUIT
Neurons throughout the pursuit pathway have been studied

in the rhesus monkey. Similar to the saccadic system, neuronal activity in structures closer to the retina has obligatory responses to visual stimuli, but closer to the oculomotor nuclei the neural activity is more closely aligned with motor behavior. For example, most neurons in V5 are selective for the direction of stimulus motion that is not tracked. At the motor end, the smooth eye-velocity signal is elaborated in several pontocerebellar circuits, including the dorsolateral and the medial pontine nucleus and the nucleus reticularis tegmenti pontis, together with cerebellar pursuit areas: the flocculus, paraflocculus, and dorsal vermis. Many neurons in these structures respond as a fairly direct function of pursuit velocity.

The critical step in this sensorimotor transformation underlying pursuit is provided by neurons that respond to target motion, but *only* (or principally) when and if the target is *selected* for foveation/pursuit. The smooth pursuit zone of FEF is a candidate site. It lies downstream from V5 and other areas that provide most of the visual motion information for smooth pursuit but upstream from pontocerebellar and brainstem circuits that effect smooth pursuit movements (Fig. 96.3), (Stanton et al., 1998). Many FEF pursuit cells discharge to the motion of a pursuit target in a particular direction over nearly all of the visual field, but discharge remarkably little to targets moving in the same direction that are not pursued (Fukushima et al., 2000; Gottlieb et al., 1993, 1994; MacAvoy et al., 1991; Tanaka and Fukushima, 1998; Tanaka and Lisberger, 2001). Figure 96.10 shows such a neuron and the pursuit deficit caused by discrete inactivation at the site of that neuron. Interestingly, fMRI data in humans indicate that FEF and PEF are strongly activated by attentive tracking of moving targets (over their activation during passive viewing of the same visual motion), but the posterior temporal motion areas such as V5 are not rendered more active in the tracking condition (Culham et al., 1998).

FEF and disjunctive eye movements

Gamlin and Yoon (2000) found elicited vergence eye movements and neuronal responses during natural vergence movements in a small region of macaque cortex between the posterior tip of the principal sulcus and the FEF boundary at the anterior lip of the arcuate sulcus. In general, these phenomena involved purely vergence movements without saccades, and the authors concluded that this region should be regarded as a vergence (and accommodation) zone of FEF. Ferraina et al. (2000) found that visual responses throughout FEF were generally selective for binocular disparity, with a range of crossed and uncrossed disparities coded across cells. Their finding raises the possibility that the FEF may command suitably disjunctive saccades whenever the target is at a different depth than the fixation point.

FEF Unit Responsive in conjunction with Ipsilateral (leftward) Smooth Pursuit

Not Responsive to Motion-only Control

Good Pursuit prior to muscimol injection at site of above pursuit neuron

Deficient Ipsilateral Pursuit following muscimol Injection

Summary

Eye movements require the integration of a diverse spectrum of physiological activities: sensory, motor, efferent copy, mnemonic, predictive, and cognitive. Physiological correlates of all of these activities have been identified in the primate FEF. This allows the FEF to serve as a model system of sensorimotor integration in the cerebral cortex. In humans, the frontal lobes are crucial for executing short- and long-range plans and complex coordinated behaviors by sustaining multiple specific and general goals while processing information, actions, and even thoughts directed at achieving. Parallels between such complex human behaviors and certain oculomotor behaviors suggest that understanding the physiological mechanisms of FEF function in such oculomotor situations could provide a basis for consideration of the neural mechanisms underlying more complex aspects of human frontal lobe function.

FIGURE 96.10. Activity of FEF pursuit neuron and pursuit deficits after FEF deactivation. *Top left:* the pursuit neuron, recorded in the left hemisphere FEF, was active in conjunction with leftward (negative moving on the traces) smooth pursuit, responded throughout the leftward phase in all three cycles of sinusoidal motion (0.5 Hz), and discharged prior to leftward predictive pursuit that occurred at the end of each sinusoidal tracking trial. *Top right:* the neuron responded very little to visual motion that was not pursued and was completely silent, except for three spikes on the initial cycle, when

the monkey fixated a stationary point while viewing the same sinusoidally moving stimulus. *Bottom left:* normal sinusoidal (1.0 Hz) smooth pursuit of this monkey immediately before the injection. *Bottom right:* poor smooth pursuit immediately following a small muscimol injection at the site of the pursuit neuron shown above. Leftward smooth eye velocity was lower on every cycle, especially the first, and there was no more predictive pursuit after the target extinguished. (Adapted with permission from Shi et al., 1998a.)

97 Changing Views of the Role of Superior Colliculus in the Control of Gaze

NEERAJ J. GANDHI AND DAVID L. SPARKS

LOCATED AT THE interface between sensory and motor processing, the superior colliculus (SC) serves as a useful model system for studying a number of important problems in integrative neuroscience. Based on traditional studies, the SC is known to contain maps of cells responsive to sensory stimuli, as well as a motor map of neurons involved in generating commands for saccades and short-duration and high-peak-velocity eye movements that rapidly change fixation between meaningful stimuli.

Since the last detailed review of the control of saccades by SC (Sparks and Hartwich-Young, 1989), our view of its participation in generating movements has changed significantly. Advances in understanding the role of the SC in the transformation of sensory signals into commands for orienting movements are reviewed here and in Chapter 98. The first two sections of this chapter briefly review progress in our knowledge of the anatomical organization and coding mechanisms of the SC. Subsequent sections discuss selected contemporary issues about collicular participation in achieving accuracy of saccades and in controlling other oculomotor and skeletomotor movements.

Anatomical organization in the SC

The superior and inferior colliculi form the roof of the mid-brain. In mammals the SC is composed of seven alternating fibrous and cellular layers. On the basis of anatomical and behavioral data, these layers are grouped into two functional units: (1) superficial and (2) deep compartments. The superficial layers (*stratum zonale*, *stratum griseum superficiale*, and *stratum opticum*) receive inputs devoted almost exclusively to vision. Cells in the superficial layers of each colliculus are activated by stimuli appearing in the contralateral visual field and are topographically organized according to receptive field location (Cynader and Berman, 1972). Neurons with receptive fields near the center of the visual field are located anteriorly; those with receptive fields in the periphery are located posteriorly. Cells with receptive fields in the upper visual field are located medially; those with receptive fields in the lower visual field are located laterally. The perifoveal representation is enlarged, with over one-third of the collicular surface devoted to the central 10 degrees of the visual

field. The representation of the horizontal meridian runs from anterolateral to posteromedial. The visual signals observed are in retinal coordinates; cells respond to visual stimuli if, and only if, particular regions of the retina are activated. The outputs of the superficial layers are primarily ascending and terminate, for the most part, in various regions of the thalamus, including the pulvinar (see Sparks and Hartwich-Young, 1989, for a review).

In contrast, the intermediate (*stratum griseum intermedium*, *stratum album intermedium*) and deeper (*stratum griseum profundum* and *stratum album profundum*) layers—collectively, the deep layers—receive sensory inputs of several modalities (e.g., visual, auditory, and somatosensory) and contain neurons with motor properties. In their early description of SC neurons discharging before saccadic eye movements, Wurtz and Goldberg (1972) noted that the neurons have *movement fields*, that is, each neuron discharges before or during saccades having a particular range of directions and amplitudes. The size of the movement field is a function of the amplitude of the optimal movement. Some neurons that discharge prior to saccades also have visual receptive fields, while other neurons have only movement fields. Neurons discharging in response to visual stimuli and prior to eye movements have overlapping, but not necessarily coextensive, movement and receptive fields (Anderson et al., 1998; Wurtz and Goldberg, 1972).

Based on both neural recording and microstimulation experiments in head-restrained animals, it has been established that saccade direction and amplitude are topographically organized in the deep layers of the SC (Robinson, 1972; Schiller and Stryker, 1972). Neurons discharging prior to small saccades are located anteriorly, and those firing before large saccades are found posteriorly. Cells near the midline discharge prior to movements with up components, and those on the lateral side discharge maximally before movements with down components. Microstimulation of the deep layers produces a saccadic eye movement with an amplitude and a direction similar to those of the optimal vector encoded by the neurons near the tip of the electrode.

Despite the general correspondence between the motor and overlying sensory maps, there is no essential functional

linkage between retinotopically coded visual activity in the superficial layers and saccade-related premotor activity in the deep layers of the SC. Vigorous activity may occur in the superficial layers and may not be translated into saccade-related discharge in underlying cells in the deep layers. Conversely, saccade-related activity recorded from neurons in the intermediate and deeper layers may not be triggered by activity of the overlying visual neurons coding retinal error, that is, the distance and direction of the target image from the fovea. Thus, the activity of visual neurons in the superficial layers is neither necessary nor sufficient to produce activation of saccade-related neurons in the deep layers of the underlying colliculus (Mays and Sparks, 1980).

Yet, chemical inactivation in hamster SC (Mooney et al., 1992) and *in vitro* experiments in SC slices using whole-cell patch-clamp methods (Isa et al., 1998; Lee et al., 1997) have demonstrated synaptic transmission from superficial to intermediate layers. Excitatory postsynaptic potentials, evoked with mono- and polysynaptic latencies, were recorded from neurons in the intermediate layers when the overlying superficial layer was stimulated. In the presence of bicuculline, neurons in the intermediate layers even exhibited a burst upon stimulation of the superficial layers, suggesting that the signal transmission is suppressed by GABAergic inhibition. The burst property of intermediate layer neurons was also facilitated by activation of nicotinic acetylcholine receptors (Isa et al., 1998). Behaviorally, the occurrence of short-latency express saccades increased after microinjections of the acetylcholinergic agonist nicotine in the SC of awake, behaving monkeys (see Kobayashi et al., 2001, for a review). Thus, this interlaminar circuitry may play a critical role in reducing saccadic reaction time and triggering express saccades, which are absent following ablation of the SC (Schiller et al., 1987). A description of SC participation underlying saccadic initiation has been reviewed recently (Munoz et al., 2000; see Sparks et al., 2000, for a slightly different perspective).

Unlike the interlaminar organization, the neurons within the deep layers likely use local excitation and distant inhibition mechanisms to shape the evolution of the population activity that leads to the generation of each saccade. The electrophysiological (McIlwain, 1982; Munoz and Istvan, 1998) and pharmacophysiological (Meredith and Ramoa, 1998; Pettit et al., 1999) experiments that provide credence for such connectivity monitored extracellular activity while stimulation pulses were delivered to different parts of the collicular map. Thus, intracollicular connections likely shape the spatial and temporal profiles of activity, although a potential confound may be introduced by stimulation of fibers of passage. Before and during each saccade, neurons in approximately 25 to 30% of the collicular map discharge, and the size of the active area remains relatively invariant across saccades of all amplitudes and directions (Anderson

et al., 1998; McIlwain, 1975; Munoz and Wurtz, 1995b). The SC neurons project predominantly to brainstem structures that process the collicular commands to produce an appropriate movement.

Population coding

Each SC neuron in the deep layers discharging prior to a wide range of movement vectors translates into a large population of neurons active before and during any saccade. The large movement field characteristic of these cells led to population coding schemes for specifying the metrics of the desired movement (McIlwain, 1975, 1991; Sparks et al., 1976). Indeed, results of experiments in which a small subset of the population of neurons active before a saccade was reversibly inactivated support the hypothesis that each member of the active population participates in specifying the direction and amplitude of a saccade. The evidence indicates that saccadic accuracy results from the *averaging* of the movement tendencies produced by each unit in the active population (Lee et al., 1988; Sparks et al., 1990). Small changes in the direction or amplitude of saccades are produced by slight shifts in the location of the population of active cells within the motor map. Thus, the large movement fields of collicular neurons may contribute to, rather than detract from, the accuracy of saccadic eye movements (Baldi and Heiligenberg, 1988). Because the contribution of each neuron to the direction and amplitude of the movement is relatively small, the effects of variability or noise in the discharge frequency of a particular neuron are minimized.

Lesion data indicating that the SC is not essential for saccade generation (Schiller et al., 1987) do not necessarily indicate that it does not play a critical role in the initiation and execution of saccades in normal animals. Large deficits in saccade accuracy and latency are observed following reversible inactivation of SC (e.g., Aizawa and Wurtz, 1998; Hikosaka and Wurtz, 1985, 1986; Lee et al., 1988; Quail et al., 1998). Metrics of eye movements evoked by stimulation of the frontal eye fields following inactivation of the SC also support the hypothesis that collicular neurons play an important role in controlling the direction and amplitude of saccades (Hanes and Wurtz, 2001).

Neurons in the intermediate and deeper layers of SC also exhibit large receptive fields, and population coding schemes may also contribute to the accurate localization of sensory stimuli. Many neurons are responsive to auditory, somatosensory, or visual stimuli and are organized in anatomical maps (see Stein and Meredith, 1993, for a review). In anesthetized or paralyzed preparations, the visual, somatosensory, and auditory maps appear to be aligned, implying that the sensory signals have been translated into a common coordinate system. Before data from

alert animals were available, it was commonly assumed that this alignment allowed a general, modality-independent map of the external environment to be formed. In such a map, stimuli originating from a particular region of the external world, regardless of sensory modality, would activate a particular subset of multimodal neurons (neurons that respond to visual, auditory, or tactile stimuli). The activation of these sensory neurons, in turn, could initiate orienting responses by exciting adjacent cells with movement-related activity organized in a motor map aligned with the multimodal map of sensory space. But retinotopically organized visual signals, acoustic signals localized in head coordinates, and tactile signals organized in body coordinates will not be aligned when the eyes and limbs move with respect to the head.

A remapping is required to account for changes in the position of the relevant effector. For example, the spatial locations of the receptive fields of acoustically responsive cells shift with changes in eye position. This dynamic update of the site of acoustically driven activity encodes the direction and amplitude of the movement required to look to the auditory stimulus rather than the location of the target in space (Jay and Sparks, 1987; Peck et al., 1995; Populin and Yin, 1998). Groh and Sparks (1996) reported that the response of collicular neurons to tactile stimuli was significantly modulated by the position of the eyes in the orbits. Sensory signals in SC seem to be coding the direction and amplitude of the movement required to look to a stimulus rather than to the location of that stimulus in space. This transformation of sensory signals into a motor frame of reference is necessary because the motor map in the SC is organized in relative coordinates: the signals specify the change in gaze position required to look to a target. Input signals that initiate a movement must also specify the location of the target with respect to the current gaze position, not the location of the target in body or head coordinates.

Incorporation of feedback signals in the SC

As the short duration of saccades prevents visual feedback from contributing to their trajectory, these rapid eye movements once were considered ballistic. However, Robinson (1975) proposed a model in which a “local” feedback signal enables instantaneous control of saccades. While his original version has undergone various revisions, the skeleton of the models has remained the same: a corollary discharge signal is subtracted from the desired eye movement command to compute a dynamic motor error that specifies the metrics of the remaining eye movement; the ongoing eye movement continues until the feedback drives the motor error to zero.

According to some models (see Moschovakis et al., 1996, for a review), the command specifying the metrics of the

desired eye movement originates in the SC, the feedback signal stems from the pontomedullary reticular formation in the brainstem, and the neural comparator performing the subtraction resides downstream of the SC. Therefore, the SC is in the feedforward pathway of the neural circuit controlling saccadic eye movements. This traditional view, however, has been challenged by two nonexclusive hypotheses that place the SC inside the feedback loop. To maintain control of saccades, one theory employs the temporal dynamics of SC neuron discharge, while the other exploits the topographic organization of the SC. In this section, we describe the experiments used to support and dispute these hypotheses.

TEMPORAL CONTROL SCHEME Spikes were recorded as monkeys made saccades of the optimal amplitude coded by the movement field of the isolated neuron. The spike trains were converted into a continuous waveform representing spike rate by convolving each spike with a Gaussian kernel and then summing the individual signals as a function of time (Richmond et al., 1987). SC neurons in the intermediate and deeper layers were classified into one of three categories based on the level of activity at the end of the saccadic eye movement (Waitzman et al., 1991). Neurons with saccade-related bursts that ended completely by saccade offset were termed *clipped* cells. Neurons with saccade-related bursts that declined significantly but maintained low-level activity after the end of the saccade were considered *partially clipped* cells. Neurons that failed to discharge a burst during the saccade but exhibited low-level activity before, during, and after the movement were labeled *unclipped* cells. A quantitative index indicated that, in actuality, SC neurons formed a continuum across the three categories.

The discharge rate of clipped and partially clipped neurons decreased monotonically during the saccade and, therefore, was linearly related to the motor error of the eye movement. This evidence led to the hypothesis that saccade dynamics are controlled by the discharge profiles of the SC neurons (Waitzman et al., 1991). In this model, the locus of activity on the SC encodes the desired eye movement, and the level of activity represents the dynamic motor error. Thus, subtraction of the feedback signal from the desired movement command occurs at the level of the SC, placing it in the feedback loop.

How robust is the correlation between neural activity and dynamic motor error when the dynamics of saccades are altered from their stereotypical short duration? Interrupted saccades can be produced by stimulation of the omnipause neurons (OPNs), which gate the brainstem neurons that deliver the drive to the extraocular motoneurons to produce the saccade (see Moschovakis et al., 1996, and Scudder et al., 2002, for exhaustive reviews of brainstem physiology of

the saccadic system). The stimulation, triggered on the onset of a saccade directed to a briefly flashed target, halted the ongoing movement in midflight, and shortly after the offset of the stimulation train, a resumed saccade was generated to bring the eyes to the location of the extinct target (Keller et al., 1996). Since the dynamic motor error remains constant during the interruption duration (because the eyes are not moving), the temporal control scheme predicts that SC neurons encoding dynamic motor error should exhibit a sustained discharge rate during the interruption. To test this hypothesis, Keller and colleagues (Keller and Edelman, 1994; Keller et al., 2000) recorded activity of caudal SC neurons during saccades generated to the center of the movement field but interrupted by stimulation of the OPN region. As in the control condition, the cell exhibited a pre-motor burst prior to the onset of movement. Stimulation of the OPN region at the onset of the saccade attenuated SC activity, to various degrees in different cells, with the largest suppression observed in clipped and partially clipped neurons. During the interruption duration, the activity did not stabilize at a firing rate corresponding to the remaining motor error. At the onset of the resumed movement, the same neuron active for the initial saccade discharged again, provided that the interruption duration did not exceed approximately 100 msec; thus, for short interruption durations, the locus of collicular activity was not updated prior to the second eye movement. The peak activity associated with the second burst was significantly greater than the expected firing rate according to the temporal coding scheme. Also, the correlation between the firing rate and the motor error of the resumed movement was weaker than for control saccades. These results suggest that clipped and partially clipped neurons do not quantitatively code dynamic motor error. However, it is possible that stricter dynamic control may be exerted only toward the end of a saccade because the temporal relationship appears stronger for the later part of the movement, even in the case of interrupted saccades (compare the solid and dotted curves in Fig. 11 in Keller and Edelman, 1994). For larger interruption durations, the initial and resumed movements appeared to be treated as two separate saccades, as the population of neurons activated for the resumed saccades was the same ensemble of cells that discharged for a control eye movement of the same amplitude. Thus, the desired eye movement signal may be updated during the longer-duration interruption.

Another study delivered air puffs to the eye to perturb the saccadic trajectory and analyzed the corresponding activity in SC neurons (Goossens and Van Opstal, 2000). The dynamics of the eye movements were grossly perturbed. The motor error and neural activity were not correlated linearly for many neurons, arguing against the temporal control mechanism.

The activity of SC neurons was also evaluated when the stereotyped trajectories of saccades were altered by injection of muscimol in the OPN region (Soetedjo et al., 2002a). The resulting saccades, although accurate, exhibited lower peak velocity and longer duration. Corresponding activity of SC neurons consistently increased in duration, leading the authors to propose that the SC receives a feedback signal that regulates the duration of their discharge.

Soetedjo et al. (2002a) also analyzed the peak discharge rate of the SC neurons. The authors reasoned that the peak rate of SC neurons should remain the same for all saccades of the same metrics and, presumably, the same motor error. That less than half of the SC neurons in their sample of 11 cells showed a *decrease* in peak activity led them to conclude that the feedback signal does not result in collicular neurons coding dynamic motor error. Proponents of the temporal dynamic control scheme may argue with the expectation that the collicular firing rate should be the same after inactivation of OPNs. As reviewed above, microstimulation of OPNs produces dramatic alterations in the spatiotemporal pattern of collicular activity, and inactivation could similarly modify the discharge. A more direct test would have been to perform phase plane analyses of neural activity and dynamic motor error. Failure to demonstrate a linear relationship, particularly toward the end of the saccade, would be a more convincing argument against the temporal coding scheme.

SPATIAL CONTROL SCHEME Advocates of the spatial control hypothesis use a different nomenclature to classify SC cells (Munoz and Wurtz, 1995a). *Burst* neurons reside dorsally within the deep layers of the SC, have a circumscribed movement field, and discharge a sharp burst for saccades made to locations within the movement field. *Buildup* neurons typically reside ventral to the burst neurons and generally have movement fields without a peripheral boundary (but see Freedman and Sparks, 1997a). Fixation neurons constitute an extension of the buildup layer within the rostral pole of SC. They exhibit low-level activity during visual fixation and are silent during saccades (Munoz and Guitton, 1989; Munoz and Wurtz, 1993, 1995a; Peck, 1989). The region of the fixation neurons within the SC has been labeled the *fixation zone* and is hypothesized to inhibit the burst and buildup neurons in the saccade zone in the remainder of the SC.

According to the spatial encoding hypothesis (Munoz and Wurtz, 1995b; Munoz et al., 1991), a population of burst and buildup neurons within the caudal SC is active at around the onset of a large saccade. As the eye movement progresses, buildup neurons rostral to the initial site become activated *sequentially*. It has been hypothesized that the neural network in SC integrates the eye velocity feedback signal and shifts the population of active buildup neurons rostrally.

According to this proposal, the locus of activity within the buildup neuron layer of the SC map indicates dynamic motor error, while the site of activity of the burst neuron layer encodes desired movement. As the activity in the buildup layer reaches the rostral pole, fixation neurons are reactivated, which in turn inhibit the saccade zone of the SC as well as the premotor circuitry in the brainstem.

In reality, SC neurons fall along a continuum according to the presaccadic discharge parameter used to classify them into the burst or buildup category (Anderson et al., 1998). Also, a closer examination of the discharge properties of the so-called fixation neurons (Munoz and Wurtz, 1993) reveals that they pause only during ipsiversive saccades. Many fixation neurons typically discharge a presaccadic burst during small contraversive saccades generated to fixate parafoveal targets; some neurons increase their activity for movements as large as 15 degrees in amplitude. Thus, the concepts of the fixation zone and fixation neurons have been disputed. Instead, it has been suggested that fixation neurons are the rostral extension of buildup neurons and that the rostral SC still constitutes a saccade zone (Gandhi and Keller, 1999; Krauzlis et al., 1997). Alternatively, Bergeron and Guitton (2000) proposed that each fixation neuron has a characteristic motor error, which, when reached during a movement, will resume the cell's discharge. Consequently, some fixation neurons will not pause for saccades smaller than a particular amplitude, potentially explaining the lack of pause in fixation neurons during small contraversive saccades.

Support for the spatial encoding model was based on qualitative assessments of the population response of SC neurons in both cat (Munoz et al., 1991) and monkey (Munoz and Wurtz, 1995b). However, another evaluation of the evidence (Sparks, 1993) and other quantitative analyses have disputed the notion of a systematic and sequential shift from caudal to rostral SC. A basic requirement of this hypothesis is that a neuron must discharge for all saccades in the optimal direction and for all amplitudes larger than the one dictated by its location within the topographic map. Moreover, the closer the buildup neuron is to the rostral end of the SC, the later its activation must occur relative to saccade onset (and closer to saccade end).

Results of analyses that measured parameters of the neural discharge and correlated them with movement metrics have refuted the spatial encoding hypothesis (Anderson et al., 1998; Kang and Lee, 2000; Soetedjo et al., 2002b). When activity of pairs of buildup neurons, separated on average by over 1 mm along the rostrocaudal axis of the SC, was recorded during large saccades (Port et al., 2000), caudal-to-rostral activation was observed in approximately half of the pairs; several pairs exhibited the opposite, rostral-to-caudal, sequence of activation. This analysis, however, was limited to the rostrocaudal dimension, as it could not determine the spread of activity along the medi-

olateral extent. Examination of the population activity in both dimensions, across the surface of the SC, revealed a more complicated picture (Anderson et al., 1998). Activity spread medially, laterally, and rostrally during the saccade; no significant transition of activity was observed caudal to the initially active site. While the center of gravity of activity in the buildup layer showed a small, rostrally directed shift by the end of the saccade, the shift was random, not sequential, on a millisecond-by-millisecond basis. Another study (Moschovakis et al., 2001) used [^{14}C]deoxyglucose autoradiography to visualize the two-dimensional activity in the intermediate layers of the SC during saccades and observed no indication of a rostrally directed spread of activity, although whether this method has the sensitivity required to detect the proposed rostral spread of collicular activity remains unclear.

The spatial encoding mechanism has also been tested by chemical inactivation experiments (Aizawa and Wurtz, 1998; Quaia et al., 1998). It was reasoned that temporary inactivation by injections of muscimol to a local region of the SC would prevent or compromise the rostrally directed spread of activity during large saccades. Thus, the ongoing saccade was predicted to overshoot the target. The observed postlesion saccades either undershot or landed near the target location. Thus, the notion of a rostrally directed spread of activity as a dynamic control mechanism for saccades has been refuted by many studies.

STATIC FEEDBACK The two leading hypotheses concerning the role of SC in dynamic control of saccades have been tested extensively. Relevant experiments have raised various levels of doubt about each theory and, consequently, the controversy over a dynamic role of the SC in the control of saccades still exists. However, the notion of *static* feedback, one that does not compute the instantaneous motor error, has been supported by almost every experiment that has examined the activity of SC neurons during perturbations of the eye trajectory. Referring to the interrupted saccade experiments described above (Keller and Edelman, 1994; Keller et al., 2000), for example, the caudal region active at the onset of a large saccade discharges another burst at the onset of the resumed movement. If the SC does not receive feedback about the perturbation, that is, if the SC resides upstream of the feedback loop, a second burst would not be observed during the resumed movement. Of course, the *dynamics* of the movement need not be controlled by the temporal discharge pattern. Similar observations have been made when saccades were perturbed by stimulation of cortical (frontal eye fields: Schlag-Rey et al., 1992) and other subcortical (SC: Munoz et al., 1996; Sparks and Porter, 1983) structures.

Goossens and Van Opstal (2000) proposed a conceptual model in which the SC plays a feedforward role in the

control of saccades. They found that the number of spikes discharged by SC neurons during control and air-puff-induced perturbation trials was remarkably similar. Despite the altered burst dynamics, SC neurons executed the desired number of action potentials. Thus, these authors suggested that the role of the SC is to output an approximately fixed number of spikes to produce a desired change in the line of sight. But how does the SC know that its discharge has to be altered? A nonmetric-based feedback signal must be transmitted to the SC to account for the change in burst properties (Keller and Edelman, 1994; Soetedjo et al., 2002a), and intrinsic properties within the SC ensure that more than enough spikes are generated and transmitted to downstream structures (Goossens and Van Opstal, 2000).

Contribution of the SC during other orienting responses

In the past, experiments that explored the neurophysiological substrate of oculomotor systems typically investigated each oculomotor subsystem (e.g., saccades, smooth pursuit, vergence) in isolation. In addition, the head was restrained as animals performed eye-movement tasks. In the natural environment, however, we often orient from one target to another by integrating several types of movements. For instance, head movements can often accompany eye rotation, saccades and smooth pursuit are coordinated when tracking a moving object, and saccadic eye movements can have a vergence component.

As reviewed above and elsewhere (Sparks and Hartwich-Young, 1989), the SC is considered a key structure in sensorimotor processes that control saccades. More recently, the role of the SC has been examined during saccades coordinated with head movements (head-unrestrained gaze shifts), eye movements other than saccades (smooth pursuit, vergence, accommodation), and reaching movements of the arm. In the remainder of this chapter, we will review recent studies suggesting that the SC is involved in the generation of eye movements other than saccades, as well as movements of the head and arm.

COORDINATED EYE-HEAD MOVEMENTS When the head is free to move but the trunk is restrained in the straight-ahead position, coordinated movements of the eyes and head shift the direction of gaze, defined as the line of sight and computed as the sum of eye-in-head and head-in-space positions. Gaze shifts are usually characterized by the *amplitudes* of the gaze, eye, and head movements and by the *contributions* of the eye and head to the change in gaze. The onset and offset of gaze, eye, and head movements are typically determined by velocity criteria. Their amplitude values are computed by subtracting onset and offset positions, and eye and head contribution metrics are measured as the eye and head dis-

placements, respectively, during the duration of the gaze shift (Freedman and Sparks, 1997b). In general, the head continues to move for several hundred milliseconds after the end of a gaze shift, and the eyes counterrotate in the orbits during this period to maintain stability of gaze. Thus, the contribution component, particularly for the head movement, should be less than the amplitude measure.

The eye and head contributions for a desired change in gaze depend on the oculomotor range, which is species-dependent, as well as the initial eye-in-head and head-on-trunk positions. Because of their small oculomotor range (~25 degrees), cats have a higher propensity to generate head movements and, therefore, have been excellent subjects for examining the role of SC in controlling head-unrestrained gaze shifts. Stimulation of the SC produced effects that were dependent on the stimulation site, stimulation parameters, and initial position of the eyes in the orbits (Guitton et al., 1980; Paré et al., 1994; Roucoux et al., 1980). Electrical pulses delivered to the anterior SC primarily produced saccades, even when the head was free to move. Head movements, when they occurred, were initiated at around or after the end of saccades, thus minimizing their contribution to gaze shifts. Thus, the change in gaze evoked by stimulation of the anterior SC was similar in the head-restrained and head-unrestrained conditions. In contrast, gaze shifts evoked by stimulation of more caudal regions of the SC produced different effects in the head-restrained and head-unrestrained modes. When the head was prevented from moving, stimulation drove the eyes toward a specific orbital position. Thus, both contraversive and ipsiversive saccades were evoked when the initial eye position was ipsilateral or contralateral, respectively, to the desired orbital position. When the head was allowed to move, stimulation evoked relatively constant amplitude gaze shifts executed by a coordinated movement of the eyes and the head. The eye movement in the orbit, however, appeared similar to the movement observed in the head-restrained condition; that is, the eyes moved to specific orbital positions, independent of their initial positions (Paré et al., 1994; Roucoux et al., 1980).

To corroborate the microstimulation studies, the movement fields of feline SC neurons were compared in the head-restrained and head-unrestrained conditions (Munoz et al., 1991). The neural discharge was better modulated by gaze (eye-in-space) amplitude than by either eye-in-head or head-in-space components. Furthermore, the movement fields based on gaze parameters overlapped for the head-restrained and head-unrestrained conditions, suggesting that the phasic bursts of SC neurons encode gaze displacement. Collectively, the neural recording and microstimulation experiments have led to the hypothesis that SC encodes parameters of the gaze shift, as opposed to the eye-in-head or head-in-space components.

Unlike the nonprimate models, the SC in monkeys was traditionally considered to participate in the control of saccades only. The neural mechanism of the head component of coordinated eye and head movements was thought to be of extracollicular origin. This assumption was based on studies that examined the effects of stimulation of the anterior SC only (Stryker and Schiller, 1975), which primarily evoked saccades, and was further supported by neural recording experiments that failed to find head movement signals in the SC (Robinson and Jarvis, 1974). This topic was recently revisited (Cowie and Robinson, 1994; Freedman et al., 1996; Freedman and Sparks, 1997a; Seagraves and Goldberg, 1992), and it is now assumed that the primate SC also controls coordinated eye-head movements.

As in the feline SC, the properties of stimulation-evoked gaze shifts in nonhuman primates were a function of the site and parameters of stimulation (Freedman et al., 1996). Gaze amplitude initially increased with stimulation duration and then reached a plateau level dictated by the site of stimulation (site-specific maximal amplitude). The peak velocity of the gaze shift increased and the variability in the onset decreased as the frequency of stimulation was raised. Increases in stimulation intensity had modest effects on gaze peak velocity without changing the site-specific maximal amplitude, provided that the stimulation duration was extended to accomplish the entire movement. In general, the dynamics of stimulation-induced and visually guided gaze shifts were similar. [Stimulation parameters have similar effects on saccades evoked in the head-restrained monkey (Stanford et al., 1996; Van Opstal et al., 1990).]

The head component of stimulation-evoked gaze shifts was also dependent on the stimulation parameters. For stimulation of middle and caudal sites, the head continued to move for the duration of the stimulation and even after the end of the stimulation-evoked gaze shift (Freedman et al., 1996). Presumably, the head would have stopped moving once it reached its mechanical limits, although stimulation durations long enough to test this hypothesis were not applied. Head amplitude and duration were linearly related to stimulation duration within the tested range. Average head velocity also increased linearly with stimulation frequency, although the effect was modest compared to that on gaze velocity. Thus, the head movement did not exhibit any site-specific maximal amplitude for the tested range of stimulation durations. Even though a significant proportion of the head movement continued after gaze offset, the head contribution remained relatively independent of stimulation parameters (Freedman et al., 1996).

Changing the site of stimulation along the rostral-caudal dimension produced qualitatively similar effects in head-unrestrained monkey and cat. Stimulation of the anterior SC produced gaze shifts that were accomplished primarily by the eye (Freedman et al., 1996). Head movement, if

observed, was usually initiated at around gaze offset and, therefore, the head contribution was negligible. In contrast, stimulation of middle and caudal regions produced coordinated movements of the eyes and head (Freedman et al., 1996). Across all sites, however, the eye movements observed in the head-restrained and head-unrestrained conditions were similar—fixed vector for anterior sites and goal directed for caudal regions. Thus, it appears that the movements observed during SC stimulation in the head-restrained animal were reduced by the amount the head would contribute if stimulation were applied to the same site in the head-unrestrained condition. As a consequence, the amplitude axis of the (head-restrained) saccade motor map, particularly at the caudal end, is distorted by being more compressed than the map would be if it were constructed from head-unrestrained experiments (Freedman et al., 1996).

Analyses evaluating the effect of initial eye position in the head (IEP_h) have decomposed the vector of the stimulation-evoked movement and IEP_h into horizontal and vertical components (Freedman et al., 1996). Alternatively, Klier et al. (2001) transformed the coordinate system to analyze the orthogonal component of the movement and initial gaze position (IGP). Gaze amplitude, particularly the horizontal component, evoked by stimulation remained relatively constant, while eye and head contributions varied inversely as a function of IEP_h . [An assessment of Fig. 13A–C in Freedman et al. (1996), however, suggests that the gaze amplitude as well as its horizontal component may depend on IGP.] When the IEP_h was deviated in the direction of the stimulation-evoked gaze shift, head contribution increased and eye amplitude decreased for a given change in gaze. Conversely, if the IEP_h was contralateral to the direction of the stimulation-evoked movement, head contribution decreased and eye amplitude increased for a given gaze shift. Furthermore, head onset relative to gaze onset decreased (increased) as the IEP_h was ipsilateral (contralateral) to the direction of the ensuing gaze shift. Unlike the IEP_h , the effects of head position on stimulation-evoked gaze shifts and on eye and head contributions remain to be examined systematically.

Unlike the horizontal component, the vertical and orthogonal components of the stimulation-induced gaze shift were linearly related to the vertical IEP_h and orthogonal IGP, respectively. Suppose that stimulation of a specific SC site produced a gaze shift with an upward component when the eyes were initially centered in the orbits and the head was pointed straight ahead. Stimulation of the same site with an upward IEP_h or IGP generated a smaller upward, and sometimes even downward, component of gaze compared to the corresponding component produced with a downward IEP_h or IGP. Thus, varying the IEP_h while stimulating a caudal site and maintaining identical stimulation

parameters does *not* produce gaze shifts of same amplitude and direction.

The slope of the linear regression, describing the relationship between the orthogonal gaze shift component and orthogonal IGP, changed with the stimulation site (Klier et al., 2001). At rostral sites, the slope was near zero, indicating that the stimulation-evoked gaze shifts remained constant across all IGP and, presumably, IEP_h. As the stimulation electrode was positioned at increasingly caudal sites, the slope decreased gradually to negative one as the stimulation-evoked gaze shifts became goal-directed. The data obtained from stimulation of the rostral and caudal ends of the SC are consistent with the predictions of the constant gaze-displacement and desired gaze-position models, respectively. However, Klier et al. (2001) demonstrated that the distribution of the slopes is also consistent with another model that computes gaze displacement in *retinal*, as opposed to *spatial*, coordinates (see Crawford and Guitton, 1997, for a theoretical foundation). By accounting for the geometry of the eyeball, all gaze shifts evoked by microstimulation become constant vectors across all IGPs, thereby avoiding the need to explain the transition from gaze displacement to gaze position. Hence, the updated view is that the SC controls coordinated movements of the eyes and head and, furthermore, that the metrics of the gaze shifts are encoded in retinal coordinates.

These microstimulation experiments suggest that SC neurons issue a single signal to displace gaze by a desired displacement (*gaze-displacement* hypothesis). Alternatively, one population of SC neurons can provide eye displacement signals and another group of neurons may submit head displacement commands (*separate-channel* hypothesis). If these neurons are intermingled, stimulation could evoke gaze shifts similar to those expected from activation of neurons encoding gaze displacement. If stimulation selectively activated eye or head movement neurons, the movement would be isolated to just one of the pathways. Cowie and Robinson (1994) presented evidence hinting that stimulation of certain sites within the deep layers of the SC may produce head movements without an accompanying gaze shift. Recently, Corneil et al. (2002) and Pélisson et al. (2001) reported that stimulation of the SC with parameters sub-threshold to those required to produce gaze shifts can elicit head movements without changing the gaze position. While head movements evoked by stimulation of the SC support the separate-channel hypothesis, they are not inconsistent with the gaze-displacement hypothesis. For example, the stimulation-induced output could be a gaze command that was gated by OPNs in the eye pathway but not gated in the head pathway.

To differentiate between the gaze-displacement and separate-channel hypotheses, one might suggest correlating the neural activity with the metrics of gaze, eye, and head

components. However, this approach may not be definitive for two reasons. (1) Gaze, eye, and head amplitudes and directions do not vary independently and typically are highly correlated. (2) Based on a scales of measurements argument (Sparks and Gandhi, 2003), correlation analysis may not be an appropriate statistical test for neurons organized in a place code. Thus, conditions under which the three movement metrics can be dissociated, one held constant while the other two vary, are necessary to determine the representation of gaze in SC neurons (Freedman and Sparks, 1997a).

One behavioral dissociation (Fig. 97.14) emphasizes that for large gaze shifts, the eye amplitude saturates at ~35 degrees, even as the head and gaze components vary. The shaded regions in panel *B* show for three representative gaze shifts (*a-c*; vertical lines panel *A* and rows in panel *B*) how the encoding mechanism dictates the population of active SC neurons. The gaze-displacement hypothesis (“gaze” column, panel *B*) requires that, for gaze shifts of increasingly large amplitudes, the active ensemble of neurons shifts to more caudal locations. Thus, in recording from a neuron with an optimal vector larger than the three representative gaze shifts (*black dot*, panel *B*), an increase in firing rate would be associated with a larger gaze amplitude (“gaze” column, panel *C*). An increase in firing rate is also correlated with an increase in head amplitude (“head” column, panel *C*) because it covaries with gaze amplitude. In contrast, eye amplitude would remain relatively constant despite changes in the firing rate. According to the separate-channel hypothesis, the same population of neurons encoding eye displacement would remain active for all three gaze shifts, holding the shaded region constant (“eye” column, panel *B*). Hence, a neuron in the caudal SC would discharge at the same firing rate across a large range of gaze and head amplitude, as long as the eye movement remains relatively constant (“eye” column, panel *C*). Neurons encoding head displacement, on the other hand, will behave very much like SC neurons issuing gaze-displacement commands because head and gaze amplitude covary for large gaze shifts (compare the “head” and “gaze” columns in panels *B* and *C*). Note that while this behavioral dissociation allows an evaluation of the eye encoding scheme, it does not distinguish between gaze and head displacements. Thus, an analysis of only this subset of movements may not be sufficient to distinguish between the gaze-displacement and separate-channel hypothesis.

In the second dissociation condition, SC activity is analyzed for the subset of movements for which the head metrics are held constant while eye and gaze amplitude and direction vary (panel *D*). In this case, the population of neurons encoding gaze or eye displacements will shift for different gaze shifts, but the active ensemble of neurons encoding head displacement will remain constant (panel *E*).

FIGURE 97.1. Strategy employed to determine whether the discharge of SC neurons supports the gaze-displacement or separate-channel hypothesis. *A*, *D*, *G*, Replotted schematic diagrams illustrating the behavioral dissociations of movement metrics. Analyses focused on the neural data of movements in which one of the eye, head, or gaze movements remained constant while the other two signals varied, as noted by the vertical lines marked *a–c*. *A*, Schematic of a behavioral dissociation in which eye amplitude is held constant while gaze and head amplitudes covary. *B*, Hypothetical locations of the active population of cells in the SC map as predicted by the alternative hypotheses during movements indicated in *A*, *a–c*; shaded region, active population; *filled circle*, location of the hypothetical (test) cell used to illustrate the specific predictions of the alternatives. The column labeled “gaze” outlines the locus of the active population according to the gaze-displacement hypothesis during movements (rows *a–c*). Similarly, the “eye” and “head” columns illustrate the loci of active populations according to the separate-channel hypothesis. *C*, Specific predictions of the hypotheses (columns) are outlined for the test cell

in *B*. Gaze, eye, and head movement amplitudes (rows) are plotted as functions of the hypothetical firing rate of the test cell. *D*, Schematic of a second behavioral dissociation, in which the head movement is constant while gaze and eye amplitudes covary. *E*, Loci of active populations in the SC map during three movements (*D*: *a–c*) according to the alternative hypotheses (columns labeled “gaze,” “eye,” and “head”). *F*, Specific predictions of gaze, eye, and head amplitude (rows) when plotted as a function of firing rate of test cell (*filled circle* in *E*). *G*, Schematic of a third behavioral dissociation in which gaze amplitude is held constant while eye and head contributions vary inversely as a function of horizontal initial eye position (IEP_h) in the head; contra., contralateral IEP_h ; cent., IEP_h close to zero. *H*, Loci of active populations in the SC map during three movements (*G*: *a–c*) according to the alternative hypotheses (columns labeled “gaze,” “eye,” and “head”). *I*, Specific predictions of gaze, eye, and head amplitude (rows) when plotted as a function of the firing rate of the test cell. (Figure and caption adapted from Freedman and Sparks, 1997a.)

Accordingly, the firing rate of a neuron encoding head displacement will not vary despite variations in gaze and eye directions (“head” column, panel *F*). Firing rates of neurons encoding gaze or eye displacements, on the other hand, will be related to gaze and eye directions, respectively, but not to head direction (“gaze” and “eye” columns, panel *F*). Thus, consideration of only this subset of movements allows a test of the head-displacement model, but it does not dissociate between the gaze- and eye-displacement models.

In the final dissociation condition, gaze amplitude is held constant while eye and head contributions vary inversely as a function of IEP_h (panel *G*). In this situation, the same population of neurons encoding gaze displacement is activated for the three representative movements (“gaze” column, panel *H*). The neural activity remains constant for the same gaze amplitude, despite various combinations of eye and head components (“gaze” column, panel *I*). As the IEP_h is deviated in the direction of the ensuing gaze shift, the eye amplitude decreases and the head amplitude increases. Thus, for constant gaze amplitude, the population of neurons encoding eye displacement and head displacement shift their center of activity in opposite directions as a function of IEP_h (“eye” and “head” columns, panel *H*). Consequently, the firing rate of a representative neuron encoding either eye or head displacement, while not related to gaze amplitude, would be inversely related to eye and head amplitudes (“eye” and “head” columns, panel *I*).

Freedman and Sparks (1997a) performed these analyses on 36 SC neurons recorded during head-unrestrained gaze shifts directed to visual targets. All neurons encoded gaze displacement; the relationship with gaze, eye, and head amplitudes to firing rate obeyed the predictions of the gaze-displacement hypothesis (“gaze” column, panels *C*, *F*, and *I*). Thus, these authors concluded that SC neurons encode desired gaze displacement, and that the single gaze command is separated into eye and head pathways downstream of the SC.

While the experimental design of Freedman and Sparks (1997a) is the most thorough and quantitative to date, their conclusion depends critically on the assumption that the vestibulo-ocular reflex (VOR) is inactive during gaze shifts. If the VOR is significantly active, their interpretation may be contaminated by the neural uncertainty problem (Sparks, 1999; Sparks and Gandhi, 2003). For instance, the neurons considered to encode desired gaze displacement may actually issue a desired eye movement command only. Other neural pathways may generate an accompanying head movement and, if the VOR gain is near unity, submit an ocular counterrotation signal of the amount that equals the head amplitude. Thus, the extraocular motoneurons incorporate the excitatory drive from the saccadic system and the inhibitory vestibular signal, resulting in a dissociation between the desired (encoded by SC neurons) and

executed eye movement (see Sparks and Gandhi, 2003, for simulations).

The results of Freedman and colleagues (Freedman and Sparks, 1997a; Freedman et al., 1996) can be accounted for by other hypotheses about the role of the SC in the control of gaze shifts. For example, the SC may contain separate populations of eye and head cells, but all neurons encode desired gaze displacement. Activation of either type of neuron sends signals to innervate muscles in the appropriate pathway. Downstream of the SC, the eye and head pathways can interact (via mechanisms such as cross-coupling, VOR, efference copy, or proprioception), producing a dissociation between the desired movement command and the executed movement amplitude (Sparks, 1999). Thus, a thorough understanding of collicular participation in the control of gaze shifts is likely to remain elusive until interactions between the eye and head pathways are elucidated.

SMOOTH PURSUIT Over the past decade the function of neurons in the rostral SC has come under considerable scrutiny. According to the traditional views, the cells in the rostral SC discharge prior to small saccades. A recent proposal that neurons in the rostral SC play a role in fixation was discussed in a previous section (“Spatial Control Scheme”). In the next three sections, we consider the possibility that neurons in the rostral SC participate in the control of eye movements other than saccades (smooth pursuit, vergence, and accommodation).

Behavioral experiments have demonstrated that small position errors (<3 degrees) induced by stepping a moving target produce changes in the speed of ongoing pursuit (Krauzlis and Miles, 1996; Morris and Lisberger, 1987; Segraves and Goldberg, 1994). Whether neurons in the rostral SC generate a general position error command that can be used to produce or modify smooth eye movements was the focus of a series of experiments by Krauzlis and colleagues (Basso et al., 2000; Krauzlis et al., 2000). They recorded the activity of neurons in the rostral SC during smooth pursuit eye movements and observed increases in discharge during contraversive pursuit movements, particularly when differences in target and eye speed created small position errors. Decreases in activity were observed during ipsiversive pursuit. Accordingly, one interpretation of the results is that neurons in the rostral SC issue commands used by the pursuit system. However, the same neurons also exhibited a burst of activity before small contraversive saccades. Thus, an alternative explanation is that the enhanced activity observed during pursuit eye movements could represent the *preparation* of catchup saccades—small saccades made to the moving target—that were not executed. To address this possibility, the activity of cells on trials in which catchup saccades were generated within 300 msec of the target motion (*early saccades*) was compared with the activity

of the same neuron during trials without early saccades (Krauzlis et al., 2000). If the neural activity on the trials without the early saccades reflects a saccade preparation signal, higher levels of activity should be present during the trials with early saccades because a rapid eye movement was actually produced. For most neurons, the discharge rate during the early pursuit phase was not significantly different for the trials with and without the early saccades. Thus, the authors concluded that the enhanced activity was associated with smooth pursuit, not saccades.

Artificial activation (microstimulation) and inactivation experiments were also conducted in an attempt to establish a more direct role of the rostral SC in producing ocular smooth pursuit (Basso et al., 2000). Microstimulation during fixation failed to elicit any smooth eye movements at currents above or below the threshold for evoking saccadic eye movements. This is in contrast to the smooth eye movements produced by stimulation of a small portion of the arcuate fundus and the neighboring posterior bank lying directly posterior to the principal sulcus in the frontal eye field area (Gottlieb et al., 1993; MacAvoy et al., 1991). Other studies, however, have reported that prolonged duration, high frequency, and large-intensity stimulation of the SC evoke a staircase of saccades, often interspersed with smooth eye movements during the intersaccadic intervals (Breznen et al., 1996; Missal et al., 1996; Moschovakis et al., 1998), although there is no consensus on whether these drift-like movements are actually smooth pursuit.

The failure to initiate pursuit movements with collicular microstimulation cannot be interpreted as evidence that the colliculus is not involved in pursuit eye movement. Behavioral experiments have shown that position errors introduced by jumping a moving target only affect ongoing pursuit movements (Krauzlis and Miles, 1996; Morris and Lisberger, 1987; Segraves and Goldberg, 1994). Furthermore, position steps in the direction of motion modestly facilitate pursuit, while steps in the opposite direction greatly suppress it. Thus, a stimulation-induced position error signal, which is the hypothesized output of the SC, should alter the kinematics of pursuit even if it does not initiate it. Ipsiversive pursuit should be suppressed by microstimulation, whereas contraversive pursuit should be facilitated. Basso et al. (2000) found that long-duration (300 to 400 msec) microstimulation of the rostral SC applied near the onset of a moving target produced large suppressive effects on ipsiversive smooth pursuit; these effects were significant and consistent with the predictions. The effect of microstimulation during contraversive smooth pursuit was minimal and inconsistent.

In a complementary experiment, the activity of neurons in the rostral SC was reduced by application of muscimol, a GABA agonist, and pursuit performance was assessed as animals tracked a moving target. A step-ramp task was used to assess, independently, the effects of the direction of the

pursuit and the location of the target in the visual field. Basso and colleagues (2000) observed a muscimol-induced reduction in pursuit velocity during contraversive pursuit initiation and an increase in pursuit velocity during ipsiversive pursuit. However, deficits were more dependent upon which part of the visual field pursuit targets were presented with than the direction of the pursuit movement. For example, with a right SC injection, pursuit velocities were reduced when the target was moving leftward in the left visual field, but not significantly reduced when the target was moving leftward in the right visual field. Also, with a right injection, increased pursuit velocity was observed if the target was moving rightward in the right visual field.

Collectively, these results were interpreted as support for the hypothesis that neurons in the rostral SC issue a general position error command that is used by both pursuit and saccadic subsystems (Basso et al., 2000; Krauzlis et al., 2000). According to this view, the rostral SC plays an important role in the control of pursuit eye movements. Although the data are suggestive, in our opinion a convincing case that the superior colliculus has a causative role in the initiation or maintenance of pursuit eye movements does not yet exist. A brief evaluation of the recording, microstimulation, and inactivation experiments follows.

With respect to the recording experiments, critical details of the analyses used to reject the hypothesis that increases in activity were related to the preparation of catchup saccades were not provided. For example, were the amplitudes of the movements in the early saccade trials within the center of the movement field of the neurons? Because neurons in the rostral SC have small movement fields, small changes in the saccade amplitude will result in a large change in the discharge characteristics. Furthermore, differences in firing rate in the two conditions would be easier to detect if the trials, in which saccades occurred, were aligned on saccade onset, not target motion. In the absence of information on these critical details, rejection of the hypothesis that changes in activity observed during pursuit movements are related to preparation of catchup saccades seems premature.

In the microstimulation experiments, contrary to the predictions, stimulation of many sites, particularly those represented within 1 degree of the fovea, significantly reduced pursuit velocity. This was observed during initial and maintained smooth pursuit in both contraversive and ipsiversive directions. These findings are compatible with an alternative interpretation of the data in which stimulation-evoked perturbations in pursuit movements are an indirect effect of activating OPNs. Stimulation of the OPNs in the pontine reticular formation is known to not only interrupt saccades but also attenuate ongoing pursuit (Missal and Keller, 2002). Thus, stimulation of the rostral SC, which has dense excitatory projections to the OPNs (Büttner-Ennever and Horn,

1994; Büttner-Ennever et al., 1999; Gandhi and Keller, 1997; Paré and Guitton, 1994), may increase the OPN response and, in turn, reduce pursuit velocity. This suggestion is consistent with the observation that stimulation of increasingly caudal regions, which has weaker projections to the OPNs, did not suppress smooth-pursuit (Basso et al., 2000).

The results of the inactivation experiment are puzzling. The finding that pursuit velocity effects were more dependent upon the region of the visual field in which the pursuit targets were presented than upon the direction of the pursuit movement is not the result expected if the inactivated cells are generating a motor command for a movement in a particular direction. This is the pattern of results that would be obtained if the inactivation were affecting visual motion processing in a particular region of the visual field or affecting the allocation of attention to particular parts of visual space.

Additional studies of the role of rostral SC in the control of smooth pursuit are necessary. A convincing argument can be made if a pathway from the SC to neurons in the traditional pursuit system is identified. Anatomical and functional connectivity experiments that use a combination of orthodromic and antidromic stimulation techniques may be appropriate. Furthermore, the experiments must show that the origin of the projections is limited to the rostral SC.

SACCADE-VERGENCE INTERACTIONS Eye movements to targets that are displaced in eccentricity and depth exhibit both *version* and *vergence* components, where version is the yoked, conjugate movement of both eyes and vergence refers to the nonconjugate movement of the eyes in opposite directions. In this section, we discuss the few studies exploring SC participation in these three-dimensional saccades (or saccade-vergence movements). It is reasonable to examine disparity coding and vergence movement signals in the SC since it receives projections from neurons in cortical areas that respond to spatial disparity or participate in producing vergence eye movements (e.g., Ferraina et al., 2000; Gnadt and Beyer, 1998; Gamlin and Yoon, 2000). In anesthetized cats, neurons in the superficial layers of the SC exhibit coarse disparity sensitivity, unlike the sharply tuned cells in striate cortex (Bacon et al., 1998; Dias et al., 1991). Activity of visuomotor neurons in the deeper layers of awake, behaving monkeys exhibited no systematic vergence- or disparity-related signals (Mays, 1996), although there may be a concentration of disparity-sensitive neurons located in the rostral SC (Berman et al., 1975; Jiang et al., 1996).

Recently, Chaturvedi and Van Gisbergen (1999) used microstimulation to investigate the role of the SC in saccade-vergence movements. Figure 97.2 shows the vertical component of versional (*left*) and vergence (*right*) components of

three-dimensional saccades when no stimulation was applied (V), when stimulation was delivered during fixation (E), and when stimulation was delivered during an ongoing movement (EV). Electrical stimulation (duration: 50 msec) delivered to the middle and caudal SC *during fixation* produced saccades (E; Fig. 97.2, *left*) *without* a vergence component (E; Fig. 97.2, *right*). However, effects on the vergence component were observed with stimulation of the same sites prior to or during target-directed three-dimensional saccades. As expected from previous studies (e.g., Gandhi and Keller, 1999; Schlag-Rey et al., 1989) stimulation of a SC site at *around the onset* of a visually guided saccade produced a version component (EV; Fig. 97.2, *left*) with a direction and an amplitude that were an average of those of the saccades encoded by the stimulation (E) and target-activated (V) sites. Following a brief interval, the animal compensated for the stimulation-evoked perturbation of the visually directed saccade by executing another saccade to the visual target.

During the interval when the stimulation-evoked movement was being executed, the stimulation-evoked vergence component (EV; arrow 1; Fig. 97.2, *right*) had a higher velocity than a control vergence movement without a version component (data not shown). When the stimulation-evoked version component ended (second vertical line), the vergence movement continued, albeit at a slower velocity (arrow 2), before reaccelerating during the saccadic movement made to compensate for the stimulation-induced perturbation (arrow 3).

When plotting amplitude as a function of *electrical latency*, defined as the difference between saccade and stimulation onsets, both initial saccade and intrasaccadic vergence components followed an averaging process that began when electrical latency was approximately -40 msec (stimulation led the visually guided saccade) and continued until roughly 40 msec after stimulation onset. The movement was guided primarily by the target-directed program for positive electrical latency but was dominated by the stimulation-evoked command for negative electrical latency; for electrical latency values around zero, the movement incorporated both target-directed and stimulation-evoked signals. The averaging process was highly correlated for the version and vergence components, both on a trial-by-trial basis and on average.

Because vergence movements could not be initiated without a saccadic component during the three-dimensional saccades, one conclusion that follows is that both types of movement are gated by the same mechanism (see Chapter 95). This conservative interpretation allows the commands for desired vergence movement to originate from an extracollicular source. But could vergence commands also be represented in the SC? Chaturvedi and Van Gisbergen (1999) entertained the notion that the premotor neural discharge of the SC specified both saccade and vergence metrics but that

FIGURE 97.2. Example of a perturbation induced by stimulation of the SC during a three-dimensional saccade. Temporal traces of the vertical component of versional (*left*) and vergence (*right*) eye movements directed to a visual target (V), evoked by stimulation during fixation (E), or perturbed by microstimulation during a target-directed saccade (EV; *thick dotted trace*). The fixation and saccade targets were identical in both V and EV conditions. The vertical, dashed lines mark stimulation onset and offset. Arrows 1 to 3 are referred to in the text. Averaging of the movements encoded by the neurons at the stimulation-evoked and target-activated sites is sufficient to explain the observed behavior: the stimulation-evoked output encodes a vergence movement of zero amplitude and a saccade component of nonzero amplitude. (Modified from Chaturvedi and Van Gisbergen, 1999.)

stimulation of the SC output a zero vergence command, not a lack of vergence signal. Accordingly, stimulation delivered during fixation produced no vergence component, and stimulation applied at around saccade onset averaged the zero vergence command issued by the stimulation and the depth component programmed by the target-activated site. Focusing on the trials in which the visually guided three-dimensional saccades were initiated *prior* to stimulation onset (Fig. 97.2), Chaturvedi and Van Gisbergen assumed that the desired vergence signal must be fully encoded by the time of stimulation onset, as it presumably is for control conditions. If the vergence signal does not channel through the SC, then the intrasaccadic vergence components on stimulation and control trials should be similar. But the fact that averaging of the metric was observed led the authors to conclude that vergence signals are encoded in the SC output.

Stimulation of the rostral SC *after* the onset of three-dimensional saccades produced effects comparable to those observed for the middle and caudal SC (Chaturvedi and Van Gisbergen, 2000). With longer stimulation duration (500 msec), the resumed version component was often truncated and the vergence component often reversed direction, sometimes diverging beyond the initial fixation plane. When the stimulation was delivered prior to the onset of saccade-vergence movements, the onset of the version component was delayed until after stimulation offset. Unlike the middle and caudal SC, a small vergence component was observed during the microstimulation of the rostral SC. Thus, the

onset of saccade and vergence movements could be separated when stimulation was delivered to the rostral SC. Further differences between the rostral and posterior regions of SC were uncovered when stimulation interacted with pure vergence movements without a saccade component. A vergence, but not a version, component was initiated during stimulation of the rostral SC prior to the movement in depth (Chaturvedi and Van Gisbergen, 2000). Ongoing vergence movements stopped and reversed direction, often diverging the eyes beyond the initial fixation plane.

Chaturvedi and Van Gisbergen (1999, 2000) concluded that stimulation of the SC outputs zero vergence and desired saccade commands that interact with SC commands encoded for the three-dimensional saccade directed toward the visual target. The effect of the stimulation is to evoke a movement with version and vergence metrics reflecting an averaging process. While this concept makes a strong argument for participation of the SC in the control of vergence, additional experiments are required to support the hypothesis. A neural correlate of the vergence component within SC neurons has yet to be reported (Mays, 1996). Averaging effects observed during converging movements also need to be addressed during diverging movements with and without a saccade component.

ACCOMMODATION As our eyes converge or diverge, targets in the new depth plane become blurred. Accommodation is induced by contraction of the ciliary muscle, which changes the lens's radius of curvature. Thus, an important synkinesis exists between vergence and accommodation (Stark, 1983).

Stimulation of the rostral SC for prolonged periods and at fairly low intensities can alter accommodation in both eyes. Sawa and Ohtsuka (1994) found that after a latency of approximately 200 msec, the dioptric power abruptly increased and then reached a plateau with prolonged microstimulation. The duration and maximum amplitude of the accommodative response were linearly correlated with stimulation duration and intensity, respectively. The low-threshold sites that produced accommodation were located within the superficial and intermediate layers of the rostral SC. Since the SC region that evoked accommodation overlaps, at least partially, with the location of fixation neurons, some neurons within the rostral SC may participate in active fixation as well as accommodation. Ohtsuka and Nagasaka (1999) injected different dyes into regions involved in controlling fixation (OPN region) and accommodation (e.g., posterior pretectal nucleus) and identified the retrogradely labeled cells in the SC. While double-labeled neurons were found throughout the SC, the population was highest in the rostral SC.

Given the close integration between the vergence and accommodation systems, it is important to understand

how vergence was perturbed by the stimulation; unfortunately, vergence eye movements were not recorded in these accommodation experiments. Further research is required to understand the role of SC in accommodation and vergence.

ARM MOVEMENT-RELATED NEURONS So far, we have addressed SC participation during saccades, eye movements other than saccades, and coordinated eye-head movements. Previous studies have also presented evidence that the SC participates in movements utilizing other skeletomotor systems. For example, stimulation of the cat SC evokes pinnae and vibrissae movements, and prolonged stimulation of the rat SC can evoke circling behavior (see Freedman et al., 1996, for a review). More recently, neurophysiological studies have suggested that the deeper layers of the SC and the underlying mesencephalic reticular formation in monkey may also participate in the control of arm movements (Stuphorn et al., 1999, 2000; Werner et al., 1997a; Werner et al., 1997b). These findings have important implications for our understanding of the neural control of integrated eye-hand movements.

Monkeys were trained to reach for targets in two conditions: one in which the subjects made a saccade to the target before touching it, and another in which the animals maintained fixation at the central stimulus while reaching for a target presented in the visual periphery. Arm movement-related discharge in SC neurons and electromyographic (EMG) activity from muscles of the shoulder, arm, trunk, and neck were recorded as the head-restrained animals performed the two tasks. The cross-correlations of discharge of many neurons and the EMG activity of several muscles, particularly those of the shoulder girdle, were highly significant. The discharge of most neurons and the EMG activity of many muscles led movement onset. For a small percentage of neurons, the average correlation coefficient between burst onset and movement onset was close to 1. Thus, the authors speculated that the neural discharge may provide the initiation signal for the arm movement.

The majority of these *reach* neurons did not discharge during saccades. Those that resided deeper than 4 mm below the surface of the SC and in the underlying mesencephalic reticular formation were not modulated by gaze position. Hoffman and colleagues (Stuphorn et al., 1999, 2000; Werner, et al., 1997a; Werner, et al., 1997b) proposed that these gaze-position-independent reach neurons may encode information more specific to the recruitment of appropriate muscles, although this notion needs to be tested.

Some dorsal neurons were intermingled within the saccade-related neurons of the SC, and many of them also exhibited visual, somatosensory, and/or saccade-related activity. Furthermore, the activity of reach neurons within

the SC was often modified by gaze position. Since the gaze-position-sensitive reach neurons were insensitive to the temporal profile of the reach movement, Hoffman and colleagues (Stuphorn et al., 1999, 2000; Werner, et al., 1997a; Werner, et al., 1997b) hypothesized that they might encode the amplitude and direction of the desired arm movement. It should be noted, however, that there is no evidence to support the hypothesis that either the location or firing rate of neurons with reach-related activity is related to either the amplitude or direction of an arm movement.

Although the extent of overlap in the saccade and reach movement fields still needs to be explored thoroughly, there appears to be a rough topography along the mediolateral extent—medial (lateral) regions encoding saccades and reach movements with upward (downward) movements. While saccades in the contralateral space were encoded by SC neurons, reach-related activity also included preferred movement directions into the ipsilateral hemifield. In this sense, the topography of the saccade and reach maps appears incongruent.

Summary

In this chapter, we evaluated several new lines of research that have emerged since the last detailed review of the role of SC in the control of orienting behavior (Sparks and Hartwich-Young, 1989). Over the past decade, significant research efforts have been devoted to understanding the role of collicular neurons in controlling the dynamics of saccades, determining whether the SC is inside or outside the feedback loop controlling saccade duration, and studying the participation of the SC in accommodation, fixation behavior, smooth pursuit, vergence, coordinated movements of the eyes and head, and reaching movements of the arms. We described problems in interpreting the results of experiments in which more than one movement system is active and issues that must be resolved before agreement can be reached on the expanded role of the SC in various movements.

98 The Dialogue between Cerebral Cortex and Superior Colliculus: Implications for Saccadic Target Selection and Corollary Discharge

MARC A. SOMMER AND ROBERT H. WURTZ

OUR SENSE OF VISION and our eye movements are intimately intertwined. Because high-acuity vision requires foveal inspection, we frequently make rapid or *saccadic* eye movements to shift images of interest onto the fovea. Visual perception provides information about where to look next and thus directs our saccades, and the resulting saccades move the retinas and therefore influence vision. Understanding how vision and saccades work together instead of in opposition to each other is critical for understanding how we see so effortlessly and efficiently.

It is becoming clear that cognitive processes play key roles in facilitating the cooperation between vision and saccades. By *cognitive processes*, we mean processes of information manipulation, in contrast to more rudimentary functions of sensory detection and movement execution. Cognitive processes range from the conscious and voluntary (e.g., rehearsal during short-term memory) to the unconscious and involuntary (e.g., procedural learning). In this chapter we concentrate on two cognitive processes important for visuosaccadic behavior and discuss some of the neuronal networks that mediate them.

The first cognitive process is the translation of generalized visual analysis into a specific decision about where to look next. We are usually aware of numerous objects in the visual scene, but we can make a saccade to only one object at a time. An efficient selection process is clearly needed. This first cognitive function, often conscious and voluntary in nature, might be thought of as a *forward* function in that information about the visual scene influences movement. We call it *saccadic target selection*, a term encapsulating multiple operations such as shifting attention, deciding where to look next, and preparing to move.

The second cognitive process is that which allows us to maintain a stable visual percept despite all the saccades we make. Saccades move the retinas at high velocity, and if our visual system did not have foreknowledge about these

sudden shifts, they would induce the alarming percept of a world constantly jumping around. Our visual system uses advance information about each upcoming saccade to lessen the imminent adverse effects of moving the retinas. This second cognitive function (an unconscious and involuntary one) might be thought of as a *reverse* function in that information about movement influences vision. We refer to it as a *corollary discharge* function (after Sperry, 1950), because it involves monitoring an internal correlate of a neuronal movement command. As will be discussed, corollary discharge has other uses as well, such as helping to produce a sequence of movements.

How does the brain accomplish these cognitive functions? We have known that both the cerebral cortex and the brainstem are important components of the visuosaccadic system for over a century (for a historical review see Tehovnik et al., 2000). Since about 1970, moreover, this research has benefited from a growing interest in exploring the neuronal bases of cognitive processes. Currently, it is well understood that many brain regions once thought to be primarily involved *either* in passive visual analysis *or* in eye movement generation are, in fact, involved in *both* and are additionally involved in the cognitive processes accompanying vision and eye movements. One such structure is the superior colliculus (SC), which lies on the roof of the midbrain, and other such structures lie in the cerebral cortex.

The cognitive functions that we consider are mediated by activity coursing in a network distributed throughout the brain; neither saccadic target selection nor corollary discharge arises from activity within a single brain area. As we will discuss, the projections from cerebral cortex to the SC have been studied in great detail, and the results indicate that saccadic target selection develops gradually from earlier, more visually related stages in cortex to later, more movement-related stages in the SC. Furthermore, there are at least two ascending pathways from the SC to cerebral

cortex. One seems to contribute to corollary discharge, and the other may contribute to spatial visual attention.

The interconnections between cerebral cortex and SC

Saccades are mediated by a system extending from the retina to the extraocular muscles that has been most extensively studied in the rhesus monkey, the animal model on which we will concentrate. The visuosaccadic system can be regarded as having three limbs, two of which are the afferent and efferent limbs (Fig. 98.1*A*). The afferent limb provides visual input from the retina. This pathway branches into two main routes, one coursing to the lateral geniculate nucleus and then to striate cortex (also known as V1) and another coursing to the superficial layers of the SC. The efferent limb provides motor output to the extraocular muscles. Motor commands are produced in the saccade generating circuitry in the brainstem, a collection of regions in the pons and midbrain that receives descending input from the SC and other structures.

The third limb is intermediary, connecting the afferent and efferent limbs (Fig. 98.1*B*). It is in this vast network of “in-between” areas that activity related to cognitive processes presumably resides, and interconnections between cerebral cortex and the SC are a major component of this network. Several regions of cerebral cortex project monosynaptically to the SC, and the SC reciprocates by projecting disynaptically up to many cerebral cortical regions via the thalamus (for reviews of the anatomy, see Leichnetz and Goldberg, 1988; Sparks and Hartwich-Young, 1989).

The SC and certain cortical regions are necessary for saccade generation. Reversible inactivation of the frontal eye field (Fig. 98.1*B*, FEF) causes severe deficits in the ability to make saccades to remembered targets (Chafee and Goldman-Rakic, 2000; Dias and Segraves, 1999; Sommer and Tehovnik, 1997), and similar effects have been reported for inactivation of the lateral intraparietal area (Fig. 98.1*B*, LIP) (Li et al., 1999). Reversible inactivation of the SC causes deficits in saccade production for all saccades made to either remembered or visual targets (Aizawa and Wurtz, 1998; Hikosaka and Wurtz, 1985; Lee et al., 1988; Schiller et al., 1987). Permanent ablation of either the SC or the frontal eye field causes serious deficits for a week or so, after which monkeys largely recover, but combined bilateral lesions of both the SC and the frontal eye field permanently devastate saccadic behavior (Schiller et al., 1980). The influence of many cortical regions seems to depend in large part on their projections to the SC; for example, the ability to evoke saccades electrically from the frontal eye field is severely impaired by inactivating the SC (Hanes and Wurtz, 2001), and the ability to evoke saccades electrically from the parietal and occipital lobes is abolished by ablating the SC

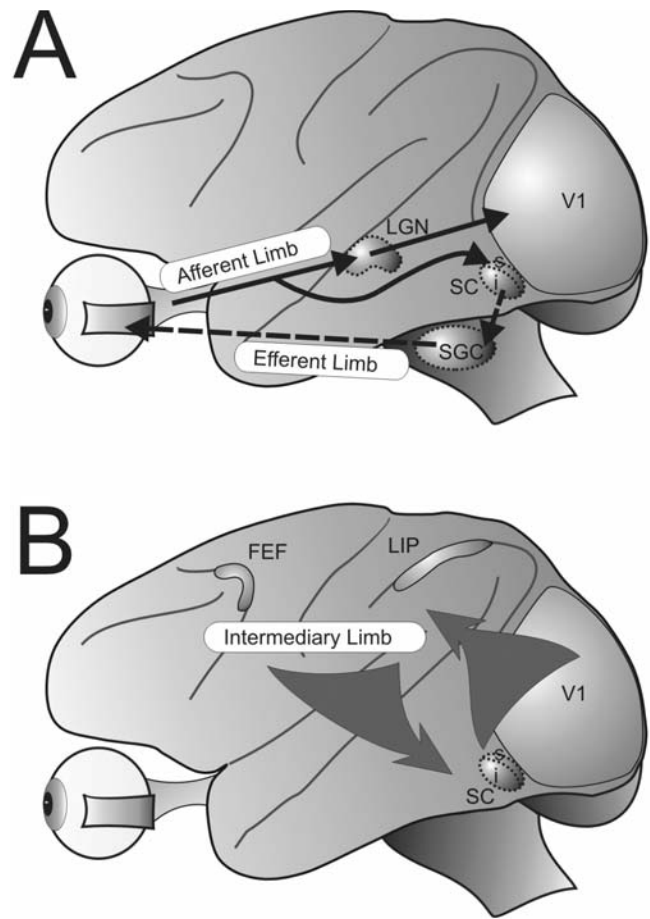

FIGURE 98.1. The three limbs of the visuosaccadic system in the monkey. *A*, The afferent limb, which provides visual input from the retina, and the efferent limb, which causes muscle contractions. Structures with dashed outlines are subcortical. There are other targets of retinal projections, too, but they are beyond the scope of this chapter. SC, superior colliculus (s, superficial layer; i, intermediate layer); LGN, lateral geniculate nucleus; V1, striate cortex; SGC, saccade generating circuitry. *B*, The intermediary limb, which connects the afferent and efferent limbs. This limb is a network of brain regions; prominent among them are the frontal eye field (FEF) and the lateral intraparietal area (LIP).

and the frontal eye field (Keating and Gooley, 1988; Schiller, 1977).

In sum, there is good reason to suspect that the overall network composed of the cerebral cortex and the SC is important for saccade generation. In the first half of this chapter, we will review what is known about the signals descending from cerebral cortex to the SC. Investigated so far have been three direct projections emanating from the frontal eye field, the lateral intraparietal area, and the striate cortex (Fig. 98.2*A*) and one indirect pathway, a basal ganglia route that relays signals from cortex to the SC via the substantia nigra pars reticulata (Fig. 98.2*B*). Then we will discuss the signals flowing in ascending pathways from the SC to cerebral cortex. Two such pathways are starting to be well

characterized, one that reaches the frontal cortex via the mediodorsal thalamus and another that reaches the parietal cortex via the pulvinar (Fig. 98.2C).

To eavesdrop on the dialogue between cerebral cortex and the SC, investigators have identified neurons that talk back and forth between the areas using two methods: antidromic and orthodromic activation. *Antidromic* activation is used to see if a recorded neuron in one region (e.g., a part of cortex) projects to another region (e.g., the SC). Figure 98.3A shows the logic. If electrical stimulation in region B causes a

recorded neuron in region A to fire at a fixed latency, and if other tests including one known as the *collision test* are successful (see the review by Lemon, 1984), then it is concluded that the neuron in region A is being activated through its own axon; therefore, the neuron projects to region B. *Orthodromic* activation is used to see if a recorded neuron in one region is receiving input from another region (Fig. 98.3B). If stimulation in region A causes a recorded neuron in region B to fire at a jittery latency and the collision test fails, then it is concluded that the neuron is being activated through synapses; therefore, this neuron receives input from region A. After a neuron's connections are identified with one or both of these methods, it is then analyzed to determine what signals it is carrying, as discussed next.

Descending projections from cortex to the SC

THE STAGES OF NEURONAL ACTIVITY RELATED TO VISUOSACCADIC BEHAVIOR Generating a saccade in response to visual stimulation involves a series of steps including analyzing the visual scene, attending to objects within it, remembering the locations of objects, deciding to look somewhere, preparing a saccade, and executing the movement. It is reasonable to presume that these steps are accompanied at the neuronal level by sequential stages of activity. Figure 98.4 illustrates examples of neuronal activity that may contribute to various stages of visuosaccadic behavior. These examples were recorded from two SC-projecting cortical neurons (a lateral intraparietal area neuron, Fig. 98.4B, *top*, and a frontal eye field neuron, Fig. 98.4B, *middle*), both identified using antidromic activation, and from a neuron within the intermediate layers of the SC (Fig. 98.4B, *bottom*). The neurons were studied while the monkey performed a visual delayed-saccade task (Fig. 98.4A, *left*). The monkey fixated a spot of light during a baseline period, and then a target flashed in the periphery (Fig. 98.4A, *top left*). The monkey was required to maintain fixation for an extended delay period (500 to 1000 msec) until the

C Ascending Pathways

FIGURE 98.2. The descending projections and ascending pathways connecting cerebral cortex and the SC that have thus far been examined. *A*, Direct projections from cerebral cortex to the SC. The frontal eye field (FEF) and lateral intraparietal area (LIP) project to the SC intermediate layers, and the striate cortex (V1) projects to the SC superficial layers. *B*, Indirect route from cerebral cortex to the SC via the basal ganglia. Many regions of cerebral cortex project to the caudate nucleus (CN), which in turn projects to the substantia nigra. The substantia nigra pars reticulata (SNr) relays these signals to the intermediate SC. *C*, The ascending pathways from the SC to cerebral cortex. The intermediate SC projects to the mediodorsal thalamus (MD), which in turn projects to the frontal eye field and other prefrontal regions. The superficial SC projects to the pulvinar (Pulv.), which in turn projects to the lateral intraparietal area and other extrastriate regions.

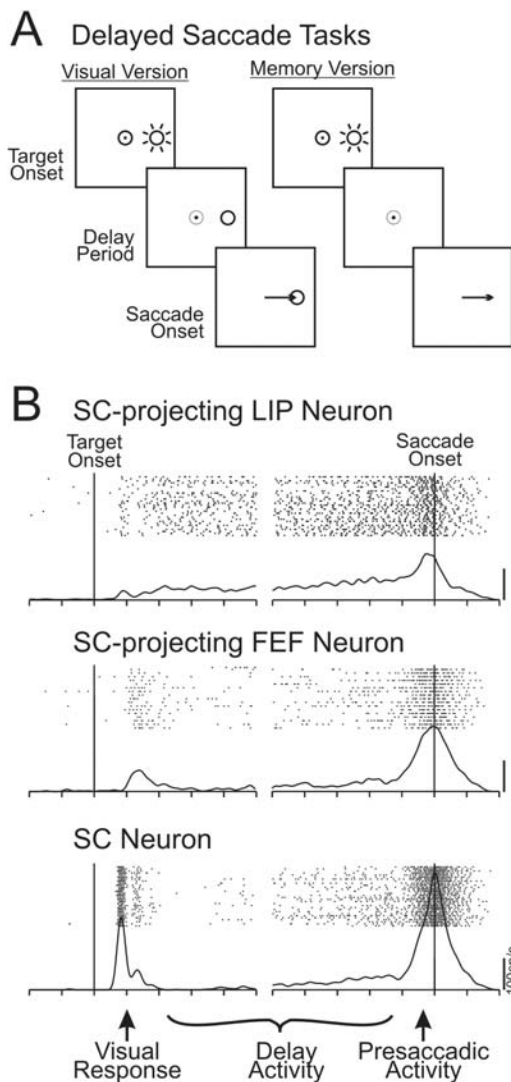

FIGURE 98.3. Methods for evaluating the signals sent between brain regions. *A*, In antidromic activation, one region, *B*, is stimulated while recording from a neuron in another region, *A*. Stimulation-evoked action potentials travel backward through the axon of the neuron and are recorded at the cell body. *B*, In orthodromic activation, one region, *A*, is stimulated while recording from a

neuron in another region, *B*. Stimulation evoked action potentials travel forward through projections and drive the neuron via synapses, and resultant postsynaptic action potentials are recorded at the cell body. (Spike waveform pictures modified from Sommer and Wurtz, 1998.)

fixation spot disappeared, which was the cue to move (Fig. 98.4*A*, middle left). Then the monkey was required to make a saccade to the location of the target (Fig. 98.4*A*, bottom left). Also used was a memory version of the task (Fig. 98.4*A*, right), which was identical to the visual version except that the target appeared only briefly so that its location had to be remembered during the delay period. These are classic delayed-response tasks similar to those introduced by Jacobsen (1935, 1936) for studying short-term memory deficits after frontal lobe damage, except that his experiments involved forelimb movements; the tasks were adapted for oculomotor research by Hikosaka and Wurtz (1983a). All the example neurons (Fig. 98.4*B*) were quiet during a baseline period before target onset and then, just after target onset, they exhibited a sudden increase of activity that probably represented detection of the target (Fig. 98.4*B*, visual response). Each neuron's activity then remained elevated above the baseline level during the delay period (Fig. 98.4*B*, delay activity). Just before saccade onset, the neurons exhibited

FIGURE 98.4. Visual, delay, and presaccadic neuronal activity. *A*, The signals carried by identified neurons typically are characterized using one or more versions of the delayed-saccade task. See text for details. *B*, Examples of activity recorded from an SC-projecting lateral intraparietal area (LIP) neuron, an SC-projecting frontal eye field (FEF) neuron, and an intermediate layer SC neuron while monkeys performed the visual version of the delayed-saccade task. In each panel the activity is aligned on target onset (left) and saccade onset (right). Rasters of dots show individual action potentials (each row is from a different trial). Curves show averaged firing rates (scale at the right). The time scale is 100 msec per tick on the abscissa. At the bottom, the visual responses, delay activity, and presaccadic activity are labeled. (Modified from Wurtz et al., 2001.)

increases in activity that probably represented commands to move the eyes (Fig. 98.4B, *presaccadic activity*).

It is the delay activity that is of particular interest to us because it occurs after the initial visual response and before a saccade is made, during the time when saccadic target selection should be occurring. Ever since the discovery of delay activity by Fuster and Alexander (1971), investigators have used a variety of methods to tease out what this activity represents. Studies of neurons throughout the brain have found that delay activity can be a correlate of nearly every cognitive function imaginable, including various types of memory, spatial attention, representation of task rules, operations linked to categorization (e.g., whether a viewed animal is a cat or dog), and movement preparation (for reviews see Fuster, 1997; Miller, 2000). Most of these studies examined neurons without identifying their connections, for example, without determining if they projected to the SC. In the following sections, we will discuss only those studies that examined neurons explicitly identified as sending delay activity and other signals to the SC.

SIGNALS SENT FROM FRONTAL CORTEX TO THE SC The first investigators to examine the signals sent from any cerebral cortical area to the SC in behaving monkeys were Segraves and Goldberg (1987), who used antidromic activation to identify SC-projecting frontal eye field neurons and studied their activity while monkeys performed a variety of tasks that included delayed saccade tasks. The results established that a variety of signals are transmitted from the frontal eye field to the SC, including visual responses, delay activity, and presaccadic bursts of activity. Segraves and Goldberg concluded, however, that the predominant output signal was a movement command represented by the presaccadic burst, implying that earlier visual detection and saccadic target selection functions are performed, for the most part, locally within the cerebral cortex.

To characterize more thoroughly the delay activity sent from frontal eye field to the SC, Sommer and Wurtz (2001a) studied SC-projecting frontal eye field neurons while monkeys performed a go/no-go delayed-saccade task. This task was similar to that diagrammed in Figure 98.4A, except that during the delay period the color of the fixation point changed. In half of the trials (go trials) the color changed to green, instructing the monkey to make a saccade to the target location after the delay period, and in the remaining trials (no-go trials) the color changed to red, instructing the monkey to maintain fixation after the delay period. This revealed whether delay activity was related to producing saccades. Separate visual and memory versions of the task revealed whether this delay activity was related more closely to working memory, to visual attention, or to movement preparation. They found, first, that delay activity was quite common in the SC-projecting frontal eye field neurons

(occurring in ~75% of the neurons) and, second, that the activity clearly did not represent only a single cognitive function. Most prevalent was delay activity related to working memory and to saccade preparation.

This study also revealed that the composition of signals sent from the frontal eye field to the SC was actually very diverse and included purely visual neurons as well as purely movement-related neurons (Sommer and Wurtz, 2000a). Reasons why these results differ from those of Segraves and Goldberg (1987), who found no purely visual neurons and a larger fraction of purely movement-related neurons, are discussed elsewhere (Sommer and Wurtz, 2000a). It is now well established that the signals carried by SC-projecting frontal eye field neurons are similar to those generally found in the frontal eye field (also noted by Everling and Munoz, 2000). This is true not only for the frontal eye field in monkey, but also for the homologous region (area 6) in cat (Weyand and Gafka, 1998a, 1998b).

Two other important signals are also transmitted from the frontal eye field to the SC. First, the projection carries fixation-related activity that starts when a monkey foveates a spot and continues even if the spot is briefly removed (Segraves and Goldberg, 1987). This activity seems to be sent to the entire SC (Sommer and Wurtz, 2000a), not just to the rostral SC where neurons with similar fixation-related signals are found (Munoz and Wurtz, 1993). Therefore, the descending fixation signals from the frontal eye field may work in parallel with rostral SC fixation signals to inhibit caudal, saccade-related SC neurons and keep the eyes steady. Second, the projection from the frontal eye field to the SC carries activity related to preparatory set (Everling and Munoz, 2000). In a task where the monkey was instructed by the fixation point color to make a saccade either toward or away from a suddenly appearing peripheral target, movement-related neurons projecting from the frontal eye field to the SC showed, on average, higher activity during the fixation period and just after target onset when the instruction was to make a saccade *toward* the target. Therefore, the projection may contribute to larger visual responses in the SC when stimuli are to be targeted for saccades, which may help shorten reaction times. These two issues, of fixation-related activity and preparatory set, are discussed further below.

Although the frontal eye field sends a multitude of signals to the SC, this does not prove that the signals affect the activity of SC neurons. To address this issue of causality, other studies used methods involving orthodromic stimulation. Guitton and Mandl (1974) showed, in paralyzed cats, that stimulating the frontal eye field can increase or decrease the activity of SC neurons. Schlag-Rey et al. (1992) examined the issue in behaving monkeys, stimulating the frontal eye field while recording from SC neurons during delayed-saccade tasks. They found that the sign of the stimulation-

evoked change in SC activity was a function of topography: when the frontal eye field and SC sites represented similar saccadic vectors, frontal eye field stimulation caused SC activity to increase, but if the vectors were mismatched, stimulation caused SC activity to decrease. Because the direct projection from the frontal eye field is presumably excitatory (glutamatergic), the decreases in activity seen in these studies likely were mediated by multisynaptic pathways, for example, via GABAergic interneurons within the SC.

In sum, the projection from the frontal eye field to the SC carries an abundance of signal types and is functionally potent. Besides the frontal eye field, other frontal regions such as the supplementary eye field also project to the SC and contain neurons having visual responses, delay activity, and presaccadic activity (reviewed by Schall, 1997). However, antidromic and orthodromic activation studies still need to be performed to determine precisely how these other areas influence the SC.

SIGNALS SENT FROM PARIETAL CORTEX TO THE SC Paré and Wurtz (1997) provided the first description of signals sent from any area of parietal cortex to the SC. They focused on the lateral intraparietal area, probably the most important parietal region for saccadic behavior. Using standard delayed-saccade tasks (Fig. 98.4.4), they demonstrated that SC-projecting lateral intraparietal area neurons carry visual, delay, presaccadic, and fixation-related activity. Not surprisingly, given the results already discussed in this chapter, the distribution of signals seemed quite similar to the distribution generally found in the lateral intraparietal area. A go/no-go task identical to that described above was used to study the delay activity in detail, revealing it to be highly diverse. In some neurons the activity seemed related to attending to or remembering the visual target, and in others it seemed more related to preparing the saccade. In all these ways, the SC-projecting lateral intraparietal area neurons were qualitatively similar to SC-projecting frontal eye field neurons. Differences could be detected only quantitatively (Wurtz et al., 2001), as discussed below.

At about the same time, Gnadt and Beyer (1998) showed that SC-projecting lateral intraparietal area neurons are tuned for binocular disparity, providing information about visual depth. This was expanded upon by Ferraina et al. (2002), who concluded that the disparity tuning was quite broad. Finally, the latter authors additionally found that some neurons in the adjacent ventral intraparietal area exhibiting strong sensitivity to visual motion also project to the SC (Paré et al., 1999).

SIGNALS SENT INDIRECTLY FROM CORTEX TO THE SC VIA THE BASAL GANGLIA In addition to the direct connections that carry signals from cerebral cortex to the SC, there is a crit-

ical indirect route through the basal ganglia. Many cerebral cortical areas project to the caudate nucleus, which in turn projects to the substantia nigra. Both of these projections are excitatory. The substantia nigra pars reticulata contains GABAergic neurons that project to and inhibit SC neurons. Unlike the signals sent from cortex to the SC, which usually take the form of elevations of activity above a quiet baseline level, the signals sent from the substantia nigra to the SC are usually manifested as decreases in activity below a steady, elevated baseline level (for review see Hikosaka et al., 2000).

Two studies examined SC-projecting substantia nigra neurons, and both found a great variety of signals transmitted. Hikosaka and Wurtz (1983b) concluded that every type of signal present in substantia nigra pars reticulata seems to be sent to the SC. This included visual signals, delay activity, and presaccadic activity. The delay activity was thought to be related to short-term visual memory, although it could have been related to movement preparation as well (experiments systematically manipulating whether a saccade occurred or not, i.e., go/no-go experiments, were not performed). They also found that the visual and presaccadic discharges of SC-projecting neurons often were influenced by the context of the task, being different when saccades were made to remembered as compared to visual targets.

Basso and Wurtz (2002) studied how the activity of substantia nigra pars reticulata neurons varied with the probability of making a saccade. In their task, multiple visual stimuli were presented simultaneously, and the probability that saccadic target selection had to occur for any one of the stimuli was manipulated by varying the number of stimuli (from one stimulus, corresponding to a 100% probability of saccadic target selection occurring for that stimulus, to eight stimuli, corresponding to only a 12.5% probability of saccadic target selection occurring for any particular stimulus). Only a minority of their substantia nigra neurons was identified as projecting to the SC, but they found no obvious differences in this subset as compared to the general sample of substantia nigra neurons examined. They previously had found that the delay activity of intermediate-layer SC neurons varied strongly with probability in this task: the greater the chance that saccadic target selection would occur for a target in the neuron's receptive field, the higher the level of delay activity (Basso and Wurtz, 1998). Surprisingly, however, this was not the case for substantia nigra neurons, which usually maintained the same level of delay activity regardless of the chance of saccadic target selection occurring for the target in the receptive field. This maintained level was only slightly different than the background firing rate. This suggests that one or more of the *direct* cortical projections to the SC, *not* the indirect route through the nigra, is primarily responsible for changes in SC delay activity

during saccadic target selection. Basso and Wurtz did find, however, that the short-latency visual responses of nigral neurons were strongly modulated by the probability of saccadic target selection. Taken together with the result of Hikosaka and Wurtz (1983b) that the visual responses of SC-projecting nigral neurons are sensitive to task context, these data suggest that the major cognitive-related influence of substantia nigra on SC is to cause visual-related changes in activity related to very early stages of saccadic target selection. Presumably these influences are primarily attentional in nature, as they are represented by altered visual responsiveness.

SIGNALS SENT FROM STRIATE CORTEX TO THE SC The final direct projection from cerebral cortex to the SC that has been investigated emanates from striate cortex. Unlike the other projections we have discussed, all of which target predominantly the intermediate layers of the SC, the projections from striate cortex target primarily the *superficial* layer (Kuypers and Lawrence, 1967; Ogren and Hendrickson, 1976). The SC superficial layer also receives direct projections from the retina (Cowey and Perry, 1980; Hendrickson et al., 1970), and neurons in this part of SC are visually responsive, with no presaccadic bursts of activity. Because it has been shown recently that striate cortical activity is influenced by attention (Haenny and Schiller, 1988; Motter, 1993; Posner and Gilbert, 1999) and may have delay activity related to short-term visual memory (Super et al., 2001), it is possible that signals in the projection from striate cortex might play some role in saccadic target selection. Whether this is true, however, remains unclear. The only study to examine this, in cat, found that SC-projecting striate cortical neurons often have enhanced visual responses when a visual stimulus is used as the target for a saccade as opposed to when it is viewed passively (Weyand and Gafka, 2001). In principle, this could represent spatial visual attention. It was not determined, however, whether the enhancement occurred only when saccades were made *toward* the target; for comparison, Wurtz and Mohler (1976a) showed that enhancement effects in monkey striate cortex are independent of saccade direction and therefore cannot represent a spatially localized shift of attention. The modulation might represent a general arousal or vigilance effect (or other effects beyond the scope of this discussion; see Weyand and Gafka, 2001).

Earlier studies of SC-projecting striate cortical neurons used anesthetized, paralyzed animals (cat: Palmer and Rosenquist, 1974; monkey: Finlay et al., 1976). These studies were valuable in describing the visual characteristics of SC-projecting striate cortical neurons (the neurons were typically binocular, complex, and orientation- and direction-tuned, with large receptive fields), but they did not address cognitive issues.

Also of interest in considering the relationship between visual cortex and the SC, at least with respect to cats, is the *Sprague effect* (Sprague, 1966): after ablation of visual cortex (including virtually all occipital visual areas, not just striate cortex), cats fail to orient to contralateral visual stimuli, but recovery occurs if the SC contralateral to the ablated cortex is lesioned or if the collicular commissure is cut. In a series of experiments, Rosenquist and colleagues showed that this recovery is likely due to disinhibition of the SC caused by interruption of fibers in the collicular commissure coming from the substantia nigra pars reticulata and from the pedunculo-pontine region (for a summary, see Durmer and Rosenquist, 2001). The Sprague effect has not been investigated in monkeys because the recovery of visual orienting is so fast following lesioning of visual cortex (in this case limited to striate cortex) that no subsequent interventions at the level of the SC are required for nearly complete recovery of orienting saccadic eye movements (Mohler and Wurtz, 1977).

GRADUAL PROGRESSION OF SACCADIC TARGET SELECTION FROM CORTEX TO THE SC As discussed above, neurons in the frontal eye field and the lateral intraparietal area send to the intermediate layers of the SC a wide range of signals related to visuosaccadic behavior, which leads to two questions. First, are the signals leaving these two cortical regions similar to each other or radically different from each other? And second, how do the signals sent from these cortical areas compare with signals in the recipient structure, the SC? To answer these questions, Wurtz and colleagues studied SC-projecting frontal eye field neurons, SC-projecting lateral intraparietal area neurons, and intermediate layer SC neurons using identical tasks, equipment, and analytical techniques (for detailed analysis, see Wurtz et al., 2001). They found that, qualitatively, the signals carried by SC-projecting neurons in both cortical areas were quite similar to each other and to the signals within the SC. Neurons in all three populations exhibited visual responses, delay activity, and presaccadic activity in nearly every possible combination.

When the signals were analyzed quantitatively, however, important differences were uncovered. First, the delay activity was examined to see if it was more strongly influenced by the visual target or by the upcoming movement. To gauge the influence of *visual stimulation* on the delay activity, the activity was compared in the visual and memory versions of the standard delayed-saccade task (Fig. 98.44). It was found that delay activity in the SC-projecting neurons of both cortical regions was strongly enhanced by visual input (to a similar degree in both regions), whereas delay activity in the SC intermediate layers was much less visually related, being equal whether a target remained in the receptive field or disappeared. To measure the influence

of *upcoming movement* on the delay activity, the activity was compared in the go and no-go trials of the go/no-go delayed-saccade task described above. Delay activity in the SC was much more strongly enhanced by upcoming movement than was delay activity in SC-projecting neurons of either cortical population.

Next, the visual responses and presaccadic activity of the neurons were compared. Visual responses in the three populations of neurons were not markedly different. The presaccadic activity, however, was much more intense in SC neurons (nearly always 200 to 600 spikes per second) than in cortical output neurons (rarely >200 spikes per second). Also, when the two populations of cortical output neurons were compared, SC-projecting frontal eye field neurons often were found to have presaccadic activity as their only signal (so-called pure movement neurons), whereas this was never seen in the SC-projecting lateral intraparietal area neurons.

In sum, this investigation answered both questions posed above. First, signals leaving the two cortical areas are not radically different from each other; they are similar, with only limited differences. Second, signals sent to the SC intermediate layers and signals within the SC intermediate layers are similar, except for important quantitative differences. Compared to the cortical output neurons, the SC neurons are more movement-related and less visually related. From cortex to the SC intermediate layers, there seems to be a gradual change in signal content corresponding to a progression in saccadic target selection processes from more visually related (i.e., processes of attention and visual memory) to more movement-related (i.e., processes of saccade preparation).

Other, less direct comparisons of cortical and SC activity support this idea. Everling and colleagues (Everling and Munoz, 2000; Everling et al., 1999), for example, examined neurons in the SC intermediate layers and in the frontal eye field using identical techniques. Here we consider their total sample of frontal eye field neurons, the projections of which were not identified except for a minority shown to project to the SC (results pertaining specifically to these SC-projecting neurons were discussed above). Neurons in both the frontal eye field and the SC had higher activity throughout trials when monkeys had to make saccades toward, as opposed to away from, a visual stimulus in the receptive field. Furthermore, activity in both areas predicted reaction time and the occurrence of errant saccades, indicating that the activity was strongly related to saccade production. The investigators concluded, however, that although these effects were similar in the two areas, they were weaker in the frontal eye field than in the SC.

Several other studies have examined cognitive-related activity in the SC intermediate layers as well (for detailed reviews see Basso, 1998; Wurtz et al., 2000). Glimcher and

Sparks (1992) were the first to examine systematically SC delay activity. They presented two peripheral visual stimuli, one within and one outside of the neuron's receptive field, and instructed monkeys by means of a central color cue which stimulus would be the saccadic target. They found that shortly after the monkeys were instructed to make their eventual saccade into a neuron's receptive field, activity of the neuron increased dramatically. Building on this result, Basso and Wurtz (1998) and Dorris and Munoz (1998) showed that the intensity of cognitive-related activity in SC neurons is directly correlated with the graded probability of making a saccade to a particular visual stimulus. In these and similar studies (Dorris et al., 1997; Everling et al., 1998, 1999), it was repeatedly found that cognitive-related SC activity predicted saccadic reaction times and the production of errant saccades, indicating that it was strongly movement-related. In contrast, Sommer and Wurtz (2001a) showed that delay activity sent from the frontal eye field to the SC does *not* seem to predict either reaction time or errant saccades. Taken together, these studies reinforce the model of a gradual progression in saccadic target selection processes that becomes more movement-related from cerebral cortex to the SC.

To see if delay activity in the SC really does influence saccadic target selection, Kustov and Robinson (1996) combined single-unit recordings with electrical stimulation to evoke saccades. They used tasks in which a peripheral or central cue elicited a shift of attention to one of two possible targets, one of which was located in the part of the visual field represented by the site studied in the SC. Monkeys exhibited decreased reaction times in making saccades to the cued targets, indicating that they shifted their attention as expected. The investigators found that delay activity in the SC increased during the attentional shifts and that when the SC was stimulated, evoked saccades were deviated toward the locus of attention. Hence, not only is the activity of SC neurons correlated with attentional shifts, but also it seems to affect the saccadic system such that electrically evoked saccades are altered. Similar conclusions were reached in a recent frontal eye field study (Moore and Fallah, 2001). In that experiment, subthreshold stimulation for evoking saccades in the frontal eye field caused enhanced performance in a spatial attention task, but only for attended targets located in the part of the visual field represented by the frontal eye field site. In summary, these studies confirm the underlying assumption that delay activity, at least in the SC and the frontal eye field, is in fact vital for the act of selecting a saccadic target.

Finally, Munoz and colleagues found neurons in the rostral pole of the SC that seem to inhibit, rather than facilitate, saccade production (for a review, see Wurtz et al., 2000). Whereas neuronal activity in more caudal SC is low during fixation and increases prominently just prior to

saccade production, activity in the rostral pole is high during fixation and decreases just prior to saccade production. Using orthodromic stimulation within the SC, they showed that the rostral pole's influence on neurons of the caudal SC is inhibitory (Munoz and Istvan, 1998). Therefore, some of the increased delay activity in caudal SC neurons during the experiments described above might be due in part to disinhibition caused by rostral SC afferents. Of course, this begs the question of what controls the rostral SC neurons; some of their input likely comes from cerebral cortex (Sommer and Wurtz, 2000a), but beyond that, little is known.

Ascending pathways from the SC to the cortex

The SC sends projections downstream, to the brainstem saccade-generating circuitry, and also *upstream*, to the thalamus. Ascending projections from the SC to the thalamus were identified anatomically decades ago (e.g., Benevento and Fallon, 1975), and it has long been presumed that these projections terminate on relay neurons that in turn project up to the cerebral cortex (e.g., Benevento and Rezak, 1976; Goldman-Rakic and Porrino, 1985). Very recently, these disynaptic pathways from the SC to cortex via the thalamus have been elucidated more directly using a novel anatomical method in which herpes viruses that pass retrogradely through synapses were injected into cerebral cortex. Primary and secondary labeling was detected in thalamic nuclei and the SC, respectively (Clower et al., 2001; Lynch et al., 1994).

Two major ascending pathways exist: one from the intermediate SC to the mediodorsal nucleus of the thalamus to the prefrontal cortex, and another from the superficial SC to the pulvinar region of the thalamus to extrastriate cortex. We will discuss the mediodorsal nucleus pathway in this section and the pulvinar pathway in the next.

THE ASCENDING PATHWAY THROUGH THE MEDIODORSAL NUCLEUS TO THE PREFRONTAL CORTEX Even before its presence was demonstrated explicitly by Lynch et al. (1994), a disynaptic pathway from intermediate SC to the prefrontal cortex was posited and there was much speculation regarding its possible function. Is it a *feedforward* route through which visual signals, some of which might be attentionally modulated, are relayed from the SC to prefrontal cortex (as hypothesized by Goldberg and Bushnell, 1981; Suzuki and Azuma, 1983; Wurtz and Mohler, 1976a)? Or is it a *feedback* route, through which prefrontal cortex is informed of the saccadic commands produced by the SC?

Evidence supporting both hypotheses was obtained in the first exploration of single neurons in primate visuomotor thalamus (Schlag and Schlag-Rey, 1984; Schlag-Rey and Schlag, 1984). Neurons located in or near the lateral edge of the mediodorsal thalamus, where SC-to-prefrontal cortex

relay neurons are found (Lynch et al., 1994), were shown to exhibit both visually related and saccade-related activity. The connections of these neurons were not physiologically identified, however, and thus it was unknown whether they actually projected to prefrontal cortex or received projections from the SC.

Recently, a set of studies used both identified neuronal recordings and reversible inactivation techniques to examine the pathway from SC to mediodorsal thalamus to frontal eye field (Sommer and Wurtz, 1998, 2000b, 2001b, 2002; Wurtz and Sommer, 2000). Every neuron in these experiments was shown with antidromic and/or orthodromic activation to be part of this ascending pathway. Three populations of neurons were studied: SC neurons projecting to the mediodorsal thalamus, mediodorsal thalamus relay neurons, and frontal eye field neurons targeted by the pathway. The conduction speed in this pathway is very fast: orthodromic and antidromic activation latencies confirmed that it only takes ~2.5 msec for signals to reach the frontal eye field from the SC through this route.

To characterize the signals carried by these neurons, delayed-saccade tasks were used, as described in previous sections. Neurons at every level of the pathway were active during these tasks, with most neurons having both a visual response and a presaccadic burst of activity and others having only one or the other signal. Therefore, both of the hypotheses noted above were supported in that the pathway definitely carries both visually related and movement-related discharges. Little delay activity was found in the ascending pathway, and therefore this activity was not characterized in detail using go/no-go or similar tasks.

Although the hypothesis that this pathway carries movement information was supported by the recording results, the results could not distinguish between two alternative possibilities regarding the function of these movement signals. Were they used as feedback, that is, corollary discharge, to inform the cerebral cortex about impending saccades, or were they used in a feedforward way to help in the execution of saccades? Both possibilities were supported by the characteristics of the neuronal activity in that the presaccadic bursts began ~100 msec prior to saccade onset and encoded specific vectors of saccades (i.e., the neurons usually had restricted movement fields).

To distinguish between these possibilities, reversible inactivation experiments were performed (Sommer and Wurtz, 2002) (Fig. 98.5A). The relay neurons were inactivated with the GABA agonist muscimol while monkeys performed either standard single-saccade tasks or else a double-step task that required corollary discharge information (Becker and Jürgens, 1979; Duhamel et al., 1992; Gaymard et al., 1994; Heide et al., 1995; Mays and Sparks, 1980). It was found that single saccades were not affected by inactivation, indicating that saccade-related signals in the ascending pathway

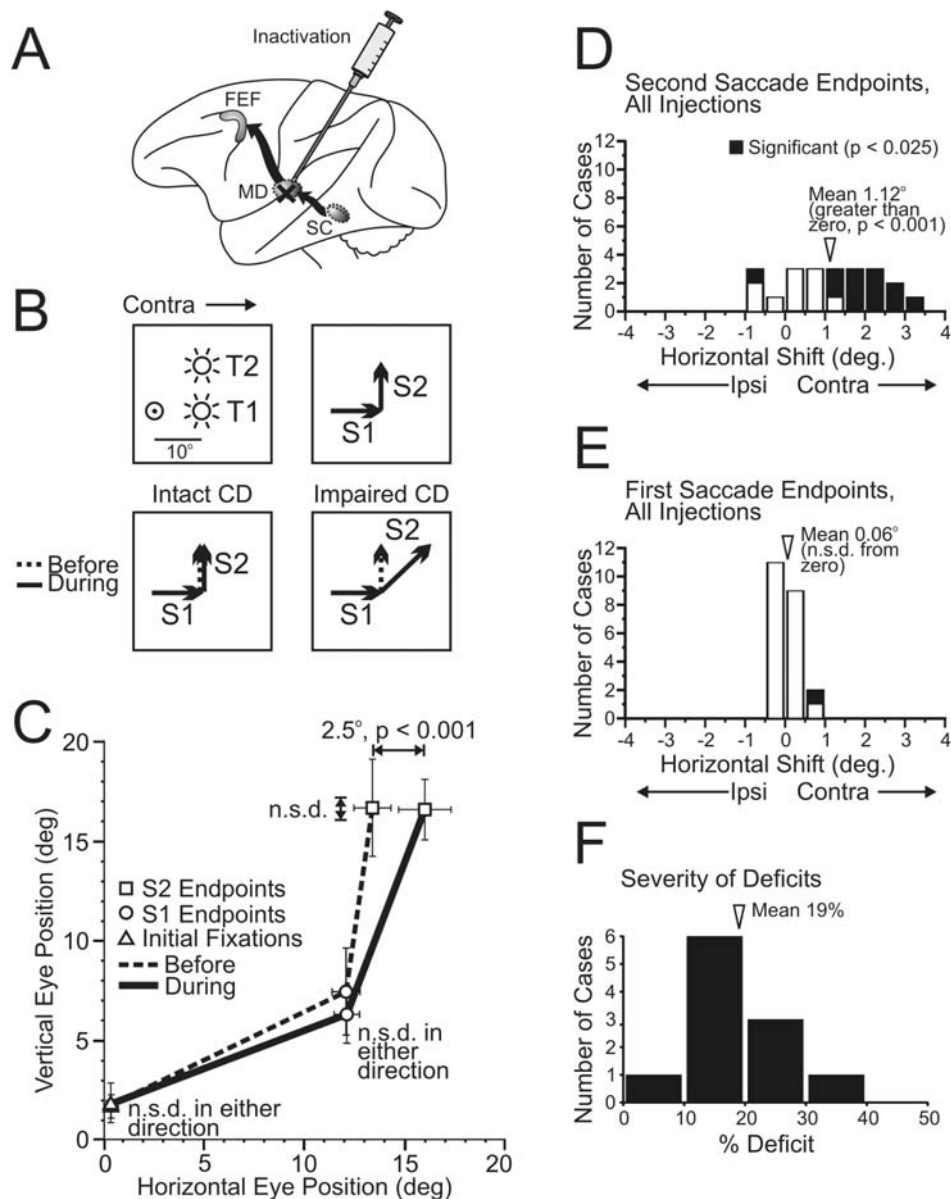

FIGURE 98.5. Test of the hypothesis that the ascending pathway through mediodorsal thalamus carries a corollary discharge signal. *A*, Muscimol was injected at the site of previously recorded mediodorsal thalamus relay neurons to inactivate them. *B*, Schematic of the double-step task. See text for details. T1, T2: first and second flashed targets, respectively; S1, S2: first and second saccades; CD, corollary discharge; Contra, contraversive to the injection site. *C*, Example results from a single injection. First saccades were shifted upward slightly as an artifact of being made in complete darkness (Gnadt et al., 1991). The differences in average locations, during versus before inactivation, were tested in both the horizontal and vertical directions for the initial fixation locations, the first saccade end points, and the second saccade end points. The only significant difference was a horizontal contraversive shift in second saccade end points as predicted by loss of corollary dis-

charge. n.s.d., not significantly different. *D*, Histogram of the horizontal shifts in second saccade end points for all cases (i.e., all the during vs. before pairs of saccadic sequences) in all injections. In nearly every case there was a contraversive shift. The mean shift was significantly greater than zero, as indicated, and many of the cases had an individually significant contraversive shift. The significance level is $p < .025$, which is Bonferroni-corrected from $p < .05$ because the data were tested in two directions. Ipsi, ipsiversive shift; Contra, contraversive shift. *E*, In contrast, first saccade end points were not shifted horizontally by inactivation (hence, the second saccade end-point shifts are not artifacts of prior first saccade end-point shifts). *F*, Histogram of the severity of deficits for all cases that had an individually significant shift. See text for a description of measuring severity of deficit. The mean deficit is indicated. (Adapted from Sommer and Wurtz, 2002.)

were not important for the general execution of saccades. However, consistent deficits were found during the double-step task, indicating that corollary discharge was impaired, as described next.

In the double-step task, a monkey fixated a spot and then two sequentially flashed targets were presented briefly in the periphery (Fig. 98.5*B*, *upper left*). The monkey had to look at the locations of the targets in the order in which they had appeared (Fig. 98.5*B*, *upper right*). Hence, to make the second saccade correctly, the monkey had to know whether it made the first saccade correctly. There was no visual feedback because the targets disappeared before saccades were initiated. Proprioception plays little or no role in the on-line control of saccades, so it could not help the monkey in keeping track of its first saccade (Bridgeman, 1995; Guthrie et al., 1983; Lewis et al., 2001; Steinbach, 1987). To perform the task, therefore, the monkey had to monitor a corollary discharge representation of the first saccade. If inactivation did not affect corollary discharge, then during the inactivation the monkey would make its first saccade and know that it did so; therefore, the second saccade would go straight up to the second target location from the end point of the first saccade, just as it did before inactivation (Fig. 98.5*B*, *lower left*). If inactivation totally eliminated corollary discharge, however, then during inactivation the monkey would make the first saccade and *not* know that it did so; hence, the second saccade would be made as if the monkey were still looking at the center of the screen, and it would go up at an angle so that its end point would be shifted contraversively (rightward) (Fig. 98.5*B*, *lower right*). This is in fact what happened: as shown in the example (Fig. 98.5*C*) and in the population data (Fig. 98.5*D*), there was a consistent contraversive shift in the end points of second saccades during inactivation. First saccade end points were not shifted on average, however (Fig. 98.5*E*), and neither were the initial fixation locations. In the vertical dimension there were no mean shifts in second saccade end points, first saccade end points, or initial fixation locations. Surprisingly, the deficits were partial, not total; in the example case, for instance, there was a 2.5 degree shift when a 10 degree shift had been expected, representing a 25% deficit. Overall there was a mean deficit of 19% (Fig. 98.5*F*), and thus although the effect was consistent, it was modest in magnitude. This suggests that other pathways, unaffected by the inactivations, also carry corollary discharge signals.

In summary, the results support two hypotheses regarding the function of this fast-conducting ascending pathway through mediodorsal thalamus. First, the pathway carries visual signals. Although the meaning of this finding is not yet fully understood, it demonstrates that visual signals in the frontal eye field do not arrive only in afferents from extrastriate cortex, as seems to be commonly believed. They also arrive from the intermediate layers of the SC, raising the

possibility that some interesting attributes of frontal eye field visual neurons (e.g., their ability to discriminate visual targets from distractors; reviewed by Schall, 1997) might be due in part to antecedent processing in the SC. Second, the pathway carries presaccadic discharges to frontal cortex, and reversible inactivation of the pathway demonstrated that these are corollary discharge signals. The corollary discharge signals contribute to the ability to make sequences of saccades. They may also contribute to visual scene stability during saccades, although this possibility has yet to be explicitly tested.

THE ASCENDING PATHWAY THROUGH THE PULVINAR TO THE VISUAL CORTEX While the SC intermediate layers have a prominent projection to cerebral cortex through mediodorsal thalamus, the superficial layers of the SC project to the cortex primarily through a pathway that includes the pulvinar nucleus of the thalamus (Clower et al., 2001). Neuronal activity in the SC layers that contribute to these two pathways also are different: neurons in both the superficial and intermediate layers exhibit short-latency responses to visual stimulation of the retina (about 40 to 60 msec; Wurtz et al., 1980) and nearly always have clear receptive fields (for reviews, see Sparks and Hartwich-Young, 1989; Wurtz and Albano, 1980), but in contrast to intermediate layer neurons superficial layer neurons show no presaccadic burst of activity. There is some overlap in the distribution of these visual and visual-movement neurons in that both are found in the lower levels of the superficial layers (the stratum opticum; Ma et al., 1991), but the extent to which neurons in this ventral superficial region contribute to one ascending pathway, to the other, or to both remains unknown. In this section, we will concentrate on the neurons with visual receptive fields but not presaccadic activity, and the term *SC neurons* in this section will refer to these superficial visual neurons.

The major inputs to these neurons are from the retina and striate cortex, as discussed above. It is reasonable to assume a priori that the signals sent from superficial SC up to cortex are visual in nature, but since recordings in the pulvinar of the monkey (Bender, 1981; Petersen et al., 1985) have not physiologically identified the source of any of the inputs to the neurons, and because there are inputs to pulvinar from visual cortex (Ogren and Hendrickson, 1976; Ungerleider et al., 1983, 1984), at this point we can only estimate the signal content in this pathway by reviewing studies of the general populations of neurons in the superficial SC, the pulvinar, and the parietal cortex.

This ascending pathway from the SC to cortex has been referred to as a *second visual pathway* or *second visual system* (Diamond and Hall, 1969; Schneider, 1969), and it has been considered important not only as a phylogenetically older pathway but also as one that may provide an alternative

route for visual information to reach cortex. Such an alternative route takes on particular importance in explaining the residual visual abilities (*blindsight*) (Stoerig and Cowey, 1997; Weiskrantz et al., 1974) and the residual visually related neuronal activity in extrastriate cortical areas (Girard et al., 1992; Rodman et al., 1989, 1990) that persist after removal of striate cortex.

Currently, there appear to be two major types of signals that could be conveyed through the pathway from the superficial SC to cortex via the pulvinar. One type is a visual response modulated by corollary discharge input, and this will be discussed first. The other is a visual response modulated by attention, discussed second.

One of the earliest investigations of the effect of a corollary discharge on visual processing in the primate was on superficial layer SC neurons (Robinson and Wurtz, 1976). The test for the effect of a corollary discharge was simply to determine if the neurons responded the same way when a saccadic eye movement swept their receptive field across a stationary stimulus as when the stimulus was swept across the receptive field while the eye was stationary. Many superficial layer SC neurons did not respond to the stimulus during the saccade, which was interpreted to be the effect of an extraretinal input to the SC present during the eye movement but not during the stimulus movement. This is in contrast to the lack of any such evidence for an extraretinal input to striate cortex neurons (Wurtz, 1969).

In principle, the extraretinal signal used by superficial SC neurons could have come either from a corollary discharge or from proprioceptive inflow from the eye muscles. To determine which, Richmond and Wurtz (1980) paralyzed the eye muscles and determined when eye movements were attempted by recording in the brainstem motor nuclei. Even in the absence of actual movement, modification of the visual response still occurred, leading the investigators to conclude that corollary discharge was sufficient for this modulation. Subsequent experiments on neurons in the pulvinar showed that their visual responses, too, were modified by eye movements (Robinson and Petersen, 1985). Given that the pulvinar receives afferents from the SC, this modulation could be a reflection of activity sent from the SC.

Thus, in the pathway from the superficial SC to the pulvinar, there is an indication of the influence of an extraretinal signal, which in the case of SC neurons has been demonstrated to involve corollary discharge. Note, however, that these neurons acted as if they *received* corollary discharge signals, as exhibited by changes to their visual responses. Where these particular corollary discharge signals come from remains unknown. In contrast, in the other ascending pathway, via mediodorsal thalamus, neurons carry a corollary signal *itself*, one sent up to the cerebral cortex, and we know that this signal comes from the SC intermediate layers.

Neuronal signals related to attention also have been studied in the SC-pulvinar pathway. When the monkey selects a target for its next saccade that lies in the receptive field of an SC neuron, the visual response of the neuron is frequently enhanced compared to the case in which the monkey selects a target well outside the receptive field of the neuron (Goldberg and Wurtz, 1972). This enhancement is consistent with a shift of attention to the visual target for the impending saccade, and such enhancement has been seen clearly in a number of regions including frontal cortex, parietal cortex, and the substantia nigra pars reticulata (for reviews, see Hikosaka and Wurtz, 1989; Wurtz et al., 1980). The relation of the enhancement to the generation of the saccade differs between the areas, however, as determined by comparing modulation of neuronal activity when the monkey must use the stimulus as the target for a saccade as opposed to holding its eyes steady and reaching out to touch the stimulus. This distinction was first made in the SC (Wurtz and Mohler, 1976b), where the enhancement accompanying saccades to a target was absent with a reach to the target. The same was true for neurons in the frontal eye field (Goldberg and Bushnell, 1981). In the parietal cortex, however, neurons showed an enhanced response with both saccades and reaching (Bushnell et al., 1981), suggesting that the modulation represented movement-independent visual attention. Enhancement found in the SC and the frontal eye field, in contrast, is more appropriately regarded as a correlate of target selection *specifically* related to saccade generation (Wurtz et al., 1980, 1982).

Gattass and Desimone (1996) tested whether enhancement of superficial SC visual neurons really was inextricably linked to saccade generation using a different method (as a caveat, they indicated that some of their neurons may have been in the pulvinar). They cued the monkey with a peripheral stimulus falling inside the visual receptive field of the neuron but required the monkey to make a visual discrimination at the site of the cued stimulus instead of making a saccade to the stimulus. The neurons showed an enhanced visual response when the cue was in the receptive field as opposed to when it was not. The enhancement was present even in the absence of the saccade, suggesting that it is dissociable from saccade generation. However, when they then used a symbolic cue at the fixation point, they found no such enhancement even though saccades still were not produced. This implies that the monkey may have been planning a saccade in response to the peripheral cue even though one was not executed; such a planned but withheld saccade would not be expected for symbolic cues at the fixation point. The results therefore do not seem to refute the idea that enhancement in the SC is devoted to saccade generation.

This link between enhancement of visual responses in the SC and saccade generation is further supported by the

observation that as the time at which a saccade is made shifts closer to the time of the visual response, the enhancement increases (Wurtz and Mohler, 1976b). It is as if the presaccadic activity in the SC intermediate layers acts on superficial layer neurons to facilitate the enhancement. This remains entirely hypothetical, however. No such connection has been verified either anatomically or physiologically, although connections from superficial to intermediate layers are now clearly established (e.g., Isa and Saito, 2001; Lee et al., 1997). At this point, the exact mechanism causing the enhancement remains unknown.

Many superficial SC neurons are known to convey visual information to the pulvinar, as shown using antidromic activation (Marrocco et al., 1981). Because that study used paralyzed monkeys, attentional effects on the visual responses leaving the SC could not be assessed. Attention has been studied, however, within the structure receiving these projections. The retinotopic maps of the inferior and lateral pulvinar regions have been clearly delimited (Bender, 1981, 1982), and neurons showing changes in activity related to saccadic eye movements or visual modulation have been found mainly in the inferior area (PI) and in another visually responsive area (Pdm) of the lateral pulvinar (Petersen et al., 1985; Robinson et al., 1986). These neurons showed visual enhancement for stimuli in the contralateral visual field similar to that seen in the SC, but with the striking difference that enhancement here occurred regardless of whether an eye movement to the target was made or a lever press was made (Petersen et al., 1985). Because the enhancement did not depend on the motor modality, it was an extremely sound candidate for mediating visual attention.

That these neurons contribute to shifts of attention made by the monkey was demonstrated conclusively by Petersen et al. (1987), who inactivated the region of the pulvinar where neurons were modulated by attention. First, they recorded neurons in this area and found that they were enhanced during an attentional task in which monkeys had to detect the dimming of a target in the neuron's receptive field. Then they inhibited the neurons with muscimol while monkeys performed a task in which a peripheral cue elicited attentional shifts, as measured by improvements in manual reaction time. In valid trials (Fig. 98.6A, *top*), the peripheral cue and the subsequently presented target appeared in the same hemifield and the reaction time to release a lever in response to target onset was relatively short, presumably because attention was drawn to the target location by the preceding cue (other experiments showed similar reaction time decreases when a central symbolic cue was used, demonstrating that these effects probably were not related to covertly preparing a saccade to the peripheral cue; Bowman et al., 1993). In invalid trials (Fig. 98.6A, *bottom*), the peripheral cue and the target appeared in opposite hemi-

fields and the reaction time was longer, presumably because attention was drawn away from the target location. During pulvinar inactivation, there was no effect on reaction time if both cue and target were presented ipsilaterally to the injection site (Fig. 98.6B, *top*: ipsilateral valid cue). However, if both the cue and target were presented contralaterally to the injection site, the reaction time was substantially increased (Fig. 98.6B, *bottom*: contralateral valid cue). The deficit appeared to represent an impairment in the ability to shift attention contraversively in response to the cue. On the other hand, injection of a GABA antagonist, bicuculline, did not seem to cause swifter attentional shifts (Fig. 98.6B, *bottom*); this may be a floor effect caused by the monkeys being so well trained that they could not possibly shift their attention faster. For brevity, results from invalid cue trials are not discussed here, but they further supported the conclusion that inactivation caused impairment of attentional shifts.

To summarize, currently we know that some pulvinar neurons show visual enhancement, that the enhancement is not dependent upon the execution of an eye movement, and that inactivation of the pulvinar impairs attention. While anatomy suggests that the regions of the monkey pulvinar studied lie on the pathway to cerebral cortex (Benevento and Fallon, 1975), a remaining caveat is that the extent to which various regions of pulvinar convey information from the SC to cortex is still unknown (e.g., Stepniewska et al., 1999).

Also not known is the extent to which the pulvinar-to-cortex projection modifies neuronal activity in cortex, particularly in the lateral intraparietal area considered previously in this chapter. As noted above, Bushnell et al. (1981) found movement-independent visual enhancement in parietal cortex similar to what was seen in the pulvinar. More recent experiments in parietal cortex (Robinson et al., 1995) showed enhancement using a peripheral cuing task similar to that used in the pulvinar inactivation experiments described above. Again, we do not know whether these parietal neurons received input from pulvinar, but anatomically this was quite possible. Another set of attention experiments in parietal cortex studied the effects of attentive fixation on the visual response of neurons (Mountcastle et al., 1981, 1987), and a recent study verified these observations and showed similar effects in the pulvinar (Bender and Youakim, 2001). Exactly what the SC-pulvinar pathway contributes to attentional activity in parietal cortex (and in other extrastriate areas; see reviews by Desimone and Duncan, 1995; Maunsell, 1995) remains a critical question.

In net, while the possible functional contributions of the pathway from the SC to cortex via the pulvinar have received more attention over a longer period (Diamond and Hall, 1969; Schneider, 1969) than has the pathway from the SC to cortex via the mediodorsal thalamus, the function of

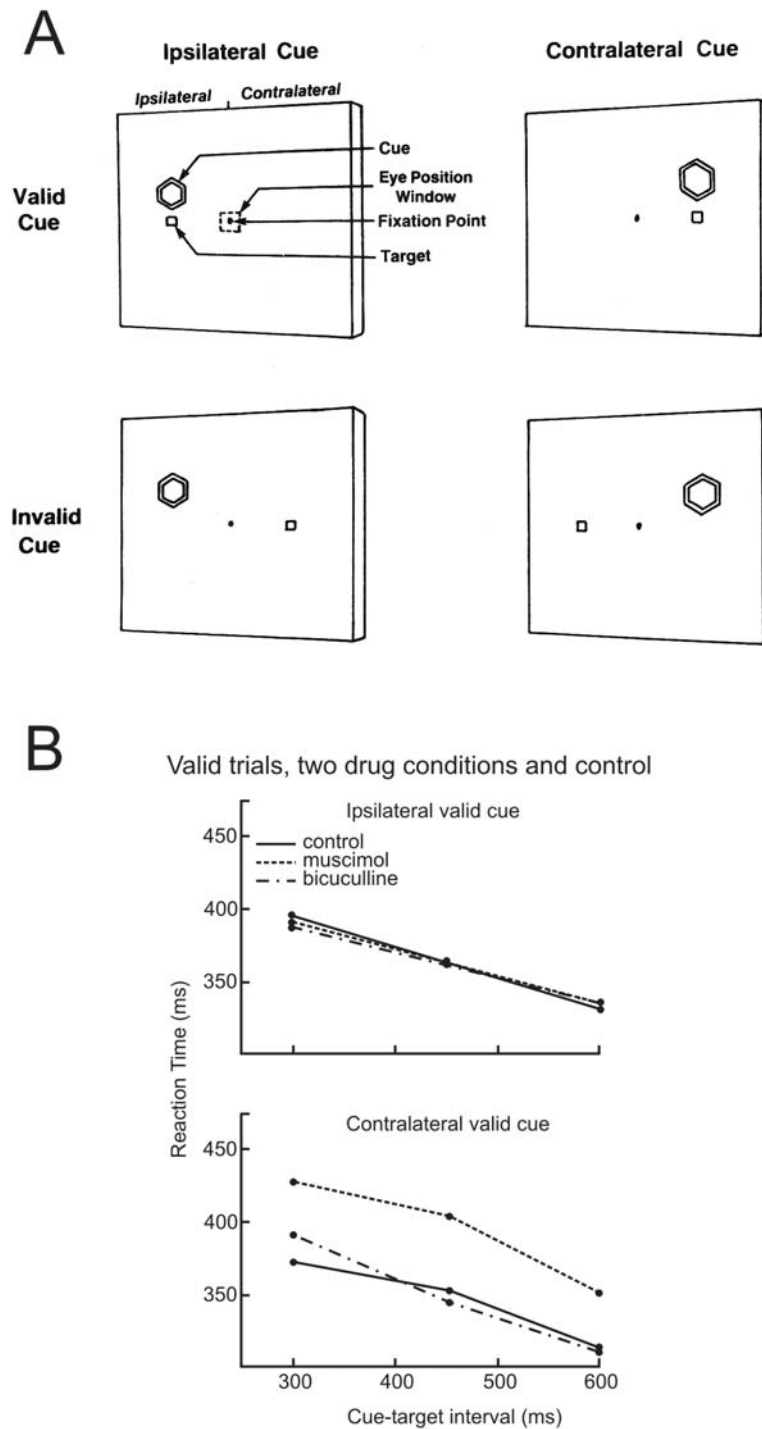

FIGURE 98.6. Test of the hypothesis that the ascending pathway through pulvinar carries an attention signal. *A*, Diagram of the task. The monkey foveated the fixation point and had to keep its eyes within the eye position window at all times. Then a cue stimulus was flashed, a cue-target interval ensued, and a target was presented. The monkey's task was to report detection of the target by manually depressing a lever. During valid cue trials (*top*), the cue and target appeared in the same hemifield; during invalid cue trials (*bottom*), they flashed in opposite hemifields. Ipsi- and contralateral

are with respect to the injection site. *B*, Effects of inactivating pulvinar on reaction times during valid cue trials. There was no effect of inactivation when the cue and target were presented ipsilaterally (*top*), showing that the monkey still could shift its attention in that direction. However, when the cue and target were presented contralaterally (*bottom*), the reaction time was abnormally slow during inactivation (muscimol data). Also shown are the results of bicuculline injection, which caused no deficits. (Adapted from Petersen et al., 1987.)

the pulvinar pathway is less well specified. Identified recordings in behaving animals are still needed to determine explicitly the signals conveyed in this pathway. The current data strongly suggest that neuronal activity all along the pathway is related to attention, changing from being more saccade-specific in SC to being more visual, that is, more motor modality-independent, in pulvinar and cortex.

Finally, it should be noted that an additional ascending pathway appears to course from the superficial SC layer, reaching koniocellular neurons in the lateral geniculate nucleus that presumably project, in turn, to striate cortex (for a review, see Hendry and Reid, 2000). Visually related activity certainly must be relayed in this pathway, but as koniocellular neurons are extremely heterogeneous, it is difficult to speculate further about these ascending signals.

Conclusions

In this chapter, we described what is currently known about the dialogue between the cerebral cortex and the SC during visuosaccadic behavior. Figure 98.7 shows a summary diagram of the descending and ascending signals. Four descending routes have been investigated using antidromic activation techniques (Fig. 98.7A). The projections richest in signals related to saccadic target selection emanate from the lateral intraparietal area and the frontal eye field. Both projections send visual responses, cognitive-related delay activity, and presaccadic activity to the intermediate SC. The basal ganglia pathway via the substantia nigra relays strong visual and presaccadic signals to the intermediate SC, but delay activity in this projection seems related only weakly, if at all, to target selection. Striate cortex sends visual signals that are potentially interesting, but still poorly understood, to the superficial SC. Ascending pathways (Fig. 98.7B) are more challenging to study. Best characterized is the pathway from the intermediate SC to the frontal eye field (via mediodorsal thalamus), which carries visual signals and presaccadic activity that appears to serve a corollary discharge function. The pathway from the superficial SC to parietal cortex (via pulvinar) is presumed to carry mostly visual signals that are highly modulated by attention. We want to emphasize that there are numerous other descending and ascending connections between cerebral cortex and the SC, some of which might also be crucially important for saccadic target selection, corollary discharge, or other cognitive functions. This chapter focused only on interconnections for which there are currently at least some satisfactory physiological results related to cognitive issues.

Our goal has not been to consider just one particular brain region, but instead to determine what can be learned from analyzing the functional relation *between* areas, specifically between cerebral cortex and the SC. Our focus on visuosaccadic behavior provides only a limited glimpse of brain

A Descending Signals

B Ascending Signals

FIGURE 98.7. The dialogue between cerebral cortex and the SC. Each diagram depicts the signals transmitted between regions using arrows containing fills that correspond to the three main types of neuronal activity considered in this chapter; see the legend at the left. Only delay activity signals that were clearly shown to be involved in cognitive functions are included. *A*, Descending signals from cerebral cortex to SC. *B*, Ascending signals from SC to cerebral cortex. Relays in thalamus have been omitted for simplicity. Abbreviations as in Figure 98.2.

organization, but it does offer the opportunity to look at the neuronal basis of several cognitive functions using techniques that allow the functional identification of a part of the underlying circuit. A few general conclusions are worth pointing out explicitly.

First, when we compare the signals leaving cortex, within the SC, and in the ascending pathways, we never see a strict segregation of function between areas. There is no level of visuosaccadic processing in one area that is absent in the next. Instead, there is always an overlap between the signals seen in one area and those in the next, with a gradual shift in signal content. There appear to be progressive sensorimotor transformations rather than abrupt changes.

Second, the recognition that signals are conveyed up to cortex with very short latencies emphasizes that the neuronal

activity seen in cerebral cortex represents not just signal processing *within* the cortex but also processing directed *back* to the cortex from brainstem areas. The cortical and subcortical areas have to be regarded as a whole unit, not as a serial chain, just as is the case for cortical areas that also are reciprocally interconnected.

Finally, our most significant generalization concerns the nature of the information conveyed to cerebral cortex from the SC. What we find striking is that the information conveyed upstream is probably not critical for extracting information about the world. Instead, ascending information from the brainstem makes its important contribution to *interpreting* the visual input in the context of an animal's actions. The pulvinar pathway appears to inform the cortex of the relative behavioral importance of objects (as expressed by enhanced visual responses). In the mediodorsal thalamus pathway, signals inform the cortex about what saccade will be made next. This corollary discharge information probably allows the visual system to distinguish between actual full-field motion of the external world and full-field motion that is a trivial artifact of making a saccade. In sum, our perception of the visual world is a result of the visual input to cerebral cortex and the interpretation of that input, and key parts of that interpretation may depend upon information relayed up from the SC through the thalamus.

99 Cerebellar Control of Eye Movements

DAVID S. ZEE AND MARK F. WALKER

THE CEREBELLUM PLAYS a pivotal role in the control of eye movements of all types. Its essential function is to optimize ocular motor performance so that images of objects of interest are brought to the fovea—where visual acuity is best—and kept there quietly—to give the brain time to analyze and interpret the visual scene. Patients with cerebellar disease report a number of disturbances of vision. These include (1) oscillopsia (illusory movement of the environment) during attempted fixation with the head still or with the head moving, (2) inability to focus on near objects, horizontal or vertical double vision, and impaired perception of the depth and orientation of objects, (3) inability to follow smoothly objects that are moving within the visual field, and (4) difficulty with tasks requiring accurate and rapid changes of fixation (e.g., reading).

Beginning with the landmark study of Westheimer and Blair (1973), who reported the effects of total cerebellectomy on eye movements in monkeys, knowledge of how the cerebellum contributes to the control of eye movements has burgeoned. Recent advances have been based on (1) the quantitative study and analysis of the functional disturbances in ocular motor performance caused by cerebellar lesions, both in human beings with cerebellar disease and in animals with enduring (surgical or electrolytic) or transient (with local anesthetics, cooling probes, or neurotoxins) experimental lesions; (2) physiological recordings of activity of single neurons during eye movements in awake, behaving primates; (3) artificial stimulation of the cerebellum, both transcranial magnetic stimulation in humans and direct electrical activation in experimental animals; (4) functional magnetic resonance imaging in intact humans; and (5) computational modeling. Taken together, these investigations have shown that the cerebellum participates in two fundamental aspects of ocular motor control: the *immediate*, “*on-line*” modulation of eye movement performance during ongoing behavior and *motor learning*, the long-term adaptive mechanisms by which motor performance is optimized. The anatomical and physiological basis of these functions is a major focus of contemporary neuroscience research.

Subclasses of eye movements

To understand how the cerebellum influences eye movements, it is useful to define the different subclasses of eye movements and to review ocular motor control signals and

their underlying anatomical substrate within the brainstem. It is on these circuits that the cerebellum exerts its influence (Leigh and Zee, 1999). *Saccades* are the rapid eye movements that quickly change the line of sight, placing the image of an object of interest on the fovea, where it can be scrutinized and its saliency determined (“fight or flight”). Saccades are characterized by their size, speed, and latency. The quick phases of nystagmus resemble saccades in their dynamic characteristics.

Vestibular slow phases are smooth eye movements that are generated by the vestibulo-ocular reflex (VOR); they act to stabilize images on the fovea when the head is rotating (rotational or r-VOR) or translating (translational or t-VOR). Vestibular slow phases are characterized by their amplitude, direction, and timing (or phase) relative to head motion. *Optokinetic* (OKN) slow phases are full-field visual following movements that can be elicited by rotation of the visual scene (e.g., with an optokinetic drum) around a subject. In natural circumstances, optokinetic slow phases act to supplement the r-VOR during sustained head rotation in the light. OKN slow phases, too, are characterized by amplitude, direction, and timing.

Pursuit is a smooth tracking eye movement that keeps the image of a moving object on the fovea. Pursuit movements are often characterized by their response to an abrupt change in target speed (*step-ramp* stimulus). The initial movement of the eye during the first ~100 msec of such tracking reflects the *open-loop* performance of the system (before visual feedback can be used to modify ongoing behavior). The acceleration of the eyes characterizes the response during this open-loop period. Sustained pursuit of a target moving at a constant-velocity is a measure of *closed-loop* behavior (which uses visual feedback to improve performance) and is characterized by a gain (eye velocity/target velocity). Predictive patterns of target motion, such as sinusoids, are also used to probe pursuit capabilities.

Vergence eye movements rotate the eyes by different amounts, usually in opposite directions, shifting gaze between objects at different distances and following objects moving in depth. This serves to maintain an image on both foveas at the same time and facilitates depth perception. Disparity (a difference between the location of an image on the two retinas), blur of images on the retina, and other features of the target (e.g., relative size) are cues that are used to signal its distance from the observer and to drive vergence.

The premotor commands that drive eye movements are understood best in terms of the active forces that must be generated to oppose the passive mechanical forces of the orbit (see Scudder et al., 2002, for a recent review). The major hindrance to rotation of the globe is orbital viscosity; the moment of inertia of the globe is relatively small. To move the eyes quickly, there must be a phasic increase in the frequency of neural discharge, which is roughly proportional to the velocity of the movement of the eye. In the case of saccades this is called the *pulse* of innervation. Once the eyes are brought to their new position, they must be held there against elastic-restoring forces of the orbital tissues, which would return the globe to the straight-ahead position. Preventing this centripetal drift requires a sustained tonic contraction of the extraocular muscles, called the *step* of innervation. Thus, to a first approximation, the premotor control signal for all types of eye movements is a *velocity position, phasic tonic, or pulse step* of innervation. This pattern of activity is reflected in the discharge of both ocular motoneurons and the eye muscles, whereas individual premotor neurons may show activity related to only one or another component of the ocular motor command.

The brainstem substrate

Premotor *eye velocity* commands are created by (largely) separate groups of neurons for each of the different types of eye movement. For example, premotor velocity commands for saccades and quick phases of nystagmus are generated in the pontine paramedian reticular formation (PPRF) by excitatory burst neurons (EBNs) for horizontal saccades, and in the rostral interstitial nucleus of the medial longitudinal fasciculus (riMLF) in the midbrain for vertical and torsional saccades. The eye position command or *step* of innervation is created by a common neural gaze-holding network or *neural integrator* that integrates, in the mathematical sense, eye velocity commands of all types to produce the appropriate position-coded information (the *step*) for the ocular motoneurons. Within the brainstem, the medial vestibular nucleus and the adjacent nucleus prepositus hypoglossi in the rostral medulla are important for the neural integration of horizontal ocular motor signals. For integration of vertical ocular motor signals, the interstitial nucleus of Cajal in the midbrain, coupled with activity in the vestibular and prepositus nuclei, is important. The cerebellum also has a key role in this critical gaze-holding function (see below).

Anatomical approach to the cerebellum and ocular motor control

Our approach to the contributions of the cerebellum to the control of eye movements will be based on *structural-functional* correlations, and we will discuss cerebellar influences on eye movements by anatomical regions. An important caveat is that the cerebellum has an important role in motor learning that permits adaptation and compensation for lesions that have occurred in other parts of the brain or in the motor effectors themselves. But almost certainly, the cerebellum also can compensate for lesions within it. Thus, a rigid compartmentalization of function, inferred from the enduring effects of lesions within the cerebellum, may not strictly apply to cerebellar contributions to the control of eye movements in intact subjects. With this limitation, our interpretation of the functions of the cerebellum will be based on the combination of the effects of acute and chronic lesions, as well as results of physiological studies. Here we will emphasize the areas within the cerebellum about which we know the most: the *flocculus/paraflocculus*, the *nodulus/ventral uvula* (lobules IX and X of the cerebellar vermis), and the dorsal *oculomotor vermis* (lobules V to VII) and its target in the posterior portion of the fastigial nucleus called the *fastigial oculomotor region* (FOR). There are other regions of the cerebellum, about which we know less, that are also concerned with eye movement control (e.g., posterior interposed nucleus, lateral cerebellar hemispheres). When possible, we will consider their ocular motor contribution. A comprehensive review of the cerebellar contribution to voluntary eye movements—saccades, pursuit, and vergence—including a review of electrophysiological studies, has recently appeared (Robinson and Fuchs, 2001).

The cerebellum has a distinctive anatomical organization. Purkinje cells of the cerebellar cortex project primarily to and *inhibit* cells within the underlying deep cerebellar nuclei; the projection of the vestibulocerebellum (flocculus, paraflocculus, nodulus, and uvula) is to the vestibular nuclei within the brainstem. Portions of the vestibular nuclei can be thought of as “displaced” deep cerebellar nuclei by their connections and embryological origin. There is a rich innervation to the cerebellar cortex from the inferior olive (as climbing fibers directly to Purkinje cells) and from various brainstem nuclei and the vestibular nerve (as mossy fibers to cerebellar granule cells and then onto Purkinje cells as parallel fibers). Purkinje cell discharges are of two types: simple spikes and complex spikes. Complex spikes occur at a relatively low frequency and arise from climbing fibers. Simple spikes discharge at a much higher frequency and originate from mossy fiber inputs. The discharge frequencies of complex and simple spikes are usually reciprocally related such that an increase in complex spike activity is associated

with a decrease in simple spike activity and vice versa. There are also direct climbing fiber and mossy fiber inputs to the underlying cerebellar nuclei, so that the cerebellar cortex can be thought of as a parallel pathway that can influence (via Purkinje cell projections) the direct flow of information, to and from the brainstem, through the deep nuclei.

Vestibulocerebellum: the flocculus/paraflocculus

The flocculus and paraflocculus, together with the caudal portions of the cerebellar vermis (nodulus and uvula), are part of the oldest portion of the cerebellum—the archicerebellum, also called the *vestibulocerebellum*. In rhesus monkeys, what had been called the flocculus has been divided on the basis of its afferent mossy fiber inputs into a caudal group of five folia, now called the *flocculus*, receiving its inputs primarily from the vestibular nucleus and nerve, the nucleus prepositus hypoglossi, the nucleus reticularis tegmenti pontis, and the mesencephalic reticular formation; and a rostral group of five folia, now considered part of the ventral paraflocculus, receiving their inputs largely from the pontine nuclei (Nagao et al., 1997a, 1997b; Rambold et al., 2002). The dorsal paraflocculus also receives visual information relayed via brainstem nuclei (Glickstein et al., 1994). Both the flocculus and paraflocculus receive climbing fiber inputs from the contralateral inferior olive. The flocculus also receives an input from the cell groups of the paramedian tracts, located in the midline near the medial longitudinal fasciculus in the pons and medulla (Büttner-Ennever and Horn, 1996). The main efferent pathways of the flocculus and paraflocculus are to the vestibular nuclei.

A number of investigators have recorded from neurons within the flocculus/paraflocculus and have related their activity to eye movements and to visual and vestibular stimuli. Neurons can be found that discharge in relation to various features of the stimulus, as well as to the position of the eye in the orbit and the movement of the eye during smooth pursuit, vergence, and the slow phases of nystagmus during various patterns of active and passive head motion (e.g., Belton and McCrea, 2000a, 2000b; Fukushima et al., 1999; Gomi et al., 1998; Hirata and Highstein, 2000; Kobayashi et al., 1998; Krauzlis, 2000; Leung et al., 2000; Suh et al., 2000; Takemura et al., 2001). This multiplicity of behaviors is not surprising considering the many type of abnormalities that can be produced by lesions in the flocculus/paraflocculus.

PURSUIT Lesions of the flocculus and paraflocculus lead to a characteristic ocular motor syndrome (Waespe et al., 1983; Zee et al., 1981). Smooth visual tracking of a moving target is impaired, either when the head is still (smooth pursuit) or moving (VOR suppression or cancellation) (Fig. 99.1). Both the initiation of pursuit and the response during sustained

tracking can be affected. Complete lesions of the flocculus/paraflocculus lead to a considerably decreased steady-state gain (eye velocity/target velocity), though pursuit does not appear to be as profoundly disturbed as it is after total cerebellectomy. Pursuit adaptation is also impaired after floccular/parafloccular lesions (Rambold et al., 2002). There is considerable recovery of pursuit function, even with relatively complete floccular/parafloccular lesions, implicating other parts of the cerebellum in the control of pursuit eye movements (see below). There may be differences in the role of the flocculus/paraflocculus in pursuit during combined eye-head tracking, depending upon whether the head is actively or passively rotated (Belton and McCrea, 2000a, 2000b). Likewise, there may be differences in the relative roles of the flocculus and paraflocculus in the generation of pursuit (Nagao and Kitazawa, 1998; Rambold et al., 2002). A number of investigators have recorded neural activity during pursuit and have shown a tight relationship between various parameters of eye motion and Purkinje cell discharge (Krauzlis, 2000; Takemura et al., 2001). No consensus, though, has been reached on the relative roles of the flocculus/paraflocculus in initiating versus sustaining pursuit or in responding to novel versus predictive patterns of target motion.

GAZE-HOLDING, POSTSACCADIC DRIFT, AND THE NEURAL INTEGRATOR A second cardinal feature of lesions of the flocculus/paraflocculus is *impaired gaze-holding*. After eccentric horizontal eye movements, the eyes drift centripetally (Fig. 99.2). This finding indicates that the flocculus/paraflocculus

FIGURE 99.1. Horizontal eye position (*solid line*) during pursuit tracking of a small laser target moving at constant velocity (10 deg/sec) in a patient with spinocerebellar ataxia type 6. Note the reduced slow-phase gain, particularly for leftward pursuit, and the superimposed corrective quick phases (saccadic pursuit). Right is positive.

functions in the control of the brainstem neural integrators that convert velocity into position commands for all types of conjugate eye movements. The neural integrator cannot sustain its tonic output, and the eyes drift centripetally due to unopposed elastic restoring forces. Single-unit recordings within the flocculus/paraflocculus reveal that some Purkinje cells discharge in relation to the *position* of the eye in the orbit, as would be expected if the flocculus/paraflocculus contributes to the neural integrator (Miles et al., 1980).

A third distinctive feature of lesions in the flocculus/paraflocculus is *downbeat nystagmus*, in which the eyes drift up (slow phase) and are brought back to the fixation target by a corrective downward saccade (quick phase) (Fig. 99.3). This nystagmus seems to combine two types of defects produced by the removal of the flocculus/paraflocculus. The first is a tonic imbalance leading to an upward slow-phase drift even when the eyes are in the center of the orbit. The imbalance likely reflects a removal of inhibition from Purkinje cells in the flocculus/paraflocculus on vestibular pathways within the brainstem that mediate upward slow phases (Zee et al., 1981). This effect could be on pathways that mediate the r-VOR, the t-VOR, or pursuit, or at some point where these signals are already combined (Bohmer and Straumann, 1998). A second feature of the upward drift is that it can have either a decreasing or an increasing slow-phase velocity waveform (Fig. 99.3). The different velocity profiles can be explained by differences in the effect of the lesion on the vertical neural integrator. If the integrator is “leaky” such that its discharge decays with time, the velocity will decrease until reset by a quick phase. If the integrator is “unstable” (its discharge increases with time), an increasing velocity waveform will result. Some monkeys with experimental floccular and parafloccular lesions show downbeat nystagmus with a decreasing velocity waveform; others show an increasing velocity waveform. The effect of vertical eye position on the intensity of nystagmus varies with the waveform type. With an increasing

velocity waveform, intensity is greatest when looking up; with a decreasing velocity waveform, intensity is greatest when looking down.

A simple hypothesis to explain the effects of lesions of the flocculus/paraflocculus on gaze-holding is based upon the idea that there is an inherently poor, leaky ocular motor integrator within the brainstem (Zee et al., 1981). The neurons in the paramedian tracts and in the medial vestibular nucleus and the nucleus prepositus hypoglossi are probably important constituents of this integrator network (Aksay et al., 2001; Nakamagoe et al., 2000). In this scheme, the cerebellum improves the performance of this brainstem network by acting on a positive feedback loop around the brainstem neural integrator, acting to sustain the discharge of neurons in the absence of an ongoing external input. The flocculus/paraflocculus would then modulate the gain of this feedback loop. For the horizontal system, monkeys with floccular/parafloccular lesions always develop a gaze-evoked nystagmus with a velocity-decaying waveform, indicating that the flocculus/paraflocculus is critical for improving the performance of the inherently leaky horizontal brainstem neural integrator. The effect on the waveform of upward slow phases is less profound and more variable from animal to animal, suggesting that for the vertical integrator circuits the flocculus/paraflocculus has a more subtle modulatory role.

Another feature of the floccular/parafloccular syndrome is a brief drift of the eyes, lasting for several hundred milliseconds following saccades, called a *glissade*. Glissades occur in patients with cerebellar disease and in animals with experimental lesions in the flocculus/paraflocculus. This postsaccadic drift reflects a mismatch between the pulse (phasic) and the step (tonic) of innervation for saccades and is due to abnormal amplitude of the step output of the neural integrator relative to its velocity input, the pulse. Normally, these two premotor signals are precisely matched so that the eye stops abruptly at the end of the saccade. In monkeys with lesions of the flocculus/paraflocculus, the direction of the

glissade, onward or backward, is variable from animal to animal.

VESTIBULAR-OCULAR REFLEXES The flocculus and paraflocculus are not critical for the r-VOR in the sense that the r-VOR is still present in animals with lesions of the flocculus/paraflocculus or even after complete ablation of the cerebellum. The amplitude, however, may be normal, increased, or decreased.

Patients with diffuse cerebellar lesions show abnormalities of the direction and conjugacy of the r-VOR (Fig. 99.4). In response to a high-acceleration horizontal rotation of the head (*head thrust*), a dynamic upward bias may appear so that the eyes move up as well as horizontally, producing a *cross-coupled* VOR (Walker et al., 2002). There are also inappropriate torsional components. Furthermore, the responses in the two eyes are disconjugate, with relatively more torsion in one eye and more vertical rotation in the other. Recent work has shown a similar type of abnormality in a monkey with a bilateral lesion of the flocculus (Zee et al., 2002).

Of particular current interest is the role of the cerebellum in the t-VOR, and the flocculus/paraflocculus may be involved in its generation, though this is still unproven. The t-VOR itself can be measured alone (e.g., side-to-side or fore-and-aft motion on a linear sled) or in combination with the r-VOR (when the axis of rotation of the head is ahead of or behind the labyrinths, which leads to a combined rotation and translation). Patients with cerebellar lesions can have a profoundly impaired t-VOR even when the r-VOR is intact (Fig. 99.5) (Wiest et al., 2001; Zee et al., 2002). They also have defects in adjusting the r-VOR for the distance of the target of interest and for the displacement of the orbits from the axis of head rotation. These are necessary require-

ments for adequate gaze stabilization during head rotation, since virtually all head rotations are accompanied by some translation of the orbits. The flocculus/paraflocculus has neurons that discharge in relation to vergence, and it is possible that this information is used to adjust the VOR for target distance, a necessary requirement whenever translation is a component of head motion (Snyder and King, 1996).

In patients with diffuse cerebellar disease, there also appears to be an association between deficits in the t-VOR and in smooth pursuit (Baloh et al., 1995). The t-VOR and pursuit normally work closely together; both act to stabilize on the fovea the images of objects that are moving across the visual field at a particular depth, either due to self-motion or to object motion. Thus, it is reasonable to speculate that the flocculus/paraflocculus has a role in both pursuit and the t-VOR, and that both types of eye movement also share cerebellar circuitry, in accord with their close functional relationship. Other parts of the cerebellum, including the dorsal vermis and the underlying fastigial nuclei (see below), may also play a role in the t-VOR, as they do for pursuit.

Vestibulocerebellum: the nodulus/ventral uvula

The *nodulus* and adjacent *ventral uvula* are the most caudal aspects of the cerebellar vermis. They receive afferents from the vestibular nuclei, nucleus prepositus hypoglossi, inferior olive, and vestibular nerve. The nodulus/ventral uvula acts on the “low-frequency” components of the VOR via its projections to the velocity-storage mechanism within the vestibular nuclei (Sheliga et al., 1999). In the case of a constant-velocity rotation of the head, the velocity-storage mechanism acts to extend the duration of the VOR response

FIGURE 99.4. Binocular dual-axis scleral search coil recordings in a patient with cerebellar degeneration. Angular velocity components for both eyes and the head (inverted) are shown for head rotations in both horizontal directions. Note the increased horizontal gain, the upward vertical slow-phase component (cross-coupling) with horizontal head rotations in either direction, and the torsional

cross-coupling that changes direction with the direction of horizontal head rotation. The responses are also disconjugate. *A*, Rightward head rotation. *B*, Leftward head rotation. Right, up, and clockwise (relative to the patient) are positive. (From Walker et al., 2002, with permission.)

FIGURE 99.5. Horizontal eye velocity in response to interaural translation (0.7 Hz, peak acceleration 0.36 *g*) in a normal subject (*dashed line*) and in a patient with cerebellar degeneration (*solid line*). Recordings were made in complete darkness except for a small center fixation target that flashed intermittently for 20 msec every 1000 msec to maintain orbital position and vergence angle. The dotted line shows the ideal eye velocity response based on the stimulus and target distance. The velocity “spikes” are quick phases. Note that the slow-phase gain is substantially reduced.

beyond that expected from the mechanical properties of the cupula-endolymph system within the semicircular canals. This perseverating action slows the decay of nystagmus during a constant-velocity rotation in the dark and improves the low-frequency performance of the reflex. Recordings of neural activity within the vestibular nerve during constant-velocity rotations in the dark reflect the time course of the change in the position of the cupula (which slowly returns to its neutral position after the onset of head rotation at a constant speed); recordings of activity within neurons in the vestibular nuclei reflect the additional action of the velocity-storage mechanism, and their activity outlasts the activity on primary afferents. During sustained “off-vertical axis” rotation of the head, when there is an imposed change in linear acceleration due to the continuous reorientation of the head relative to the pull of gravity, the velocity-storage mechanism modulates the *direction* of compensatory slow phases, reorienting the axis of eye rotation relative to the axis of head rotation.

Lesions of the nodulus have several effects. The duration of vestibular responses to a constant-velocity input is increased (the VOR time constant is increased). There is a loss of habituation to repetitive stimulation (the VOR time constant no longer decreases with repetitive stimulation). Tilt suppression of postrotary nystagmus, a phenomenon by which the decay of postrotary nystagmus is hastened by pitching the head down immediately following the end of a constant-velocity rotation, no longer occurs (Waespe et al.,

1985). With nodulus lesions, the VOR no longer shows the reorientation of the axis of eye rotation that normally occurs with an imposed linear acceleration (Angelaki and Hess, 1995; Wearne et al., 1998). Patients with diffuse cerebellar disease may show abnormally directed slow phases, or cross-coupling, even when there should be none, for example, during low-frequency head rotation around an earth-vertical axis, during sustained optokinetic stimulation with the head upright, and after horizontal head shaking (Walker and Zee, 1999). These abnormalities of VOR direction in response to low-frequency stimuli likely reflect dysfunction of the nodulus.

Periodic alternating nystagmus (PAN), a horizontal jerk nystagmus that changes direction every few minutes, may appear following lesioning of the nodulus. PAN reflects the combined actions of a (1) disinhibited brainstem vestibular velocity-storage mechanism (due to loss of inhibition from Purkinje cells in the nodulus that project to vestibular nuclei) and (2) an intact adaptive mechanism that acts to null any sustained unidirectional nystagmus, allowing PAN to change direction. This same adaptive mechanism produces the reversal phases of rotary and caloric nystagmus in normal subjects and the reversal phases of head-shaking-induced nystagmus in patients with labyrinthine lesions. Because Purkinje cell inhibition is mediated through GABA-b receptors, treatment with baclofen (a GABA-b agonist) disengages the velocity-storage mechanism and stops PAN.

The nodulus and uvula may have other ocular motor functions; lesions there also alter smooth pursuit and optokinetic nystagmus, but their exact contribution to these visual-following reflexes is unclear (Heinen and Keller, 1996).

FUNCTIONAL DIFFERENCES BETWEEN THE FLOCCULUS/ PARAFLOCCULUS AND THE NODULUS/UVULA The vestibulo-cerebellum has many functions, and lesions produce a variety of abnormalities. Can we extract any overriding principles about the functions of these two areas of the cerebellum? One simple hypothesis is that the flocculus and paraflocculus are more concerned with relatively immediate and fast-acting, foveally related ocular motor functions, such as smooth pursuit, the t-VOR, and steady gaze following saccades, all of which relate to holding images steady on the fovea. The nodulus and ventral uvula are more concerned with generating eye movements that determine the duration and axis of eye rotation in response to low-frequency vestibular stimuli and so determine the orientation of images on the entire retina (Sheliga et al., 1999). This idea remains speculative, and even within the flocculus/paraflocculus (Rambold et al., 2002) and nodulus/uvula there is likely a further segregation of function (Wearne et al., 1998).

Dorsal cerebellar vermis and the posterior fastigial nucleus

The dorsal vermis [lobules V to VII, called the *oculomotor vermis* (OMV)] and the underlying posterior fastigial nucleus (called the *fastigial oculomotor region*, FOR) are important in the control of saccades and pursuit. The OMV receives mossy fiber inputs from the paramedian pontine reticular formation, nucleus reticularis tegmenti pontis (NRTP), dorsolateral and dorsomedial pontine nuclei, vestibular nuclei, and nucleus prepositus hypoglossi; and climbing fiber inputs come from the inferior olive. The main projection of the Purkinje cells of the OMV is to the FOR. The FOR also receives axon collaterals of climbing fiber inputs from the inferior olive, and axon collaterals from mossy fibers projecting to the dorsal vermis from neurons within the pons. The main projection from the FOR crosses through the other fastigial nucleus and enters the uncinate fasciculus, which runs in the dorsolateral border of the superior cerebellar peduncle to reach the brainstem. The main targets of the FOR are the omnipause neurons and premotor saccadic burst neurons in the medulla, pons, and midbrain. In addition, the nucleus of the posterior commissure, the mesencephalic reticular formation, and the rostral pole of the superior colliculus receive inputs from the FOR. There are also projections to other structures including the NRTP, the dorsolateral pontine nuclei, vestibular nuclei, the superior

colliculus, and the nucleus prepositus hypoglossi. Thus, the OMV and FOR are poised to influence virtually all the critical neural structures within the brainstem that control saccade and pursuit eye movements.

SACCADES Considerable evidence points to the OMV and FOR playing an important role in the control of virtually every aspect of saccades. Lesions in the OMV lead to changes in the accuracy, latency, and dynamic properties of saccades (Fig. 99.6), as well as in the ability to undergo saccade adaptation (Barash et al., 1999; Takagi et al., 1998). Physiological studies in monkeys reveal that Purkinje cells in the OMV discharge before saccades, and stimulation of this same area can elicit saccades (Krauzlis and Miles, 1998; Thier et al., 2000). In humans, too, artificial stimulation using transcranial magnetic stimulation (Hashimoto and Ohtsuka, 1995) and functional magnetic resonance imaging scanning while subjects make saccades (Desmurget et al., 2000; Dieterich et al., 2000) confirm the participation of the OMV in the generation of saccades. Neurons in the FOR also discharge in relation to saccades. They supply a pre-saccadic burst for contraversive saccades (i.e., the right FOR bursts before leftward saccades) and a “braking” discharge, late during the saccade, for ipsiversive saccades (Robinson and Fuchs, 2001). Thus, each FOR acts to facilitate contraversive saccades and contributes to the termination of

FIGURE 99.6. Representative traces of horizontal saccades in response to a leftward 20 degree target jump from a monkey with a lesion in the OMV. Ten consecutive trials were plotted. The left panel indicates prelesion data and the right panel early postlesion

data. Saccades were realigned to the same starting position. Note the hypometria and larger variability after lesioning. (From Takagi et al., 1998, with permission.)

ipsiversive saccades. Purkinje cells in the OMV behave in a similar way to those of the FOR, though, as predicted from their inhibitory nature, their “sign” is opposite. Thus, each side of the vermis acts to facilitate ipsiversive saccades and contributes to the termination of the contralateral saccades. Consequently, FOR lesions cause ipsiversive saccadic hypermetria (overshoot) and contraversive hypometria (undershoot). Bilateral FOR lesions cause bilateral hypermetria (Optican and Robinson, 1980). Since Purkinje cells of the OMV inhibit the ipsilateral FOR, the effects of OMV lesions are opposite to those of FOR lesions: hypermetric contraversive and hypometric ipsiversive saccades. Bilateral lesions in OMV cause hypometric saccades in both directions.

FUNCTIONAL LESIONS OF THE FOR The pattern of saccadic dysmetria that appears after unilateral inactivation of the FOR mimics an archetypical clinical neuro-ophthalmologic syndrome—*lateropulsion* of saccades—that occurs with vascular lesions in the dorsal lateral medulla (Wallenberg’s syndrome). With lateropulsion there is an inappropriate horizontal component *toward* the side of the lesion during attempted vertical saccades. Likewise, horizontal saccades overshoot when directed toward and undershoot when directed away from the side of the lesion. Together this pattern of saccadic dysmetria is called *ipsipulsion*. Why should a brainstem lesion produce lateropulsion of saccades? Here an understanding of basic cerebellar physiology suggests the answer (Waespe and Baumgartner, 1992). The lesion in the dorsolateral medulla interrupts, at the level of the inferior cerebellar peduncle, the climbing fiber projection to the Purkinje cells of the OMV. The removal of the climbing fiber input leads to an increase in the simple-spike discharge rate of the Purkinje cells because of the reciprocal relationship between the climbing fiber and simple-spike discharge rate of Purkinje cells. Consequently, there is an increased inhibition of the FOR on the side of the lesion. Hence, one can attribute ipsipulsion of saccades in Wallenberg’s syndrome to a loss of facilitation of contralateral saccades and a failure of inhibition of ipsilateral saccades. This is an example of a functional lesion of the FOR; the structural lesion is actually in the brainstem involving the inferior cerebellar peduncle.

HOW DOES THE CEREBELLUM INFLUENCE THE CIRCUITS WITHIN THE BRAINSTEM THAT GENERATE SACCADES? In spite of the considerable evidence relating the OMV and FOR to the control of saccades, many questions remain about how descending signals from the cerebral hemispheres and superior colliculus are transformed and shaped into the correct saccade premotor command. The FOR is clearly involved in this process, but not known are the precise source and timing of the signals that provide the input to the FOR.

Equally unclear is how the FOR, and the OMV through its projections to the FOR, influence the brainstem circuits that generate saccades. There are a number of possible targets by which the FOR could influence saccades. The early influence of the FOR on the initiation of saccades could be mediated through the excitatory burst neurons (EBN) within the brainstem reticular formation. The late influence of the FOR on stopping saccades could be through the inhibitory burst neurons (IBN) in the brainstem reticular formation. These neurons could act to “choke” or “brake” the saccade by strongly inhibiting the abducens nucleus that had been driving the agonist muscles during the saccade. Projections of the FOR to omnipause neurons (OPN), which inhibit premotor saccadic EBN—either directly or via projections to OPN from the fixation zone of the rostral pole of the superior colliculus—would be other routes by which the FOR could help bring the saccade to an end. Modulation of the trajectories of saccades on-line has also been suggested as a function of the FOR, with the OMV receiving information about performance during saccades and adjusting its inhibition upon the FOR to ensure saccade accuracy. In this scheme, the OMV would also recognize contexts (e.g., the position of the eye in the orbit) and adjust the output of the FOR to fit the particular circumstances in which the saccade must be generated. Though attractive, these speculations about cerebellar function in the control of saccades await experimental confirmation. (See Optican and Quaia, 2002; Robinson et al., 2002; and Scudder et al., 2002, for discussion of these issues.)

PURSUIT As with saccades, there is considerable evidence that the OMV and FOR participate in the generation of pursuit eye movements. Lesions in the OMV lead to changes in smooth pursuit as well as in the ability to undergo pursuit adaptation (Fig. 99.7) (Takagi et al., 2000). Electrical stimulation of the OMV can enhance ipsiversive or impair contraversive pursuit in monkeys (Krauzlis and Miles, 1998), and transcranial magnetic stimulation of the posterior cerebellum in humans can also evoke pursuit eye movements in the same pattern (Ohtsuka and Enoki, 1998). There are neurons in both the OMV and the FOR that discharge in relation to pursuit (Robinson and Fuchs, 2001). In the case of the FOR, neurons discharge early during contraversive pursuit and late for ipsilateral pursuit, analogous to activity associated with saccades. Thus, each FOR can act to facilitate contraversive pursuit and can contribute to the termination of ipsiversive pursuit. Purkinje cells in the OMV probably behave similarly to those of the FOR, though, as predicted from their inhibitory nature, their sign is opposite. Each side of the vermis acts to facilitate ipsiversive pursuit and contributes to the termination of contralateral pursuit.

FIGURE 99.7. Step-ramp tracking for monkey (target velocity, 20 deg/sec) following lesioning in the OMV. Velocity traces are shown, with an average of 10 trials, pre- (gray line) and post- (black line) lesioning. Note the decrease in tracking velocity during the initial open-loop portion of visual tracking. The arrow indicates 100 msec after the onset of tracking (the open-loop period). (From Takagi et al., 2000, with permission.)

The pursuit deficits that have been reported after lesioning in the OMV and the FOR are largely in accord with the physiological findings. As expected, with a lesion in the FOR, contralateral pursuit is impaired. Bilateral FOR lesions would be expected to produce reasonably symmetrical and relatively intact pursuit, and this appears to be the case, though a detailed analysis of the open-loop behavior of such animals is not yet available. On the other hand, bilateral lesions of the OMV produce bilateral pursuit deficits.

One other remarkable finding after OMV lesioning in monkeys is that there are quantitative similarities in the effects of the lesions on saccade amplitude, and on pursuit velocity at the end of the open-loop initial period of pursuit tracking (the first 100 msec of tracking after a target has started moving or has changed its speed) (Takagi et al., 2000). This similarity suggests that the OMV functions in the control of the preprogrammed open-loop component of eye movements, and furthermore that saccades and the open-loop portion of pursuit share neural circuitry, not only in the cerebellum but also in the brainstem and superior colliculus. Compatible with this idea is the finding of neurons within the OMV that discharge for both pursuit and saccades, and that stimulation of the OMV can alter ongoing saccades or pursuit, depending on the parameters of the stimulus (Krauzlis et al., 1997).

WHY ARE THERE MULTIPLE AREAS WITHIN THE CEREBELLUM RELATED TO PURSUIT AND TO SACCADIC EYE MOVEMENTS? Before leaving the FOR and OMV, one must ask why there are multiple areas within the cerebellum that seem related to pursuit. For example, the uvula (Heinen and Keller, 1996) and the interposed nucleus (Robinson and Brettler, 1998), the flocculus/paraflocculus, and the FOR/OMV complexes

all have neurons that discharge with pursuit eye movements. Lesions in the uvula (Heinen and Keller, 1996) and within the lateral cerebellar hemispheres (Straube et al., 2001) also have been associated with pursuit deficits. One dichotomy to consider is that the OMV/FOR is more concerned with the initiation and termination of the preprogrammed, open-loop, initial portion of pursuit, and the flocculus/paraflocculus is more concerned with pursuit during sustained tracking. Such a strict segregation of function, however, is not yet proven. Furthermore, after partial lesioning in the cerebellar cortex there is considerable recovery of function, implying a striking ability for one part of the cerebellum to take over for another.

For saccades, too, there are neurons in areas of the cerebellum apart from the FOR/OMV that show saccade-related activity. They include the posterior portion of the interposed nucleus (Robinson, 2000), the basal interstitial nucleus (Takikawa et al., 1998), and the lateral cerebellar hemispheres (Mano et al., 1991). Both pursuit and saccades are commonly associated with other motor behaviors. Pursuit frequently works with (or against) the VOR during combined movements of the eyes and head or eyes and arms. Saccades, too, are associated with arm tracking and with leg movements during ambulation, and also form an important component of the compensatory response to translational movement of the head (Ramat and Zee, 2002; Wiest et al., 2001). Thus, one can envision a number of areas within the cerebellum associated with different motor behaviors that might want to “know” or use information about associated eye movements to help optimize their own performance.

Other abnormalities of ocular motor control associated with cerebellar dysfunction

ABNORMALITIES OF TORSION DURING FIXATION The torsional orientation of the eye during fixation is precisely controlled and is described by Donders’ and Listing’s laws (Fetter et al., 1997). Donders’ law states that during steady fixation, the torsional orientation of the eyes is fixed for a given eccentric (horizontal and vertical) eye position. Listing’s law describes the way in which Donders’ law is implemented; it defines the kinematic features of eye rotations that fix the torsional orientation of the globe for a given horizontal and vertical position of the eyes in the orbit. Listing’s law specifies a *primary position* of the eyes from which eccentric eye positions can be reached without a rotation of the eye about its line of sight. If the primary position is coincident with the straight-ahead reference position, all other positions can be reached from this position by rotation around an axis that lies in a plane (Listing’s plane) that is perpendicular to the primary position. How Listing’s law is implemented is a current area of intense investigation. Both

peripheral (mechanical) orbital and central factors likely play a role (Demer, 2002).

Patients with cerebellar lesions frequently show abnormalities of the torsional orientation of the eye during attempted steady fixation (Helmchen et al., 1997; Straumann et al., 2000). Listing's law can also be examined during pursuit by measuring the tilt of the axis of eye rotation when the orthogonal position of the eye is changed—for example, the amount of torsional eye velocity associated with horizontal tracking with the eye in elevated versus depressed positions (Walker et al., 2002). The pattern of torsion during pursuit is abnormal in patients with cerebellar disturbances and, together with the abnormalities of torsion during attempted fixation, implies that the cerebellum plays a role in the elaboration of Donders' and Listing's laws (Walker et al., 2002). Which part of the cerebellum serves this function is not yet known. The flocculus/paraflocculus might be involved, given its effect on three-dimensional orientation of the eyes during vestibular and optokinetic stimulation. The OMV could be involved, given the finding that lesions in the nucleus reticularis tegmenti pontis, which has strong projections to the OMV, lead to disturbances of the torsional orientation of the eye immediately following saccades (Van Opstal et al., 1996).

ABNORMALITIES OF TORSION DURING PURSUIT Another type of abnormality in the control of torsion occurs in patients with lesions involving the middle cerebellar peduncle (Fitzgibbon et al., 1996). In this case, there is inappropriate torsional eye velocity during vertical pursuit. The magnitude of the torsional velocity is proportional to the vertical velocity and the sign (clockwise or counterclockwise) changes, depending on whether the vertical component is up or down. The cause may be the interruption of fibers in the middle cerebellar peduncle that carry pursuit-related visual information between the pontine nuclei and the flocculus, paraflocculus, and OMV. Combined vertical-torsional eye velocities are also seen in the slow phases evoked by stimulation of individual vertical semicircular canals. This suggests that visual information for pursuit eye movements may be encoded in a vestibular (labyrinthine) coordinate frame and that the cerebellum may be important for the coordinate transformation that adjusts the axis of eye velocity. This interpretation emphasizes visual-vestibular interactions and the importance of the vestibular system in many aspects of the control of eye movements.

The cerebellum and binocular ocular motor control

Most of the findings relating the cerebellum to ocular motor control have dealt with conjugate eye movements. Much less is known about the role of the cerebellum in disconjugate ocular motor control, either of the relative positions of the

eyes during fixation (static alignment) or during movement (dynamic alignment or yoking of the eyes). Vestibular responses, especially those that take into account the translation of the head, must have a capability for disconjugate ocular motor control. Hence, it seems plausible that the cerebellum would have developed mechanisms for ensuring that each eye rotates by the correct amount during movement of the head. We have already discussed the finding that lesions within the flocculus produce disconjugate vestibular responses.

Physiological recordings from monkeys have identified neurons in several areas within the cerebellum that discharge in relation to vergence eye movements. The flocculus/paraflocculus (related to vergence angle), FOR (primarily related to convergence), and interposed nucleus (primarily related to divergence) all show activity related to vergence (Gamlin, 2002; Miles et al., 1980). Likewise, some of the pontine-cerebellar relay nuclei are also important for binocular control of eye movements (Gamlin et al., 1996).

DISORDERS OF STATIC ALIGNMENT WITH CEREbellar LESIONS

There is additional evidence from lesion studies implicating the cerebellum in binocular motor control (Versino et al., 1996). Patients with cerebellar damage sometimes show a skew deviation, a vertical misalignment of the eyes that cannot be attributed to an oculomotor or trochlear nerve palsy. The misalignment often changes its sense with horizontal eye position; most commonly, the abducting eye is higher. It has been suggested that this particular pattern of vertical misalignment of the eyes could arise from lesions in the vestibulocerebellum, perhaps the nodulus, and relate to phylogenetically old otolith-ocular reflexes in lateral-eyed animals, which produce a skew deviation that varies with horizontal eye position during fore and aft head tilt (Zee, 1996).

Patients with cerebellar abnormalities commonly have an esotropia (convergent squint in which the eyes turn inward), sometimes attributed to a divergence paralysis since the esodeviation is usually greater at distance. Patients with caudal cerebellar lesions may also have a divergence-beating nystagmus (convergent slow phases with divergent quick phases). These types of abnormalities hint at an excess of convergence tone with some cerebellar lesions.

Experimentally, too, there is evidence that cerebellar lesions lead to abnormalities of disconjugate eye movement control. Lesions of the FOR produce convergence failure, while lesions of the OMV produce esodeviations (Takagi et al., 2001). Alternating skew deviations have been reported in monkeys with large cerebellar lesions (Burde et al., 1975), and cooling of the midline deep cerebellar nuclei in monkeys produces dysmetric saccades with both a disconjugate and a conjugate component (Vilis et al., 1983). Patients with diffuse cerebellar atrophy also show disconjugate saccade dysmetria

in which the movements of the two eyes during and immediately after saccades are not yoked (Versino et al., 1996). Physiological studies also suggest a role for the interposed nucleus of the cerebellum in vergence and especially divergence control (Zhang and Gamlin, 1998). Taken together with the results of anatomical and physiological studies, there is compelling evidence for a role for the cerebellum in the disconjugate control of eye movements, though much needs to be learned about these particular aspects of cerebellar function.

Ocular motor learning and the cerebellum

Perhaps the most exciting aspect of cerebellar function is its role in motor learning. Considerable theoretical, experimental, and clinical effort has gone into understanding how this “neuronal learning machine” participates in this critical brain function. The flocculus/paraflocculus has a clear role in ocular motor learning (Ito, 2000; Lisberger et al., 1984; Optican et al., 1986; Rambold et al., 2002; Schultheis and Robinson, 1981). Monkeys or cats with complete floccular/parafloccular lesions cannot adaptively adjust the amplitude (gain) or the direction (relative to head motion) of the r-VOR or the pulse-step ratio for saccades. There is evidence that these same structures are also involved in pursuit adaptation (Kahlon and Lisberger, 2000; Nagao and Kitazawa, 2000; Rambold et al., 2002). The OMV, too, has a role in ocular motor learning. Adaptive modification of the initial acceleration of pursuit and of the amplitude of saccades is impaired with dorsal vermal lesions (Fig. 99.8) (Barash et al., 1999; Takagi et al., 1998, 2000). As expected, the FOR also plays a role in saccade (and presumably pursuit) adaptive control (Robinson et al., 2002). Disconjugate ocular motor control is also certainly subject to motor learning and is likely under cerebellar influence. One example is phoria adaptation, a mechanism by which ocular alignment is adaptively readjusted; phoria adaptation can be impaired with lesions in the cerebellum (Takagi et al., 2001). The particular areas within the cerebellum that participate in ocular motor learning have also been suggested from functional imaging studies (Desmurget et al., 2000), which complement findings from lesion and physiological studies.

The effect of lesions within the cerebellum on ocular motor function often varies from animal to animal. Examples discussed above include the pattern of postsaccadic drift (onward or backward), the amplitude of the gain of the VOR (up or down), and the waveform of the slow-phase velocity of downbeat nystagmus (velocity increasing or velocity decreasing), which appear after floccular/parafloccular ablation. While differences in the extent of lesions may explain some of this variability, another interpretation relates to the central role of the cerebellum in long-term ocular motor learning. In this formulation, the cerebellum

FIGURE 99.8. Trial-by-trial change in eye acceleration in the open-loop period during training in the increasing ($\times 2$) adaptation paradigm for a monkey following lesioning in the OMV. The abscissa indicates the trial number and the ordinate the average eye acceleration in the first 100 msec of tracking; this is a negative value, as tracking was leftward. One hundred trials were used in this training session and are demarcated by the inner vertical dashed lines. Note that after lesioning the increase (negative value) in average eye acceleration is attenuated. (From Takagi et al., 2000, with permission.)

acts to compensate for differences in motor performance that are idiosyncratic from animal to animal, depending on its particular genetic makeup and the “life history” of disease, trauma, as well as the interaction between inherent capabilities and environmental influences during development and aging. Consider, for example, human beings who become blind later in life. After a period of time, usually months to years, their eye movements begin to resemble those of a cerebellar patient with nystagmus and unsteady fixation (Leigh and Zee, 1980). In this case, the cerebellum has been deprived of the sensory error signals that it normally uses to keep the brainstem premotor circuits correctly calibrated for optimal visual and vestibular motor performance. The exact pattern of abnormality will depend on that patient’s particular life history. In other words, ocular motor learning is a dynamic process in which unwanted, spontaneous fluctuations in activity within brainstem ocular motor circuits must be detected and corrected. Without error signals, the cerebellum cannot “know about” and hence correct for this unwanted premotor activity, and there will be a slow, inevitable loss of calibration of ocular motor reflexes.

While there is no doubt that the cerebellum is important for ocular motor learning, the exact mechanisms are unclear, and their elucidation is a major focus of contemporary neuroscience. A number of uncertainties exist. For example, what are the precise *cellular and electrophysiological* mechanisms

of motor learning—for example, the role of climbing fiber versus mossy fiber inputs and the role of long-term depression (Anastasio, 2001; Frens et al., 2001; Hansel et al., 2001; Ito, 2001; Raymond and Lisberger, 2000)? What is the role of specific *neurotransmitters* such as nitrous oxide synthetase in motor learning (Li et al., 1995; Nagao and Kitazawa, 2000)? What are the relative roles of the cerebellar cortex and the deep cerebellar nuclei in *acquisition versus maintenance* of motor learning (Doyon et al., 2002; Robinson et al., 2002)? What are the differences in mechanisms between *short* (minutes to hours) and *long-term* (days to weeks) motor learning (Barash et al., 1999; Straube et al., 2001)? What are the differences in mechanisms between relatively simple motor learning (e.g., adjustment of the amplitude of the VOR for all head movements) and relatively complex, *context-specific motor learning* (e.g., adjustment of the amplitude of the horizontal VOR as a function of vertical eye position or adjustment of the same motor behavior, depending on internal or external cues (Gancarz and Grossberg, 1999; Straube et al., 2001; Thach, 1998)? What is the nature of the *error signals* that trigger motor learning? What are the relative roles of proprioceptive error signals (which may be important for disconjugate adaptation) (Lewis et al., 1995, 1999), visual error signals such as motion of images on the retina during head movement (Kahlon and Lisberger, 2000; Raymond et al., 1996), and efference copy error signals by which errors in performance are inferred based on monitoring of corrective ocular motor commands? What is the role of the cerebellum in generating *predictive* versus more *reflexive* motor behavior (Mauk et al., 2000; Miall and Reckess, 2002; Schultz and Dickinson, 2000)? What are the *pathways* through which cerebellar influences on adaptive control are mediated [e.g., the possible role of cerebral cortex in saccade adaptation via cerebello-thalamo-cortical pathways (Gaymard et al., 2001)]?

Summary

The cerebellum plays a central role in the coordination and calibration of all types of eye movements. Diseases and experimental lesions of the cerebellum result in a variety of ocular motor disturbances that impair vision by disrupting foveal stabilization during fixation, pursuit, or the VOR; making saccadic gaze-shifts inaccurate; and causing misalignment of the eyes. Long-term adaptive processes are disrupted. The control of torsion during fixation and eye movement is altered. A careful study of these abnormalities is contributing to a greater understanding of the function of the cerebellum in eye movement control and in the pathophysiology of cerebellar diseases.

XII ATTENTION AND COGNITION

100 Visual Perception and Cognition in Honeybees

SHAOWU ZHANG AND MANDYAM SRINIVASAN

DESPITE THE OBVIOUS optical differences between the “camera-type” eye of humans and the compound eye of the bee, research over the past two decades has begun to reveal that the fundamental principles of early visual processing in the two nervous systems may be quite similar, at least in a qualitative sense.

The worker honeybee carries a tiny brain. It occupies a volume of about 1 mm^3 , weighs about 1 mg, and contains fewer than 1 million neurons. Nevertheless, this creature, by virtue of its lifestyle, is a spectacularly suitable organism for studying the principles of pattern recognition and navigation, as well as those of learning in a more general sense (Menzel, 1990; Von Frisch, 1971). Gathering nectar and pollen is the *raison d’être* of a forager’s existence. To forage successfully, a bee has to learn and remember not only the color and shape of flowers that are bountiful in these nutrients, but also how to get to them (Chittka et al., 1993; Lehrer et al., 1995; Vorobyev and Menzel, 1999; Wehner, 1981). Since the species or flowers that are in bloom one week are likely to be replaced by a different species at a different location the next week, the bee needs, and has indeed evolved, an impressive ability to learn colors, odors, shapes, and routes quickly and accurately. A bee can learn a new color in about half an hour (after it has made about 5 visits to collect a food reward), a new pattern in about half a day (after 20 to 30 rewarded visits), and a new route to a food source in about 3 to 4 visits (provided that the route is not through a complex labyrinth). The biology of the honeybee thus offers a tailor-made opportunity for studying the mechanisms by which sensory stimuli are recognized and navigational strategies are learned, remembered, and applied.

Over the past decade, work on the honeybee has begun to suggest that insects may not be the simple, reflexive creatures that they were once believed to be. Bees display perceptual and “cognitive” capacities that are surprisingly rich, complex, and flexible (Menzel and Müller, 1996; Srinivasan, 1994; Srinivasan and Zhang, 1998). This chapter reviews recent studies that have challenged the perceptual capacities of honeybees by posing question such as: Can bees learn abstract concepts? Do they generalize these concepts? Is sensory processing influenced by prior knowledge and

experience? Can bees learn complex tasks such as navigating through labyrinths? What information do bees acquire, memorize, and use when they learn how to tackle complex tasks?

This review is not intended to be exhaustive. Rather, it highlights important advances in our understanding of the processes underlying pattern recognition and perception, as well as the learning of complex tasks by the honeybee. The review will not cover some important areas in honeybee vision, such as the perception of color and motion. These topics have been discussed comprehensively in other reviews (Backhaus, 1998; Backhaus et al., 1987; Kevan et al., 2001; Menzel and Backhaus, 1989; Srinivasan et al., 1999; Chapter 80).

Three milestones in honeybee pattern recognition

The study of pattern recognition in the honeybee has seen three major milestones, or eras (Horridge, 1999; Srinivasan, 1994; Srinivasan and Zhang, 1998). The studies of the first era, by Karl Von Frisch (1915) and Hertz (1929), were carried out by cutting two or more patterns out of black paper, placing them flat on a horizontal table, and training a group of bees to collect a reward of sugar water at one of the patterns. The positions of the patterns were varied frequently to ensure that the bees learned to come to a specific pattern rather than to a specific location on the table. By analyzing the bees’ performance in this task, they proposed the *flücker* hypothesis, which states that honeybees discriminate between visual patterns in terms of the frequency of on/off stimuli experienced by the compound eye as they cruise above the patterns (Hertz, 1933).

The next era commenced with the work of Wehner and Lindauer (1966), who began experimenting with patterns presented in the vertical plane. Although this may seem to be a simple modification at first glance, it opened up a whole new dimension in research on pattern recognition in bees. The reason was that one could now ask, for the first time, whether bees can distinguish between patterns that are rotated with respect to each other. This could not be done with patterns laid flat on a table, as the bees could approach such patterns from any direction. An interesting observation

made in these studies was that during training, the bees tended to hover stably in front of the training pattern for a second or two before landing on the entrance tube leading to the reward behind the pattern (Wehner and Flatt, 1977). This led Wehner to propose the *template* hypothesis, according to which bees fixate the pattern and memorize it in a photographic sense. When, after training, the bee is offered a choice between the rewarded pattern and another pattern, the bee evaluates the two patterns by comparing the extent to which each pattern matches the stored template that the bee has acquired of the rewarded pattern during training (Wehner, 1967, 1981). The template theory of pattern recognition was corroborated by the work of Gould (1985, 1986), who showed that bees could be trained to distinguish rather small differences between patterns, suggesting that recognition does indeed involve a fairly precise spatial evaluation of the extent to which the black and white regions in the viewed pattern match the corresponding regions in the template.

The third era of pattern recognition in honeybees began when investigators began to wonder whether bees could learn abstract features, or properties, of patterns instead of, or in addition to, memorizing them photographically (Van Hateren et al., 1990; Wehner, 1971). This was an important step toward gaining insights into the cognitive capacities of the honeybee brain. In the next section, we outline the progress made in this era.

Can bees abstract general properties of patterns?

There can be little doubt that bees use some kind of neural “snapshot” to remember and recognize patterns and landmarks (Collett and Cartwright, 1983; Judd and Collett, 1998). However, it is hard to imagine that this is all there is to pattern recognition. In their daily lives, bees are required to remember a number of different patterns and their properties. Examples include the shape of the nest or hive, shapes representing nectar-bearing flowers, and shapes of important landmarks on the way to the food source and back. If snapshots were the only mechanism for remembering shapes, bees would require a large memory to store all of these images. Given that the brains of bees contain far fewer neurons than do ours, it seems unlikely that they can afford the luxury of a large memory.

One would imagine, therefore, that bees also possess other, more economical means of representing patterns. Can bees abstract general features of a pattern—such as its orientation—without memorizing the pattern in its entirety? An early paper by Wehner (1971) hinted that bees could indeed abstract pattern orientation in this way. This question was pursued further by Van Hateren et al. (1990), who presented random gratings at two different orientations in a Y-maze apparatus (Fig. 100.1A, B). The stimuli were pre-

sented in the vertical plane, each at the end wall of one of the tunnels of the maze. The stimulus representing one of the orientations was associated with a reward of sugar water. The stimulus representing the other orientation offered no reward.

During training, the positions of the stimuli were interchanged frequently, and the reward was moved along with the positive stimulus, to prevent the bees from simply learning to fly to a specific tunnel. Two properties of the apparatus and the training paradigm prevented the bees from acquiring a template of the positive pattern. Firstly, the bees had to choose between the two stimuli at a considerable distance away from them; the stimuli could not be fixated at this distance. Secondly, the gratings were frequently replaced by other random gratings which were similarly oriented but had different spatial structures (Fig. 100.1B). Thus, to identify the positive stimulus correctly, the bees had to abstract its orientation, and not merely memorize a pattern in a photographic way.

Van Hateren et al. (1990) found that bees could be trained in this way to distinguish between vertical and horizontal orientations, as well as between two oblique directions (Fig. 100.1C–E). Furthermore, bees trained to distinguish between two mutually perpendicular orientations were able to discriminate the orientations of other patterns which they had never encountered previously (Fig. 100.2). Thus, bees are able to extract orientation information from patterns on which they are trained and to use this information to distinguish novel patterns.

How does the bee’s visual system extract the orientation of a pattern independently of its structure and without memorizing the pattern in a literal fashion? Srinivasan et al. (1993) provided evidence that the orientation of a pattern is discriminated by the geometrical cues that are intrinsic to the pattern and not by the cues derived from the direction of apparent image motion. Yang and Maddess (1997) found orientation detection neurons at lobula level in the bee with large fields and coarse orientation tuning. Recently, Horridge (1999) suggested that bees possess large-field filters that respond selectively to abstract stimulus properties such as symmetry, relative proportion of radial and tangential edges, angular size, orientation, and so on. The existence of filters is inferred when bees demonstrate that they can respond to a generalized cue extracted from a group of patterns that they encounter.

Recent work in our laboratory and elsewhere has revealed that bees can detect and learn other general properties of patterns, such as radial and circular symmetry (Horridge and Zhang, 1995). Bees can learn to detect bilateral symmetry and discriminate its axis as well (Giurfa et al., 1996; Horridge, 1996). Bees can also extract other abstract characteristics of objects, such as their color and size, without having to memorize the objects’

FIGURE 100.1. Discrimination of pattern orientation. In this and other figures, the vertical bars depict choice frequencies for the two stimuli in training or transfer tests, and n indicates the number of choices analyzed. Also shown is the probability value associated

with a t -test for examining whether the bees' preferences are significantly different from random choice. Details are given in the text. (Modified from Van Hateren et al., 1990).

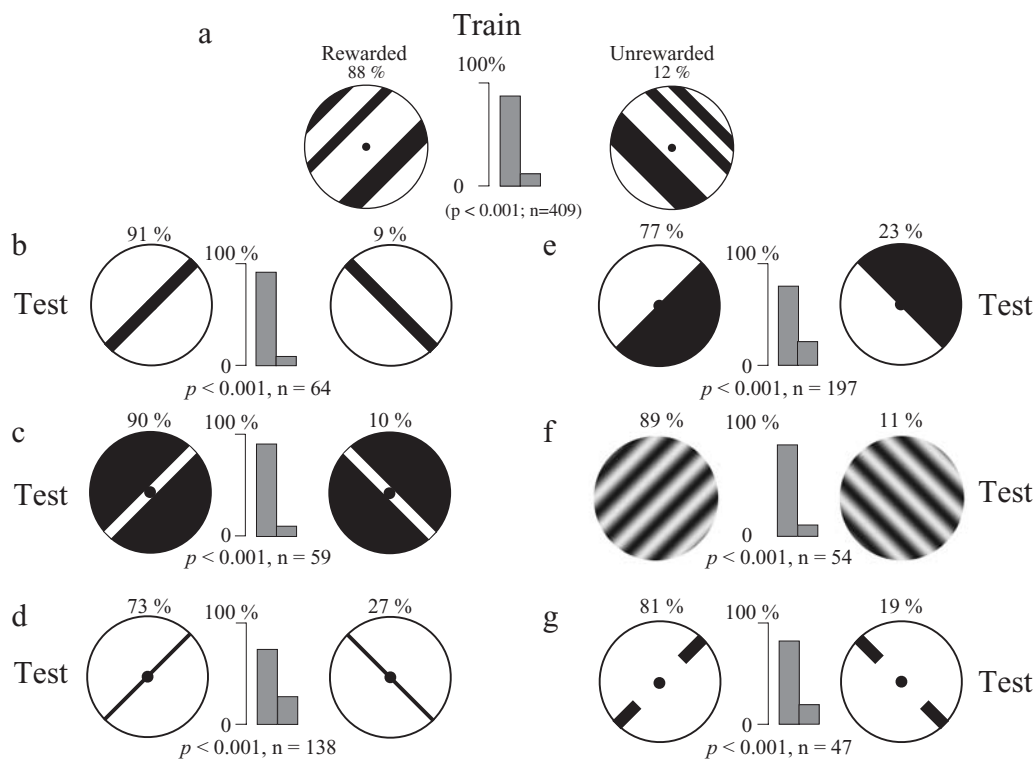

FIGURE 100.2. Bees, trained to distinguish between random gratings oriented at +45 degrees and -45 degrees (a), are able to extract the orientation information in these gratings and use it to discrim-

inate the orientations of other patterns (b-g) which they have never previously encountered. (Modified from Van Hateren et al., 1990).

images literally (e.g., Horridge et al., 1992a; Ronacher, 1992).

In all of the above-mentioned studies, bees clearly demonstrated that they are capable of extracting abstract cues of objects, then generalizing them and using the same criteria in novel discrimination tasks. It is important to emphasize that in all of the above experiments, the ability to generalize has been demonstrated by training bees to not one but a number of stimuli that differ individually in detail but share the property that is to be generalized. For example, the rewarded patterns all possessed the same orientation or the same kind of symmetry (e.g., left-right symmetry). These stimuli were shuffled randomly during the training. Such a training procedure ensures that the bees learn the critical cue that is associated with the reward (Horridge, 1999).

Top-down processing

It is well known that prior knowledge or experience aids us greatly in uncovering objects that are poorly visible, partially hidden, or camouflaged. Many of us who view the scene in Figure 100.3 for the first time do not see a familiar object, especially if we are unaware of the picture's content. Once the camouflaged dalmatian has been discovered, however, it is detected and recognized instantly every time the picture is encountered. Evidently, prior experience or knowledge aids the visual system significantly in the task of uncovering objects (Cavanagh, 1991; Goldstein, 1989; Lindsay and Norman, 1977).

Top-down processing of this kind can speed up the analysis of the retinal image when a familiar scene or object is encountered and can help fill in, or complete, details that are

FIGURE 100.3. A familiar but camouflaged object. (Readers experiencing difficulty in recognizing the dalmatian may wish to view the picture upside down.) (Photo courtesy R. C. James. Reprinted from Lindsay and Norman, 1977, with permission of the authors and publisher.)

missing in the optic array (Cavanagh, 1991). Is the ability to enhance processing in this way restricted to highly developed visual systems such as those of humans and higher mammals? Or does it extend to relatively simple visual systems such as those of invertebrates?

Zhang and Srinivasan (1994) approached this question by investigating whether bees are able to use prior experience to facilitate the detection of objects and the discrimination of their shapes. They first attempted to train bees to distinguish between two shapes—a ring and a disc—when each shape was presented in a camouflaged fashion as a textured figure positioned 6 cm in front of a similarly textured background (Fig. 100.4A). It turned out that bees were unable to learn to make this discrimination, despite lengthy training incorporating over 100 rewards per bee. Next, Zhang and Srinivasan examined whether bees could learn to distinguish the camouflaged patterns if they were first trained on a related but simpler discrimination: that of distinguishing between a black ring and a black disc, each presented 6 cm in front of a white background. The ring and the disc were of the same size and shape as their textured counterparts, and their spatial configuration in relation to the background was identical to that in the previous experiment. The bees were able to learn this new task (Fig. 100.4B). When these pretrained bees were tested on the task of Figure 100.4A, they could distinguish between the patterns immediately (Fig. 100.4C). Although the figures in Figure 100.4A are camouflaged, they can be detected by virtue of the relative motion between the images of the figure and the more distant background as the bee approaches the figure. Evidently, the bees were able to learn to use this motion parallax as a cue to break the camouflage—but only after they had been pretrained on uncamouflaged versions of the same shapes.

Thus, the bees were using knowledge acquired from the simpler black-white patterns of Figure 100.4C, to discern the camouflaged objects. Moreover, bees trained in this step-by-step fashion could learn to distinguish between other camouflaged objects that they had never previously encountered, such as two differently oriented bars (Fig. 100.4E), without any pretraining on black-and-white versions of the new shapes. This suggests that the enhancement in the bees' performance was not restricted to the specific training shapes, such as the camouflaged ring and disc. Rather, it appears that the bees were learning to look at the stimuli by extracting a novel cue—motion parallax—and using this cue to see and distinguish between novel shapes.

Honeybees perceive illusory contours

The human visual system possesses a remarkable ability to perceive and recognize objects even when they are partly occluded. An example of this is shown in Figure 100.5A.

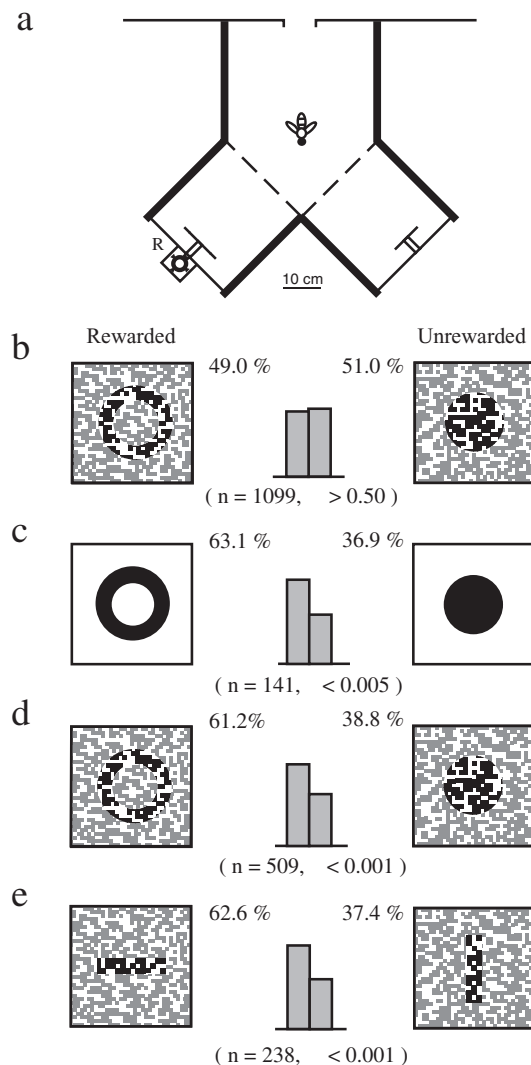

FIGURE 100.4. Investigation of top-down processing in honeybees. Details are given in the text. (Adapted from Zhang and Srinivasan, 1994.)

The figure shows one triangle, comprising the broken black lines. However, the gaps in the lines and the cutouts in the black circles create a strong impression of another triangle, laid upside down to occlude part of the original triangle. The *illusory contours* of this white triangle are particularly vivid. Interestingly, there are neurons in the visual cortex of the monkey that respond to such illusory contours (Von der Heydt and Peterhans, 1989; Von der Heydt et al., 1984).

Van Hateren et al. (1990) explored whether illusory contours such as those described above are also experienced by honeybees.

They trained bees to enter a Y-maze, as in Figure 100.1B, and to distinguish between randomly striped patterns that were oriented at +45 degrees and –45 degrees, by rewarding them on the +45 degree orientation. The bees were able

to learn this task well (Fig. 100.5B). When these trained bees were tested with rectangles oriented at +45 degrees and –45 degrees, they preferred the rectangle with the same orientation as the learned orientation (Fig. 100.5C). Thus, the bees were able to abstract the orientation information that they had learned in the training and apply it to the novel rectangular shapes. When the stripe-trained bees were tested with illusory rectangles oriented at +45 degrees and –45 degrees, they showed a significant preference for the +45 degree rectangle (Fig. 100.5D). This suggests that the bees were indeed perceiving the patterns in Figure 100.5D as rectangles. To examine this possibility further, the bees were confronted with the patterns in Figure 100.5E, where the illusion had been broken by scrambling the pacman-shaped figures. To us, the illusory rectangles are no longer visible: they have been destroyed. Interestingly, the bees behaved as if they could not distinguish between the two new patterns: they chose both patterns equally often (Fig. 100.5E).

There is evidence that insects experience many of the illusions that humans experience. Some other examples are the *waterfall illusion* (Srinivasan and Dvorak, 1979), the *Benham illusion* (Srinivasan et al., 1987), and the *Mueller-Lyer illusion* (Geiger and Poggio, 1975). Thus, the visual systems of insects may process information in ways akin to ours. Horridge et al. (1992b) have also reported the existence of neurons in the insect visual pathway that respond to illusory contours.

Learning to negotiate complex mazes

The ability to learn mazes has been investigated extensively in a number of higher vertebrates, notably rats, mice, and pigeons (Dale, 1988; Pick and Yanai, 1983). Relatively few studies, however, have explored the capacity of invertebrates to learn mazes. Can bees learn complex labyrinths requiring several correct decisions to be made to reach the goal?

Zhang et al. (1996) explored this question by attempting to train bees to fly through a variety of complex mazes to find a reward of sugar solution in the presence or absence of specific visual cues. The experiments were carried out in an All Weather Bee Flight Facility at the Australian National University's Research School of Biological Sciences. Each maze consisted of a 4 × 5 matrix of identical cubic boxes. Each wall of a box carried a hole in its center. The path through the maze was created by leaving open some of the holes between boxes and blocking others. Bees had to fly through a sequence of boxes to reach the goal, which was a feeder containing sugar solution. The experimental maze was placed on a movable table, and its position and orientation were varied frequently to prevent the bees from using landmarks external to the maze as navigational cues.

FIGURE 100.5. Like humans, honeybees perceive illusory contours. Details are given in the text. (Modified from Van Hateren et al., 1990.)

LEARNING TO NEGOTIATE A MAZE BY FOLLOWING A MARK
One series of experiments investigated the ability of bees to find their way through the maze by learning to *follow a color mark* that signaled the correct exit in each box. The mark was a 4×4 cm green square affixed immediately below the appropriate hole in each box to indicate the correct path (Fig. 100.6A). Bees were trained to enter the maze and take the correct path through it. This was accomplished by moving a feeder step by step along the correct path until it reached the third box in the path. During this period, the bees had the opportunity to learn that the mark in each box signaled the correct exit. After the bees had reached this stage, the feeder was moved directly to the last box on the path, left there briefly and then moved to its final destination, namely, the feeder cage behind the last box.

The bees' performance was tested immediately thereafter. During the test, only one bee at a time was allowed into the maze. Performance was scored by assigning each flight to one of four categories. Category 1 comprised flights in which a bee flew through the entire path and arrived at the goal without making any mistakes. Category 2 represented flights in which the bee turned back and retraced its path (once or many times) but remained on the correct path and arrived at the goal within 5 minutes. Category 3 comprised flights in which a bee made one or more wrong turns at the decision boxes but still arrived at the goal within 5 minutes. The last category, 4, represented unsuccessful searches, defined as flights in which the bee did not reach the goal within 5 minutes of entering the maze (regardless of whether it was

on the correct path or not). In some tests, the bees' performance was also evaluated by measuring the time required to reach the goal from the moment of entering the maze. Before each test, the boxes were swapped to remove possible olfactory cues.

The results show clearly that bees, trained initially to follow color marks through only a small initial part of the maze, are immediately able to "blaze a trail" by using the same cue to find their way through the rest of the maze (Test 1 in Fig. 100.6B). Performance continues to be good when the bees are tested on a new path, created by rearranging the boxes and marks (Test 2 in Fig. 100.6B). The control depicts the results of a test that measured the performance of the trained bees in following an unfamiliar route in an unmarked maze. This test represents a baseline against which the performance of the bees in the tests can be compared. Evidently, the trained bees had learned to follow the marks to the goal and were immediately able to use this rule to trace a novel path through the maze. The bees' performance in Tests 1 and 2 is significantly better than that in the control test.

LEARNING TO NEGOTIATE A MAZE BY USING A SYMBOLIC CUE
Another series of experiments examined whether bees could learn to negotiate mazes by *using a symbolic cue* (Zhang et al., 1996). Left and right turns were signaled according to a color placed on the back wall of each box where a turn had to be made (Fig. 100.6C). The training and testing procedures were similar to those described above. The results showed

FIGURE 100.6. Learning to negotiate complex mazes by using visual cues. Details are given in the text. (Modified from Zhang et al., 1996.)

that bees learned this task very well too. In fact, their performance in this maze was just as impressive as in the mark-following maze.

Here again, bees trained to use the symbolic cue on a particular route were immediately able to use the cue to trace novel paths through the maze (Tests 4 and 5, Fig. 100.6D). The performance in all tests (Tests 4 to 6) was significantly better than that in the control test (Fig. 100.6D).

Walking honeybees are also capable of route-specific learning with respect to visual stimuli that function as navigational “signposts” (Zhang et al., 1998).

Context-dependent learning

The above maze experiments reveal that honeybees are capable of using symbolic color marks to make choices. Can bees learn tasks in a context-dependent way?

Gadagkar et al. (1995) examined whether honeybees could learn to associate environmental cues with rewards in a context-dependent manner. Two different contexts were set up, one at the hive and one at a feeder 12 m away. At the feeder, bees were offered a choice of two colors: blue and green. They had to choose the color green in order to gain access to the feeder. At the hive, they were again offered a choice between blue and green, but this time they had to choose blue—that is, make the opposite choice—to enter the hive. The bees were able to learn this task very well, showing a strong preference for green at the feeder and for blue at

the hive (Fig. 100.7, Exp. 1A). In a complementary experiment, a group of new bees was trained to choose blue at the feeder side but green at the hive side. They also learned this task very well (Fig. 100.7, Exp. 1B). Similar results were obtained using stimuli that consisted of gratings that were oriented vertically or horizontally (Fig. 100.7, Exp. 2A, B). Thus, bees can learn tasks in a context-dependent manner. In these experiments, the average flight time between the hive and the feeder was only 2 seconds, showing that bees can reverse their preference in a very short time.

Colborn et al. (1999) examined context-dependent learning by bumblebees. They investigated whether contextual cues can prevent interference during the acquisition of potentially competing visuomotor associations. Their findings are consistent with the hypothesis that different contextual signals are associated with approaching the nest or approaching the feeder, and that these contextual signals facilitate learned associations between orientation detectors and motor commands.

Learning principles of symbolic matching

One of the more complex tasks that has been used to investigate principles of learning and memory has been the *delayed match-to-sample* (DMTS). This task has been investigated in many different species such as the monkey (e.g., D’Amato et al., 1985), dolphin (e.g., Herman and Gordon, 1974), and pigeon (e.g., Roberts, 1972).

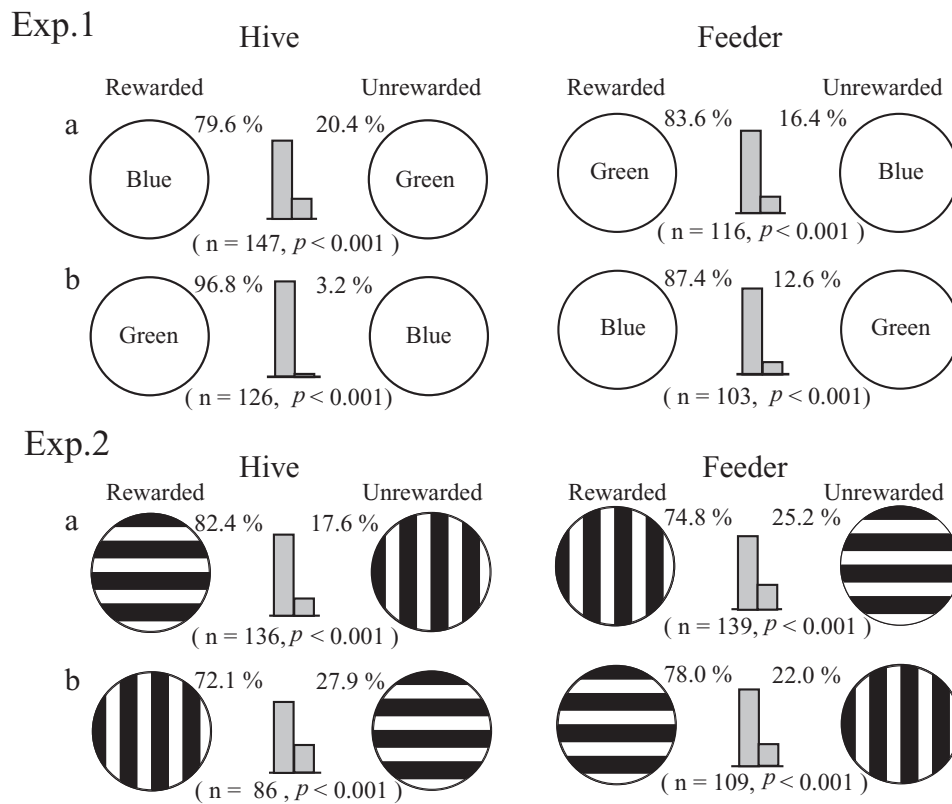

FIGURE 100.7. Context-dependent learning by honeybees. Details are given in the text.

Most DMTS tasks follow the same general procedure. Each trial begins with the presentation of a sample stimulus. The sample is followed by a delay or retention interval and then by the presentation of two or more test stimuli, one of which is identical to the sample stimulus. If the animal chooses the test stimulus that corresponds to the sample, then it obtains a reward (hence the name *delayed match-to-sample*). Most experiments use two or three sample stimuli, which are varied randomly from trial to trial.

A more complex variant of this task is the *symbolic delayed match-to-sample task* (SDMTS). In this task, none of the test stimuli physically match the sample: the experimenter arbitrarily designates the correct choice. Here the animal has to learn to associate the correct test stimulus corresponding to each sample stimulus.

Can bees learn such tasks? Their foraging behavior may give us some hints. Honeybees have evolved a number of navigational skills that enable successful foraging. Collett and Wehner have suggested that foraging insects traveling repeatedly to a food source and back to their homes navigate by using a series of visual images, or “snapshots,” of the environment acquired *en route* (Collett, 1996; Collett and Keblar, 1988; Collett et al., 1993; Judd and Collett, 1998; Wehner et al., 1990, 1996). By comparing the currently viewed scene with the appropriate stored image, the insect

is able to ascertain whether it is on the correct path and make any necessary corrections. Thus, successful foraging may require the bee to be able to solve tasks analogous to SDMTS tasks. Therefore, it is of interest to explore whether bees can learn DMTS and SDMTS tasks.

LEARNING THE SDMTS TASK IN THE VISUAL MODALITY
One series of experiments examined the bees’ ability to learn an SDMTS task in the visual modality (Zhang et al., 1999). Honeybees were trained to fly through a compound Y maze consisting of a series of interconnected cylinders (Fig. 100.8A). The first cylinder carried the sample stimulus. The second and third cylinders each had two exits. Each exit carried a visual stimulus, between which the bees had to choose. A bee, having made a correct choice in the second as well as in the third cylinder, arrived in a fourth cylinder, where it found a feeder with sugar solution. Thus, the second and third cylinders acted as decision stages: at each of these cylinders the bee had to choose between two stimuli. It was the single sample stimulus in the first cylinder that determined the choices the bees had to make in the subsequent decision stages.

During training, the sample stimulus was a black-and-white grating oriented either horizontally (Stimulus A) or vertically (Stimulus A’), respectively. The second cylinder (first decision stage) offered a choice between a blue square

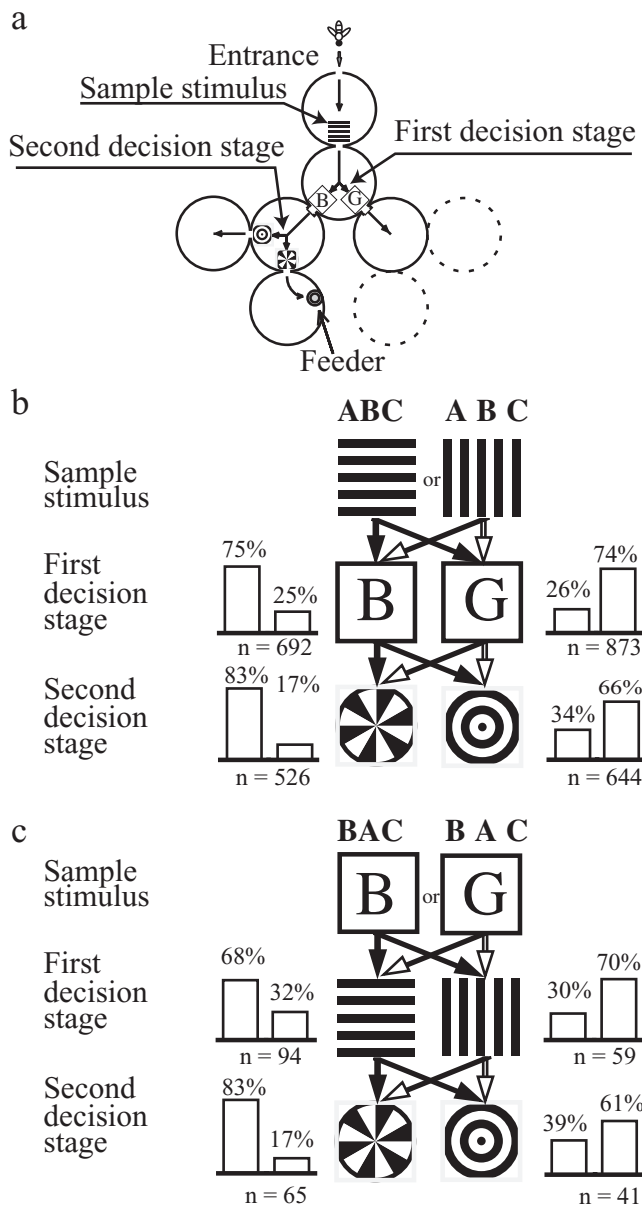

FIGURE 100.8. Learning a SDMTS task in the visual modality. Details are given in the text. (Modified from Zhang et al., 1999.)

(Stimulus B) and a green one (Stimulus B'), and the third cylinder a choice between a pattern consisting of a sectored disc (C) or of concentric rings (C') (Fig. 100.8B). When the sample stimulus was the horizontal grating, the feeder could only be reached if the bee chose blue in the second cylinder and the sectored disc in the third. However, when the sample was the vertical grating, the bee could reach the reward only if it chose green in the second cylinder and the ring pattern in the third.

After training, the bees were tested not only on the training sequences ABC and A'B'C' (learning tests) (Fig. 100.8B), but also in transfer tests which represented five other permutations of the training sequences. The results of tests

on one of the permuted sequences (BAC and B'A'C') are illustrated in Figure. 100.8C.

The results showed that bees are indeed capable of learning SDMTS tasks. Clearly, viewing the sample stimulus (horizontal or vertical grating) triggers recall of the stimulus that should be chosen in each of the subsequent stages (Fig. 100.8B). Furthermore, the trained bees continued to choose the appropriate stimulus at each stage of the maze even in the transfer test (Fig. 100.8C) as well as in tests using other permutations of the stimulus sequence (Zhang et al., 1999). These findings indicate that, in general, exposure to any one of the stimuli that were encountered in the training (A,B,C or A',B',C') was sufficient to trigger associative recall of all of the other stimuli belonging to that set. In all of the tests, changing the sample stimulus (from A to A', B to B', or C to C') caused the bees to change (and reverse) their preference for the stimuli that they encountered at subsequent stages of the maze. It should be noted that in this experiment, the bees were not specifically trained to distinguish between A and A', which were the sample stimuli in the training. Nevertheless, the bees distinguished between them in the transfer tests because they associated them with the stimulus sets ABC and A'B'C', respectively. It is also clear from this set of tests that the bees were capable of treating the stimulus pairs (B, B') (Fig. 100.8C) as well as (C, C') (not shown in the figure) as sample stimuli, even though these were never encountered as sample stimuli in the training.

The above findings suggest that bees solve the SDMTS task by mapping the six visual stimuli that they encounter in the training into two distinct sets, (A,B,C) and (A',B',C'), as illustrated in Fig. 100.9. After training, exposure to any stimulus belonging to a member of one of these sets triggers recall of the other two members belonging to that set. Thus, exposure to B, for example, triggers recall of A and C, whereas exposure to C' triggers recall of A' and B'.

LEARNING THE SDMTS TASK ACROSS SENSORY MODALITIES
Can bees learn an SDMTS task when they are required to make associations that span different sensory modalities? Clearly, humans display impressive cross-modal associative recall. It is a common experience that a smell or a sound can trigger a vivid recollection of an associated event in the past, even if it involves a different sensory modality and even if the episode occurred a long time ago (Baddeley, 1993).

Srinivasan et al. (1998) explored this capacity in bees by asking whether bees could learn to associate specific scents with specific colors. The apparatus consisted of a compound Y maze, as in the above experiments, but with a single decision stage. The sample stimulus, presented in the first cylinder, was a scent that was either lemon or mango. The decision stage offered a choice of two colors, blue or yellow. When the bees encountered lemon at the entrance, they had to learn to choose blue in the decision stage; when they

FIGURE 100.9. A model for associative grouping derived from the results of the SDMTS experiments. Details are given in the text.

encountered mango, they had to choose yellow. The bees learned this task very well. The scent of lemon evidently evoked recall of blue, whereas that of mango triggered recall of yellow. Bees could also be trained to make the opposite associations: lemon with yellow and mango with blue. They could also be trained to make symbolic matches in the opposite direction; that is, they could learn to associate a color in the entrance with a scent in the decision stage.

The evidence presented here clearly shows that honeybees are able to learn the SDMTS task, not only in the visual modality, but also across sensory modalities. Learning an SDMTS task requires that the bee be able, when presented with a sample stimulus, to recall other stimuli that are associated with the sample stimulus. For a foraging honeybee, cross-modal associative recall could facilitate the search for a food source. For example, detecting the scent of lavender could initiate a search for purple flowers.

Learning the concepts of sameness and difference

A related question is whether honeybees are able to group stimuli according to certain rules, or concepts, such as sameness or difference. In vertebrates, the capacity to acquire such concepts has been studied using two experimental procedures, the DMTS task and the DNMTS (*delayed nonmatch-to-sample*) task (Holmes, 1979; Zentall and Hogan, 1978). The DNMTS task is similar to the DMTS task except that the animal is required to respond to the stimulus that is different from the sample. It should be pointed out, however, that the ability to learn the concept of *sameness* or *difference* would be proven only if the animal is able to transfer the ability to choose correctly the matching (or nonmatching) stimulus to a completely novel set of stimuli which it had not experienced during training.

Giurfa et al. (2001) examined whether honeybees could learn the concepts of *sameness* and *difference*. The experiments were carried out at the Australian National University in Canberra as well as at the Free University in Berlin, independently and at the same time. The two laboratories

obtained the same results and decided to publish the study together.

The apparatus used in the experiments was similar to that used for the SDMTS tasks. Bees were trained on sector and ring patterns; that is, they had to learn to choose the sector or the ring pattern in the decision chamber, according to whether the sample stimulus at the entrance was the sector or the ring pattern. The bees learned this task well, showing a clear ability to choose the matching stimulus in each case (Fig. 100.10A, left-hand panel). The trained bees were then subjected to a transfer test, in which the stimuli were two colors, blue and yellow. The bees were immediately able to transfer the matching task to the colors, despite the fact that they had never been trained on them (Fig. 100.10A, right-hand panel). They were also able to transfer the matching ability to other novel stimuli, such as gratings oriented at +45 degrees and -45 degrees (data not shown).

FIGURE 100.10. Learning the concept of *sameness*, and transferring it into novel stimuli in the same sensory modality and in different sensory modalities. *a*, Results of learning tests with sector and ring patterns (*left panel*) and transfer tests with colors (*right panel*). *b*, Learning tests with odors (*left panel*) and transfer tests with colors (*right panel*). Details are given in the text. (Modified from Giurfa et al., 2001.)

Bees can also learn to match odors, as shown in the left-hand panel of Figure 100.10B. Furthermore, bees trained on odors can immediately transfer the learned matching ability to colors, as shown in the right-hand panel of Figure 100.10B. Thus, the concept of *matching*, once learned, can be transferred even across sensory modalities.

Finally, bees can also learn the concept of *difference*. That is, they can be trained to choose the nonmatching stimulus rather than the matching one. Figure 100.11A shows learning curves obtained in two experiments investigating this capability. In one experiment, the training stimuli were colors (blue and yellow). Here bees had to learn to choose yellow in the decision chamber when they encountered blue at the entrance and *vice versa*. In another experiment, the training stimuli were linear gratings oriented horizontally and vertically. There bees had to learn to choose the verti-

cal grating in the decision chamber when they encountered a horizontal grating at the entrance and *vice versa*. It is evident from Figure 100.11A that the bees learned both nonmatching tasks well. Furthermore, in each case, the trained bees were immediately able to transfer the learned nonmatching concept to novel stimuli. Bees trained on the colors were able to perform nonmatching on the gratings and vice versa (Fig. 100.11B, C).

These findings demonstrate that honeybees can indeed learn rather abstract concepts, such as *sameness* and *difference*, and apply them to novel situations—situations on which they have not directly been trained.

Conclusions and discussion

Research over the past 30 years or so is beginning to suggest that learning and perception in insects are much more intricate and flexible than was originally assumed. Honeybees are capable of a variety of visually guided tasks that involve cognitive processes that operate at a surprisingly high level. Bees can abstract general properties of a stimulus, such as orientation or symmetry, and apply them to distinguish between other stimuli which they have never previously encountered. They can be taught to use new cues to detect camouflaged objects. Like humans, bees even experience visual illusions. They can learn to use symbolic rules to navigate through complex mazes and to apply these rules in flexible ways. Honeybees are able to form concepts, and to group and recall stimuli associatively. While the processes of learning and perception are undoubtedly more sophisticated in primates and mammals than in insects, there seems to be a continuum in these capacities across the animal kingdom rather than a sharp distinction between vertebrates and invertebrates. The abilities of an animal seem to be governed largely by what it needs in order to pursue its lifestyle, rather than whether or not it possesses a backbone.

The brain of the honeybee is tiny and carries about a millionfold fewer neurons than the human brain. However, like the brains of humans and higher mammals, the honeybee brain is highly compartmentalized and has evolved into an organ with specialized morphological and functional structures.

In recent years, much attention has been devoted to unraveling the functioning of the visual and olfactory pathways of the honeybee's brain. About half of the neurons in the brain belong to the optical lobes. Visual information is acquired by a pair of compound eyes that take up a substantial part of the head. The visual pathway comprises four distinct neuropils: the retina, lamina, medulla, and lobula. Like humans, honeybees possess trichromatic color vision, spatial vision, and motion-sensitive vision. Their trichromatic visual system features ultraviolet, blue, and green photoreceptors that are well suited to flower discrimination

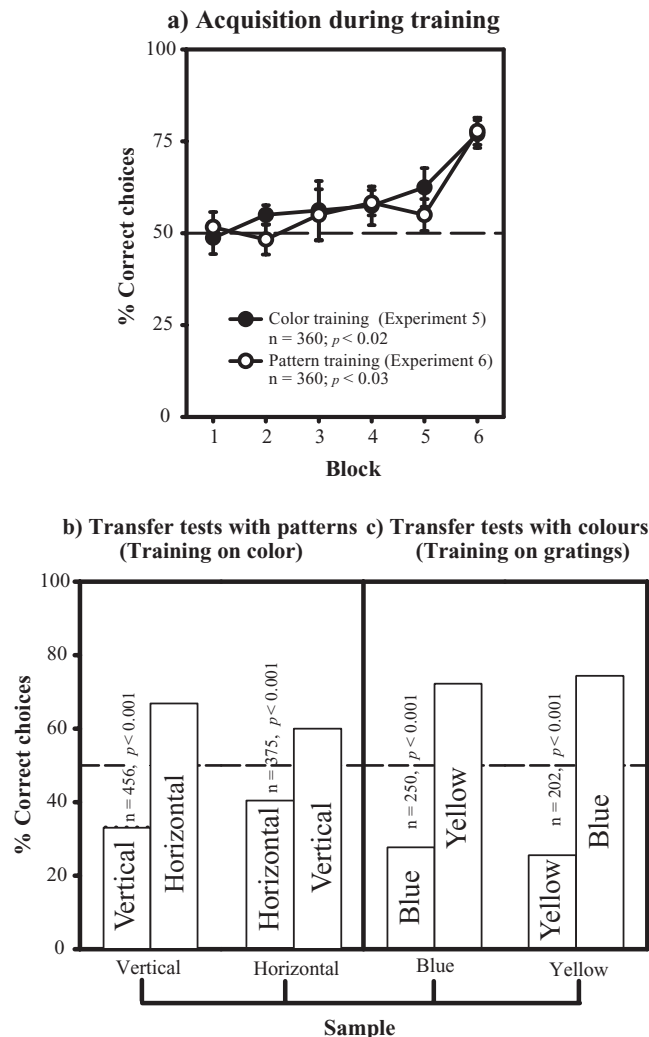

FIGURE 100.11. Learning the concept of *difference*. a, Learning curves for bees trained on colors (filled circles) and on gratings (open circles). b, c, Results of transfer tests. Details are given in the text. (Modified from Giurfa et al., 2001.)

(Vorobyev and Menzel, 1999). Shape perception in honeybees has evolved to respond innately to certain features of natural flowers, resulting in a spontaneous preference for flower-like patterns, such as radiating as well as symmetrical patterns (Lehrer et al., 1995). Bees also appear to have acquired the ability to extract a variety of abstract features, such as the orientation of edges or lines. There is evidence for the existence of orientation-analyzing mechanisms in the insect visual system that might be comparable functionally to those known to exist in the mammalian cortex (Srinivasan et al., 1993, 1994).

The antennal lobes receive their principal sensory input from olfactory receptors on the antennae (Hertel and Maronde, 1987; Winston, 1991). The *mushroom bodies* in the protocerebrum are believed to be the structures of the insect brain that are most closely associated with higher-order sensory integration, associative learning, and spatial memory (Mizunami et al., 1998; Withers et al., 1993). Thus, the mushroom bodies in insects may play a role similar to that played by the hippocampus in rats, birds, and higher mammals (Sherry and Healy, 1998).

The central nervous system of the honeybee is thus a promising system in which to explore the mechanisms that underlie the rich behavioral repertoire that can emerge from a relatively simple nervous system at a variety of levels: molecular, cellular, anatomical, electrophysiological, and computational.

A Neural Basis for Human Visual Attention

SABINE KASTNER

IN EVERYDAY LIFE, the scenes we view are typically cluttered with many different objects. However, the capacity of the visual system to process information about multiple objects at any given moment in time is limited (e.g., Broadbent, 1958). Hence, attentional mechanisms are needed to select relevant information and to filter out irrelevant information from cluttered visual scenes. Selective attention is a highly flexible cognitive operation. Clearly, this capacity enables us to integrate easily information from many different sensory modalities and use it to guide behavior and motivation. Recent advances in functional brain mapping techniques have made it possible to study the neural basis of selective attention in the human brain. In this chapter, I will focus on mechanisms of selective attention that operate in the visual system—the best-understood sensory system of the mammalian brain.

Attention is a broad term that subsumes a variety of mechanisms mediating the selection of behaviorally relevant information. Attention can be drawn automatically to certain objects in cluttered scenes by means of *exogenous* or stimulus-driven mechanisms. For example, if you look at the display depicted in Figure 101.1A, the vertical line will be easily and effortlessly detected among the other lines because of its salience. In this case, the salience of the line stimulus is defined by the difference in orientation relative to the surrounding lines. Stimulus salience depends on various factors, including simple stimulus attributes or features, such as line orientation or color of the stimulus (e.g., Treisman and Gelade, 1980), perceptual grouping of stimulus features by Gestalt principles (e.g., Duncan, 1984; Lavie and Driver, 1996), and the dissimilarity between the stimulus and nearby distracter stimuli (e.g., Nothdurft, 1993). Another way to draw attention exogenously to a particular location of a visual scene is by providing a spatial cue, such as the dashed circle depicted in Figure 101.1B. Even though the vertical line does not stand out among the other lines in this display, it will be detected much faster if one is cued to the spatial location where it will be shown (Posner, 1980). In the display depicted in Figure 101.1C, none of the stimuli is particularly salient, and one must actively search through the display to identify the vertical line (e.g., Treisman and Gelade, 1980).

Hence, attention is directed voluntarily or *endogeneously* to the different items in the display until the vertical target line is found.

Selective attention to a spatial location has been shown to improve the accuracy and speed of subjects' responses to target stimuli that occur in that location (e.g., Posner, 1980). Attention also increases the perceptual sensitivity for the discrimination of target stimuli (Lu and Doshier, 1998), reduces the interference caused by distracters (Shiu and Pashler, 1995), and improves acuity (Carrasco and Yeshurun, 1998). In this chapter, I will describe mechanisms of selective attention that operate in the human visual cortex and may account for many of the known behavioral effects of attention. In particular, the emphasis will be on results of functional brain imaging studies in humans as they relate to results of single-cell recording studies in monkeys. Functional brain imaging measures hemodynamic changes, blood flow in the case of positron emission tomography, and blood oxygenation in the case of functional magnetic resonance imaging (fMRI), and these can be used as indirect measures of neural activity. In the following sections, I will first describe attention-related modulation of neural activity in visual cortical areas. Second, I will describe the evidence that source areas outside visual cortex generate attentional top-down signals that are transmitted via feedback projections to visual cortex and account for attentional response modulation.

Attentional response modulation in visual cortex

Convergent evidence from single-cell recording studies in monkeys and functional brain imaging and event-related potential (ERP) studies in humans indicates that selective attention can modulate neural processing in visual cortex. Attention may affect visual processing in several ways, such as facilitating neural processing by enhancing neural responses to attended stimuli, filtering of unwanted information by counteracting suppressive interactions induced by nearby stimuli, or biasing neural signals in favor of an attended location or stimulus attribute by increasing the baseline activity in the absence of visual input.

FIGURE 101.1. Cluttered visual scenes. Typical visual scenes contain many different objects, as outlined schematically here. The information from these multiple stimuli cannot be processed at the same time due to the limited processing capacity of the visual system. *A*, Salient objects may capture attention exogenously, that is, through bottom-up stimulus-driven mechanisms. In a condition in which no stimulus is particularly salient, the scene can be actively searched by directing attention voluntarily to the different items (*C*). This search may be facilitated if attention is directed to the spatial location at which a target stimulus (e.g., the *vertical line*) will appear by means of a cue (depicted by the *dashed circle* in *B*).

ATTENTION FACILITATES VISUAL PROCESSING AT ATTENDED LOCATIONS Functional brain mapping studies in the human visual cortex suggest that attentional mechanisms operate by enhancing neural responses to stimuli at attended locations, thereby facilitating information processing in favor of stimuli appearing at that location. In a typical functional brain imaging experiment, identical visual stimuli were presented simultaneously to corresponding peripheral field locations to the right and left of fixation while subjects were asked to direct attention covertly, that is, without executing eye movements to the right or the left. Directing attention to the left hemifield led to increased stimulus-evoked activity in extrastriate visual areas of the right hemisphere, whereas directed attention to the right hemifield led to increased activity in extrastriate visual areas of the left hemisphere (Heinze et al., 1994; Vandenberghe et al., 1997). Thus, responses to the stimuli were enhanced in the regions of extrastriate cortex containing the representations of the attended hemifield. In ERP studies that used a similar experimental design, it was shown that response enhancement in extrastriate cortex due to spatially directed attention may occur as early as 80 to 130 msec after stimulus onset (Heinze et al., 1994; Hillyard et al., 1998).

These results are in accordance with single-cell recording studies, which have shown that neural responses to a single stimulus presented within a neuron's receptive field (RF) are enhanced when the animal directs its attention to the RF compared to when the animal attends elsewhere. This effect, which increases with task difficulty (Spitzer and Richmond, 1991), has been demonstrated at many levels of visual processing, including areas V1 (Motter, 1993), V2 (Luck et al., 1997; Motter, 1993), V4 (Connor et al., 1997; Luck et al., 1997; McAdams and Maunsell, 1999; Moran and Desimone, 1985; Motter, 1993; Reynolds et al., 1999),

MT/MST (Recanzone and Wurtz, 2000; Treue and Maunsell, 1996), and LIP (Bushnell et al., 1981; Colby et al., 1996; Gottlieb et al., 1998). Not surprisingly, in human cortex, spatial attention effects have been found at similar levels of visual processing. Furthermore, it has been demonstrated that these attention effects are retinotopically organized, that is, response enhancement is seen only in the regions containing the sensory representation of an attended stimulus within a visual area (Brefczynski and DeYoe, 1999; Tootell et al., 1998). At the same time, the activity of neurons that represent unattended locations of the visual field appears to be attenuated. The exact nature of this response attenuation is not known.

Importantly, there is increasing evidence from single-cell physiology and functional brain imaging studies that neural responses can be modulated by attention as early as in V1 (Ito and Gilbert, 1999; Martinez et al., 1999; Motter, 1993; Roelfsema et al., 1998). Attentional response modulation in V1 appears to be more variable than in extrastriate cortex and may depend critically on a number of factors including task difficulty, competition from surrounding objects, and the need to integrate context. Attentional effects are typically smaller in early areas such as V1 and V2 compared to more anterior extrastriate areas such as V4 and TEO, indicating that attentional response enhancement increases from early to later stages of visual processing (e.g., Kastner et al., 1998). This finding suggests that attentional effects in early visual areas may be caused by reactivation from higher-order extrastriate areas. Single-cell recording studies support this idea by showing that attentional effects in area TE of inferior temporal cortex have a latency of about 150 msec (Chelazzi et al., 1998), whereas attentional effects in V1 have a longer latency of about 230 msec (Roelfsema et al., 1998). However, these latency differences may as well be attributed to local computations within areas.

In summary, spatial attention effects operate by enhancing neural responses evoked by visual stimuli at an attended location and have been demonstrated at all stages of visual processing, including primary visual cortex.

ATTENTION FACILITATES VISUAL PROCESSING OF ATTENDED STIMULUS ATTRIBUTES OR OBJECTS Attention modulates neural responses not only to visual stimuli at attended locations, but also to attended stimulus attributes. This has been shown in experiments that compared neural activity evoked within different visual cortical areas while subjects performed a task requiring selective attention to particular features of identical visual stimuli. In one such study, Corbetta et al. (1991) found that selective attention to either shape, color, or speed enhanced activity in the regions of extrastriate visual cortex that selectively process these same attributes. Attention to shape and color led to response enhancement in regions of the posterior portion of the

fusiform gyrus, including area V4. Attention to speed led to response enhancement in areas MT/MST. Other investigations have shown that attention to faces or houses led to response enhancement in the fusiform face area (FFA) or the parahippocampal place area (PPA), respectively (Wojciulik et al., 1998). These areas are located on the midanterior portion of the fusiform gyrus and are specialized for the processing of faces, houses, and other objects. Taken together, these results support the idea that selective attention to a particular stimulus attribute modulates neural activity in those extrastriate areas that preferentially process the selected attribute.

In typical visual scenes, many different stimulus attributes are combined in a particular object. How is the object as a whole processed if only one of its many attributes is attentionally selected? O'Craven and colleagues (1999) investigated this important question by presenting their subjects with a moving face superimposed on a house stimulus or with a moving house superimposed on a face stimulus. Subjects were instructed to attend selectively either to the face, the house, or the direction of motion. The activity evoked by these complex stimuli was investigated in the FFA, the PPA, and MT/MST, that is, in those areas that are specialized for the three different attributes contained in the stimuli. When the subjects attended to the direction of motion, the activity in the FFA was larger with moving face stimuli than with moving house stimuli. A complementary result was obtained in the PPA with moving house stimuli. These studies suggest that objects as a whole rather than single attributes of objects are the units of attentional selection, even when only one single attribute is behaviorally relevant.

ATTENTION HELPS TO FILTER OUT UNWANTED INFORMATION
Thus far, selective attention has been shown to operate by enhancing neural responses to a stimulus at an attended location or to an attended stimulus attribute. However, a typical visual scene contains multiple stimuli. Recent single-cell recording studies suggest that multiple stimuli in cluttered visual scenes compete for processing resources and that selective attention biases competitive interactions. In these studies, responses to a single visual stimulus presented alone in a neuron's RF were compared with the responses to the same stimulus when a second one was presented simultaneously within the same RF (Moran and Desimone, 1985; Recanzone et al., 2000; Reynolds et al., 1999). The responses to the paired stimuli were shown to be a weighted average of the responses to the individual stimuli when presented alone. For example, if a single good stimulus elicited a high firing rate and a single poor stimulus elicited a low firing rate, the response to the paired stimuli was reduced compared to that elicited by the single good stimulus. This result indicates that two stimuli present at the same time within a neuron's

RF are not processed independently, but rather interact with each other in a mutually suppressive way. This sensory suppressive interaction among multiple stimuli has been interpreted as an expression of competition for neural representation.

Single-cell recording studies have also shown that sensory suppressive interactions can be modulated by directed attention. In particular, in extrastriate areas V2 and V4, spatially directed attention to an effective stimulus within a neuron's RF eliminated the suppressive influence of a second stimulus presented within the same RF (Reynolds et al., 1999). Attentional effects were less pronounced when the second stimulus was presented outside the RF, suggesting that competition for processing resources within visual cortical areas takes place most strongly at the level of the RF. These findings imply that attention may resolve the competition among multiple stimuli by counteracting the suppressive influences of nearby stimuli, thereby enhancing information processing at the attended location. This may be an important mechanism by which attention filters out unwanted information from cluttered visual scenes (Desimone and Duncan, 1995).

Sensory suppression among multiple stimuli and its modulation by spatial attention has also been examined in the human cortex using fMRI (Kastner et al., 1998). In these studies, subjects were presented with images of colorful, complex stimuli in four nearby locations of the upper right quadrant of the visual field while they maintained fixation. Fixation was ensured by having subjects count the occurrences of Ts or Ls at fixation, an attentionally demanding task. The stimuli were presented under two different conditions, simultaneous and sequential. In the sequential condition, a single stimulus appeared in one of the four locations, then another appeared in a different location, and so on, until each of the four stimuli had been presented in the different locations. In the simultaneous condition, the same four stimuli appeared in the same four locations, but they were presented at the same time. Thus, integrated over time, the physical stimulation parameters were identical in the two presentation conditions, but sensory suppression among stimuli could take place only in the simultaneous presentation condition. It was therefore predicted that activation in the simultaneous presentation condition would be less than in the sequential presentation condition.

Activation of V1 and ventral stream extrastriate areas V2 to TEO was found under both stimulus presentation conditions compared to interleaved blank periods. Although the fMRI signal was similar in the two presentation conditions in V1 (Fig. 101.2A), the activation was reduced in the simultaneous condition compared to the sequential condition in V2, and this reduction was especially pronounced in V4 (Fig. 101.2A) and TEO, as predicted from the sensory suppression hypothesis. Importantly, the sensory suppression effect

appeared to be scaled to the RF size of neurons within visual cortical areas. That is, the small RFs of neurons in V1 and V2 would encompass only a small portion of the visual display, whereas the larger RFs of neurons in V4 and TEO would encompass all four stimuli. Therefore, suppressive interactions among the stimuli within RFs could take place most effectively in these more anterior visual areas.

The effects of spatially directed attention on multiple competing visual stimuli were studied in a variation of the paradigm used to examine sensory suppressive interactions among simultaneously presented stimuli, described above. In addition to the two different visual presentation conditions, sequential and simultaneous, two different attentional conditions were tested, unattended and attended. During the unattended condition, attention was directed away from the visual display by having subjects count Ts or Ls at fixation, exactly as in the original study. In the attended condition, subjects were instructed to attend covertly to the stimulus location closest to fixation in the display and to count the occurrences of one of the four stimuli, which was indicated before the scan started. Based on the results of monkey physiology studies, it was predicted that attention should reduce sensory suppression among stimuli. Thus, responses evoked

by the competing, simultaneously presented stimuli should be enhanced more strongly than responses evoked by the noncompeting sequentially presented stimuli (Luck et al., 1997; Moran and Desimone, 1985; Recanzone et al., 2000; Reynolds et al., 1999).

As illustrated in Figure 101.2*B* for area V4, directed attention to the display enhanced responses to both the sequentially and the simultaneously presented stimuli (gray-shaded blocks). This finding confirmed the effects of attentional response enhancement shown in numerous earlier studies in monkeys and humans, as cited previously. More importantly, and in accordance with the prediction from monkey physiology studies, directed attention led to greater increases in fMRI signals to simultaneously presented stimuli than to sequentially presented stimuli. Thus, attention partially canceled out the suppressive interactions among competing stimuli. The magnitude of the attentional effect scaled with the magnitude of the suppressive interactions among stimuli, with the strongest reduction of suppression occurring in areas V4 and TEO. These findings support the idea that directed attention enhances information processing of stimuli at the attended location by counteracting suppression induced by nearby stimuli, which compete for limited processing resources. In essence, unwanted distracting information is effectively filtered out. The degree to which distracting information can be eliminated depends on the load of the target task. For example, Rees et al. (1997) demonstrated that activation in area MT evoked by distracting moving stimuli was totally abolished when subjects performed a high-load linguistic task at fixation compared to a low-load version of the task. Thus, the greater the attentional resources devoted to the target, the less the processing of irrelevant distracting stimuli.

In summary, areas at intermediate levels of visual processing such as V4 and TEO appear to be important sites for the filtering of unwanted information by counteracting competitive interactions among stimuli at the level of the RF. This notion has recently been supported by studies in a patient with an isolated V4 lesion and in monkeys with lesions of areas V4 and TEO (De Weerd et al., 1999; Gallant et al., 2000). Subjects were asked to discriminate the orientation of a grating stimulus in the absence and in the presence of surrounding distracter stimuli. Significant performance deficits were observed in the distracter-present but not in the distracter-absent condition, suggesting a deficit in the efficacy of the filtering of distracter information.

ATTENTION AFFECTS NEURAL ACTIVITY EVEN IN THE ABSENCE OF VISUAL INPUT There is evidence that attentional top-down signals can be obtained not only by the modulation of visually driven activity, but also in the absence of any visual stimulation whatsoever. Single-cell recording studies have

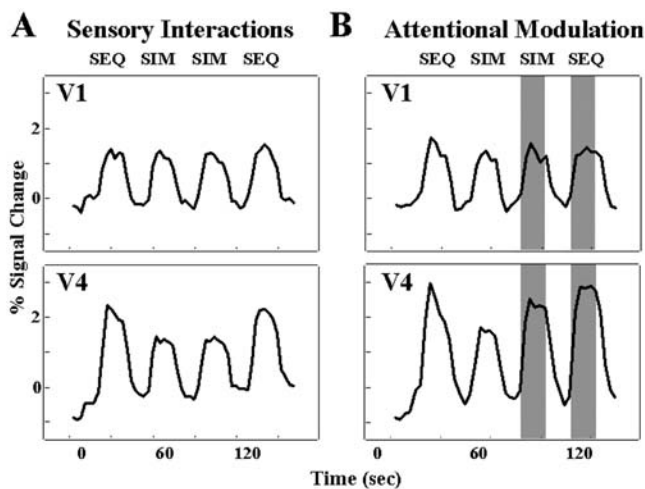

FIGURE 101.2. Sensory suppression and attentional modulation in human visual cortex. *A*, Sensory suppression in V1 and V4. As shown by the time series of fMRI signals, simultaneously presented stimuli (SIM) evoked less activity than sequentially presented stimuli (SEQ) in V4 but not in V1. This finding suggests that sensory suppressive interactions were scaled to the receptive field size of neurons in visual cortex. Presentation blocks were 18 seconds. *B*, Attentional modulation of sensory suppression. The sensory suppression effect in V4 was replicated in the unattended condition of this experiment when the subjects' attention was directed away from the stimulus display (unshaded time series). Spatially directed attention (gray-shaded time series) increased responses to simultaneously presented stimuli to a larger degree than to sequentially presented ones in V4. Presentation blocks were 15 seconds. (Adapted from Kastner et al., 1998).

shown that spontaneous (baseline) firing rates were 30% to 40% higher for neurons in areas V2 and V4 when the animal was cued to attend covertly to a location within the neuron's RF before the stimulus was presented there, that is, in the absence of visual stimulation (Luck et al., 1997). A similar effect was demonstrated in dorsal stream area LIP (Colby et al., 1996). This increased baseline activity, termed the *baseline shift*, has been interpreted as a direct demonstration of top-down feedback, biasing neurons representing the attended location and thereby favoring stimuli that will appear there at the expense of those appearing at unattended locations.

Attention-related top-down signals in the human visual cortex in the absence of visual stimulation were studied by adding a third experimental condition to the design used to investigate sensory suppressive interactions and their modulation by attention, as described above (Kastner et al., 1999). In addition to the two visual presentation conditions, sequential and simultaneous, and the two attentional conditions, unattended and attended, an expectation period preceding the attended presentations was introduced. The expectation period, during which subjects were required to direct attention covertly to the target location and instructed to expect the occurrences of the stimulus presentations, was initiated by a marker presented briefly next to the fixation point 11 seconds before the onset of the stimuli. In this way,

FIGURE 101.3. Increases of baseline activity in the absence of visual stimulation. *A*, Time series of fMRI signals in V4. Directing attention to a peripheral target location in the absence of visual stimulation led to an increase of baseline activity (EXP; textured blocks), which was followed by a further increase after the onset of the stimuli (ATT; gray-shaded blocks). Baseline increases were found in both striate and extrastriate visual cortex. *B*, Time series of fMRI signals in FEF. Directing attention to the peripheral target location in the absence of visual stimulation led to a stronger increase in baseline activity than in visual cortex; the further increase of activity after the onset of the stimuli was not significant. Sustained activity was seen in a distributed network of areas outside the visual cortex, including SPL, FEF, and SEF, suggesting that these areas may provide the source for the attentional top-down signals seen in visual cortex. (Adapted from Kastner et al., 1999).

the effects of attention in the presence and absence of visual stimulation could be studied.

It was found that during the expectation period preceding the attended presentations, regions within visual areas with a representation of the attended location were activated. This activity was related to directing attention to the target location in the absence of visual stimulation. Notably, the increase in activity during expectation was topographically specific, inasmuch as it was only seen in areas with a spatial representation of the attended location. As illustrated for area V4 in Figure 101.3A, the fMRI signals increased during the expectation period (EXP; textured epochs in the figure), before any stimuli were present on the screen. This increase of baseline activity was followed by a further increase of activity evoked by the onset of the stimulus presentations (ATT; gray-shaded epochs in the figure). The baseline increase was found in all visual areas with a representation of the attended location. It was strongest in V4 but was also seen in early visual areas. It is noteworthy that baseline increases were found in V1, even though no significant attentional modulation of visually evoked activity was seen in this area. This dissociation suggests that different mechanisms underlie the effects of attention on visually evoked activity and on baseline activity. Importantly, the increase in baseline activity in V1 has also been found to depend on the expected task difficulty. Ress and colleagues (2000) showed that increases in baseline activity were stronger when subjects expected a visual pattern that was difficult to discriminate compared to a pattern that was easy to discriminate. In areas that preferentially process a particular stimulus feature (e.g., color or motion), increases in baseline activity were shown to be stronger during the expectation of a preferred compared to a nonpreferred stimulus feature (Chawla et al., 1999).

The baseline increases found in human visual cortex may be subserved by increases in the spontaneous firing rate similar to those found in single-cell recording studies (Colby et al., 1996; Luck et al., 1997) but summed over large populations of neurons. The increases evoked by directing attention to a target location in anticipation of a behaviorally relevant stimulus at that attended location are thus likely to reflect a top-down feedback bias in favor of the attended location in human visual cortex.

Mechanisms of attentional control

Thus far, I have demonstrated that selective attention can modulate neural activity in visual cortex in the presence and in the absence of visual stimuli. There is evidence that attentional top-down signals derive from areas outside visual cortex and are transmitted via feedback projections to visual cortex. Studies in patients suffering from attentional deficits due to brain damage and functional brain imaging studies

in healthy subjects performing attention tasks have given insights into a distributed network of higher-order areas in frontal and parietal cortex. This network appears to be involved in attentional control.

VISUOSPATIAL NEGLECT: A DEFICIT OF SPATIAL ATTENTION

There is a long history demonstrating that unilateral brain lesions in humans often cause an impairment in spatially directing attention to the contralateral hemifield, a syndrome known as *visuospatial neglect*. In severe cases, patients suffering from neglect will completely disregard the visual hemifield contralateral to the side of the lesion (e.g., Rafal, 1994). For example, they will read from only one side of a book, apply makeup to only one half of their face, or eat from only one side of a plate. In less severe cases, the deficit is more subtle and becomes apparent only if the patient is confronted with competing stimuli, as in the case of visual extinction. In visual extinction, patients are able to orient attention to a single visual object presented to their impaired visual hemifield, but if two stimuli are presented simultaneously, one in the impaired and the other in the intact hemifield, the patients will only detect the one presented to the intact side, denying that any other object had been presented. These findings suggest that visual extinction reflects an attentional bias toward the intact hemifield in the presence of competing objects.

Visuospatial neglect may follow unilateral lesioning at very different sites, including the parietal lobe, especially its inferior part and the temporoparietal junction (Vallar and Perani, 1986), regions of the frontal lobe (Heilman and Valenstein, 1972), the anterior cingulate cortex (Janer and Pardo, 1991), the basal ganglia (Damasio et al., 1980), and the thalamus, in particular the pulvinar (Watson and Heilman, 1979). The finding that lesions of many different areas may cause visuospatial neglect has led to the notion that these areas form a distributed network for directed attention (Mesulam, 1999).

The classical view of inferior parietal cortex as the most typical lesion site in visuospatial neglect has recently been challenged by Karnath and colleagues (2001). They showed that the lesion site of patients with right hemispheric posterior lesions who suffered from visuospatial neglect and additional visual field defects was indeed located in the inferior parietal cortex including the region of the temporoparietal junction. However, in patients suffering from pure visuospatial neglect without additional visual field defects, the lesion site was located in the superior temporal gyrus (STG). Hence, the superior temporal cortex rather than the inferior parietal cortex may be the most important site for the control of spatial attention.

Neglect occurs more often with right-sided lesions than with left-sided lesions of the parietal or temporal cortex, suggesting a specialized role for the right hemisphere in directed

attention (Karnath et al., 2001; Vallar and Perani, 1986). Based on this hemispheric asymmetry, it has been proposed that the right hemisphere mediates directed attention to both sides of visual space, whereas the left hemisphere mediates directed attention only to the contralateral, right side of visual space (Mesulam, 1999). According to this view, in the case of a left hemisphere lesion, the intact right hemisphere would take over the attentional function of the damaged left hemisphere, whereas a right hemisphere lesion would result in a left-sided hemispatial neglect because of the bias of the intact left hemisphere for the right hemifield. This right hemispheric dominance of parietal cortex has been demonstrated only in cases of severe neglect; visual extinction appears to result as frequently from left- as from right-sided lesions (Rafal, 1994).

Importantly, stimulus-driven bottom-up mechanisms within visual cortex, such as figure-ground segmentation or perceptual grouping, which determine the salience of a stimulus, are preserved in the neglected hemifield and may influence the patient's behavior. For example, Mattingley et al. (1997) reported a patient with parietal damage whose extinction was less severe when bilateral stimuli were arranged to form an illusory Kanisza square, a percept based on automatic filling-in of illusory boundaries. This result shows that the patient could use the information from his neglected left hemifield to form the percept of a common surface. It therefore appears that following parietal damage, the competition among multiple stimuli can be biased equally well across the entire visual field by bottom-up processes, whereas mechanisms under top-down control, such as directing attention to a particular location, are biased toward the intact hemifield.

A DISTRIBUTED NETWORK FOR SPATIALLY DIRECTED ATTENTION

Results of functional brain imaging studies support the idea that top-down signals related to spatially directed attention may be generated by a distributed network of areas in frontal and parietal cortex. In addition to activations within visual cortex, activations of parietal and frontal cortex were investigated with the experimental design used to study competitive interactions and their modulation by spatial attention, as described above (Kastner et al., 1998). Results for a single subject are shown in Figure 101.4B. In this subject, the frontal eye fields (FEF) were activated bilaterally, together with the supplementary eye field (SEF) and the superior parietal lobule (SPL), when the subject directed attention to the peripheral target location compared to when the subject maintained fixation. Remarkably, none of these areas were activated to a significant degree when subjects were processing visual information in an unattended condition (Fig. 101.4A). A network consisting of areas in the SPL, FEF, and SEF was consistently activated across subjects. A similar network has been found to be activated in a variety

of visuospatial tasks (e.g., Corbetta et al., 1998; Nobre et al., 1997; Vandenberghe et al., 1997). In addition, but less consistently, activations in the inferior parietal lobule (IPL), the lateral prefrontal cortex in the region of the middle frontal gyrus (MFG), and the anterior cingulate cortex have been reported. A common feature among these visuospatial tasks is that subjects were asked to maintain fixation at a central fixation point and to direct attention covertly to peripheral target locations in order to detect a stimulus, to discriminate it, or to track its movement. Thus, there appears to be a general spatial attention network that operates independently of the specific requirements of the visuospatial task (for a meta-analysis and additional references, see Kastner and Ungerleider, 2000). Interestingly, the same areas of parietal cortex have been shown to be activated to a similar extent during different spatial and nonspatial attention tasks including peripheral shifts of attention, object matching, and nonspatial conjunction search (Wojciulik and Kanwisher, 1999). Hence, in parietal cortex, spatially and nonspatially based attentional selections may be mediated by a common neural substrate.

There are two notable differences in the results from patient studies and from functional brain imaging studies. First, the patient studies suggest a right parietal or temporal dominance in visuospatial attention; that is, directing attention to the left hemifield is presumed to be subserved exclusively by the right parietal or temporal cortex, whereas directing attention to the right hemifield is presumed to be subserved by both the left and the right parietal or temporal cortex. This notion has not been supported

unequivocally by functional brain imaging studies. Although some investigators have found a stronger or an even exclusive activation of areas in the right parietal lobe (Nobre et al., 1997; Vandenberghe et al., 1997), others have found largely symmetrical activations in the right and left parietal lobes (Kastner et al., 1999). Moreover, these symmetrical activations appeared to be independent of the visual hemifield attended (Vandenberghe et al., 1997). A second difference between the results from patient studies and from functional brain imaging studies concerns which portion of the parietal lobe plays a key role in attention. The patient literature has consistently identified the IPL, including the temporoparietal junction (Vallar and Perani, 1986), and the STG (Karnath et al., 2001) as critical lesion sites in neglect patients. By contrast, the majority of functional brain imaging studies point to the SPL rather than the IPL or the STG as the part of the parietal lobe that is involved in visuospatial attention. One possible explanation for this discrepancy is that many tasks used in the imaging studies involved a cue to indicate the location at which the visual stimulus would appear; these tasks thus had an expectancy component. Results of lesion studies suggest that the ability to maintain expectancy depends on the SPL rather than the IPL (Friedrich et al., 1998).

Evidence from fMRI studies (e.g., Hopfinger et al., 2000; Kastner et al., 1999) suggests that the attention-related activity in parietal and frontal areas does not reflect attentional modulation of visual responses; instead, the activity is due largely to the attentional operations themselves. Activations in frontal and parietal cortex during directed attention in the

FIGURE 101.4. A frontoparietal network subserving biased competition and spatially directed attention. Axial slice through frontal and parietal cortex; same subject and experimental conditions as in Figure 101.3. *A*, Visual stimulation did not activate frontal or parietal cortex reliably when attention was directed elsewhere in the visual field. *B*, When the subject directed attention to a peripheral target location and performed an object discrimination task, a distributed frontoparietal network was activated including the SEF,

FEF, and SPL. *C*, The same network of frontal and parietal areas was activated when the subject directed attention to the peripheral target location in the expectation of the stimulus onset, that is, in the absence of any visual input whatsoever. This activity therefore may not reflect attentional modulation of visually evoked responses, but rather attentional control operations themselves. L, left hemisphere.

presence and in the absence of visual stimulation were investigated in the paradigm described above (Kastner et al., 1999). During directed attention in the absence of visual stimulation, the same distributed network for spatial attention as during directed attention in the presence of visual stimulation was activated, consisting of the FEF, the SEF, and the SPL (Fig. 101.4C). A time course analysis of the fMRI signals revealed that, as in visual cortical areas, there was an increase in activity in these frontal and parietal areas due to directed attention in the absence of visual input. However, first, this increase in activity was stronger in SPL, FEF, and SEF than the increase in activity seen in visual cortex (as exemplified for FEF in Fig. 101.3B); second, there was no further increase in activity evoked by the attended stimulus presentations in these parietal and frontal areas. Rather, there was sustained activity throughout the expectation period and the attended presentations (Fig. 101.3B). Taken together, these findings suggest that the activity reflected the attentional operations of the task and not visual processing. Hence, the distributed frontoparietal attention network may be the source of feedback that generates the top-down biasing signals seen in visual cortex. Because the magnitude of the activity in the parietal and frontal areas was the same during directed attention in the absence and in the presence of visual stimulation, it appears that this activity may be independent of the particular visual task, be it detection or discrimination. This would explain the finding that functional brain imaging studies using different visuospatial attention tasks have described very similar attentional networks.

The anatomical connections of SPL, FEF, and SEF put them in a position to serve as sources of top-down biasing signals within visual cortex. In the monkey, FEF and SEF are reciprocally connected with ventral stream areas (Webster et al., 1994) and posterior parietal cortex (Cavada and Goldman-Rakic, 1989), and posterior parietal cortex is connected with ventral stream areas via the lateral intraparietal (LIP) area (Webster et al., 1994).

The functional roles of these frontal and parietal areas in attentional selection and control are not well understood. In regions of parietal cortex, it has been shown that neural responses are enhanced during covert shifts of attention to peripheral visual stimuli (Bushnell et al., 1981; Colby et al., 1996). The strongest determinant of neural responsiveness in parietal cortex turned out to be the salience of the stimulus (Gottlieb et al., 1998). Therefore, it may be speculated that parietal cortex provides a *salience map* for exogenous stimuli that will capture attention rapidly. Recent functional brain imaging studies suggest that distinct parietal regions subserve different attentional processes. It was found that regions within the intraparietal sulcus were activated when

subjects voluntarily directed attention to a pre-cued location before the presentation of a visual target stimulus. In contrast, regions of the right temporoparietal junction were activated when target stimuli were detected at unattended locations (Corbetta et al., 2000). In the FEF and SEF, attentional response enhancement was originally shown in the context of activity related to the preparation of saccadic eye movements (e.g., Wurtz and Mohler, 1976), supporting the notion that covert shifts of attention precede overt shifts of gaze. More recent recording studies suggest, however, that the response enhancement in these frontal areas during covert shifts of attention to peripheral visual stimuli does not depend on the subsequent execution of saccades (Kodaka et al., 1997). The intimate functional relationship between covert shifts of attention and eye movements in frontal cortical areas has also been demonstrated in functional brain imaging studies. Areas including the FEF and SEF that were engaged by covert shifts of attention and by executing saccadic eye movements were shown to overlap greatly (e.g., Corbetta et al., 1998). Taken together, these studies have begun to define functional roles for distinct areas within frontal and parietal cortex in attentional control, which need further refinement in future research.

Thus far, results of single-cell recording studies and functional brain imaging studies clearly converge to support the idea that areas in parietal and frontal cortex are potential sources for generating and controlling attentional top-down signals. However, because results of functional brain imaging studies demonstrate only correlated activity of distributed brain areas and cannot establish the functional significance of a particular brain area in a given task, future studies using reversible lesion techniques such as cooling of brain tissue or transcranial magnetic stimulation are needed to test these ideas further.

Conclusion

The view that has been presented in this chapter is summarized in the simple attention model depicted in Figure 101.5. The representation of objects in visual cortex is determined by both bottom-up stimulus-driven factors and cognitive top-down influences such as selective attention. In visual cortex, target or distracter stimuli are not processed independently of each other; rather, they compete for limited processing resources by means of competitive interactions. Selective attention modulates neural activity in visual cortex both in the presence and in the absence of visual stimulation. The attention-related signals are generated from a distributed network of areas in frontal and parietal cortex and are transmitted via feedback projections to visual cortex.

FIGURE 101.5 A model of selective visual attention. The representation of visual stimuli in visual cortex is determined by both bottom-up stimulus-driven factors and top-down cognitive influences such as attention. Visual stimuli are not processed independently of each other but interact competitively for limited processing resources.

102 Neural and Behavioral Measures of Change Detection

DANIEL J. SIMONS AND MICHAEL SILVERMAN

... [O]ur "experience," is almost entirely determined by our habits of attention.

William James (1892), *Psychology* (p. 172)

Our visual world seems coherent and richly detailed. A single glance in any direction produces an abundance of visual sensations, and we readily see the objects and surfaces around us. This rich sensory input is effortlessly associated with a vivid perceptual experience, leading to the impression that all the visual details of our world are readily available to us. This inference is largely true. At any instant, we can direct our attention to any aspect of our environment, and when we do, we become aware of whatever is the focus of our attention. This fact, in conjunction with the stability and continuity of objects and their properties over time and space, can lead to the false impression that the immediacy of our visual experience derives from a rich, detailed *internal* representation. That is, we believe that we store the details of objects around us internally and that these representations underlie our rich visual experience.

Recent evidence from studies of change detection, however, raises the intriguing possibility that we lack such detailed representations. That, in reality, our visual experience derives not from a complete internal representation, but from two assumptions: (1) the world is stable over time, and (2) important events will draw attention and reach awareness. The first assumption reflects a basic principle of efficient design: if details in the world typically do not change and if they are not needed from one instant to the next, they need not be stored internally (Brooks, 1991; Gibson, 1966; O'Regan, 1992; Stroud, 1955). Interestingly, the second assumption, that salient events draw attention, is not always true. People often are unaware of surprisingly large, and potentially important, events in their visual world (Mack and Rock, 1998; Neisser, 1979; Rensink, 2000b; Rensink et al., 1997; Simons, 2000b; Simons and Chabris, 1999; Simons and Levin, 1997, 1998). The fact that an object or event is salient does not guarantee its detection; even fully visible and unusual objects and events sometimes go unnoticed when attention is allocated elsewhere (Mack and Rock, 1998; Simons and Chabris, 1999). For example, experienced pilots who were asked to use a head-up display

when landing a jet in a flight simulator sometimes proceeded with their landing without ever noticing that another aircraft was blocking their runway (Haines, 1991). Similarly, when observers are focusing their attention on a simple computer task, they often fail to notice unexpected objects appearing in the display, even when the objects appear at the point of fixation (Mack and Rock, 1998). Such effects of selective looking, or "looking without seeing," have been noted for many years (e.g., Becklen and Cervone, 1983; Most et al., 2000, 2001; Neisser, 1979; Neisser and Becklen, 1975; Simons, 2000a; Simons and Chabris, 1999), and recent work has drawn closer links between this phenomenon and other failures of visual awareness.

If, as the chapter-opening quote from James suggests, awareness is limited to those items that are the focus of attention, then our experience of consciously perceiving all available details must be illusory. We cannot attend to all of the details of our environment, even if they are available to our visual system. If we are unaware of those things that are unattended, we cannot notice their absence from awareness. Consequently, our visual experience is richly detailed because we only notice the ways in which it is detailed, and we do not notice the ways in which it is sparse. This limited capacity of attention, which produces limits on conscious awareness, is revealed in our daily experiences. For example, many people will recognize the experience of looking repeatedly for car keys on a cluttered counter and simply not finding them, only to discover later that they were fully visible the entire time. The potential to see the keys is always present, but without attention, we do not become aware of their presence.

This explanation for visual experience raises two critical questions. First, what information, if any, is stored internally when observers fail to detect clearly visible objects such as the misplaced keys? Second, what mechanisms eventually lead to the conscious perception of these items? Change detection tasks provide a useful tool for the systematic exploration of both of these questions. Because successful detection requires both representations and comparisons (Simons, 2000b), when observers detect a change we can infer that they successfully represented the prechange information and

compared it (consciously or otherwise) to the postchange information. In the case of change detection failures, or *change blindness*, we can use additional measures to determine whether the failure resulted from a poor representation of the scene or from an insufficient comparison of the changed features. In other words, we can determine what, precisely, was represented from the initial display before the change was identified and how that representation differed from the internal representation when the change was eventually detected.

Failures of visual awareness such as change blindness result when visual events violate our expectations for what should happen or what typically happens—when they contravene our regular “habits of attention.” Such failures reveal the tenuous hold our visual representations have on our conscious experience of our environment. In this chapter, we discuss the relationship between attention, internal representations, and visual awareness by focusing on the phenomenon of change blindness—the inability to detect large changes to scenes when detection depends on comparing internal representations over time. Our discussion evaluates the information needed to detect changes successfully and considers the inferences that can be drawn from change blindness. We review recent evidence from behavioral, eye tracking, and neuroimaging studies of change detection, and we speculate about how further research in these areas might elucidate the mechanisms of change detection.

A brief history of evidence for change blindness

The literature on change blindness has a long history, dating back at least to the late 1970s (see Simons and Levin, 1997, for a review). Systematic work on change blindness largely began with studies of eye movements during reading (Blanchard et al., 1989; McConkie and Zola, 1979; Morris et al., 1990; Pollatsek and Rayner, 1992) and studies of displacement detection across saccades (Bridgeman et al., 1975; Li and Matin, 1990; Mack, 1970; Wallach and Lewis, 1965). Only more recently has the focus of change blindness research turned to the perception and representation of natural scenes. Early work on displacement detection focused primarily on the issue of whether or not the perception of the visual world is suppressed during eye movements and also whether information from consecutive fixations can be integrated into a single representation. In a typical experiment, observers might view a dot presented parafoveally and then, during a saccade to the location of the dot, the dot would be shifted in position. Typically, shifts of less than 10% of the extent of the eye movement are not noticed by the observer. Displacement detection is quite poor when saccades are long and the displacements are relatively short.

Unlike studies of displacement detection, change detection studies during reading have focused more on the identity than on the position of the changed item. When reading, changes that occur during saccades are rarely noticed. Observers continue reading at the same rate without noticing substantial changes to the appearance or even the presence of words that are not currently fixated. For example, if observers are asked to read text in AlTeRnAtInG cAsE, they do not notice when the case of each letter on the screen changes during every saccade (McConkie and Zola, 1979). In contrast, observers viewing the same displays with changes unconstrained by their fixation patterns cannot easily read the text because the now-visible changes produce massive transient signals throughout the display; it is difficult to read text that we see changing. The presence of a saccade during the change appears to prevent the automatic detection of changes by inhibiting or masking the transient signal that would otherwise be distracting. In order to detect case changes that occur during a saccade, observers must actively attend to the letter, memorize it, and then compare that letter before and after a saccade.

More recent studies of saccade-contingent change blindness have produced parallel results using natural scenes rather than text (Grimes, 1996; Hollingworth and Schrock, 2001; Hollingworth et al., 2001a; McConkie and Currie, 1996). For example, when studying a photograph for a subsequent memory test, observers often failed to notice when two central people in the scene swapped hats during a saccade (Grimes, 1996). Many even failed to notice when two people exchanged heads! Blindness for these scene changes disappeared entirely when the changes occurred during fixation, suggesting that something about the representation or comparison process was disrupted by the saccade.

In addition to studies of saccade-contingent change detection, a number of early experiments used change detection tasks to explore the limits of short-term visual memory (e.g., Pashler, 1988; Phillips, 1974). These experiments briefly presented an array of letters, dots, or other simple stimuli, followed by a brief delay interval and then by a slightly changed array. Unlike most of the saccade-contingent change studies, the observer’s primary goal in these studies was to try to detect changes. Consequently, change blindness cannot be attributed to the unexpected nature of the change. Instead, failed change detection was attributed to the limits of short-term visual memory. Observers were unable to hold all of the information in the array in memory during the brief delay interval.

In a seminal study in the change blindness literature, Rensink et al. (1997) adapted these one-shot change detection tasks to explore prolonged search for change. They confirmed that change blindness is not specific to changes made across saccades; it can occur during fixation and even occurs

when observers actively search for changes. These failures of visual awareness result whenever the transient signal that would otherwise accompany a change is disrupted. In their visual search *flicker* task, observers view a rapid alternation of an original and a changed scene, with a brief blank screen following each image presentation. The blank screen, like a saccade, disrupts the localized transient signal that would otherwise be produced by the change, giving the display its flickering appearance. Even though they are actively searching, observers often require many alternations to detect large changes, sometimes searching unsuccessfully for up to a minute. Notably, the level of change blindness does not appear to diminish even when subjects have extra time to study the images or when they have practiced performing the task (Rensink, 2000c; Rensink et al., 1997). Perhaps more importantly, the nature of the change influences the speed of detection: changes to objects of central interest in the scene are detected more rapidly than changes to irrelevant or peripheral objects (Rensink et al., 1997). This *center of interest* effect reflects the importance of attention in change detection. Changes to objects in a scene that are more likely to be the focus of attention are detected more rapidly than those less likely to be attended. This finding suggests that attention plays a functional role in the eventual detection of changes and that change blindness occurs when observers fail to devote focused attention to the changing item both before and after the change.

However, other work suggests that attention to an object does not guarantee detection, particularly when changes occur unexpectedly (Levin and Simons, 1997; Levin et al., 2002; Simons and Levin, 1998; Simons et al., 2002). For example, nearly two-thirds of observers failed to report any change when the only actor in a motion picture unexpectedly was replaced by a different person across a cut from one camera angle to another (Levin and Simons, 1997). In fact, from 35% to 65% of observers typically fail to notice when a real-world conversation partner is surreptitiously replaced during the middle of an interaction (Levin et al., 2002; Simons and Levin, 1998). These studies suggest that attention to an object is necessary for change detection, but it is not sufficient to guarantee detection. Rather, successful detection requires attention to the specific features of the object that are changing so that observers can encode those features and then compare them following the change.

Given that successful change detection implies the existence of a representation, evidence for change blindness has sometimes been taken to imply the absence of any internal representation of the prechange feature—that our representation of the visual world is more sparse than we might otherwise believe (e.g., O'Regan and Noe, 2001; Rensink, 2000a; Simons and Levin, 1997). Although this conclusion might well be true, it does not follow logically from existing

evidence for change blindness. The absence of detection does not necessarily imply the absence of a representation. Change detection could fail even in the presence of a complete and detailed representation of the prechange scene, provided that observers do not compare that initial representation to the postchange scene (Scott-Brown et al., 2000; Simons, 2000b).

AN ASIDE: WHAT MAKES CHANGE BLINDNESS INTERESTING

Findings of change blindness are interesting not because they imply the absence of a representation, but because they run counter to our intuitive belief that unusual or unexpected events will draw our attention. These intuitions reflect an understanding that small, irrelevant changes will not capture attention. For example, nobody would be particularly surprised by the failure to notice a subthreshold change to the color of a single pixel in a photograph of a natural scene. However, people are surprised when the changes are large and supraliminal. To some degree, these intuitions are entirely reasonable based on our daily experiences. After all, most sudden changes in the world do produce a visible change signal and rarely occur quickly enough to start and finish during a saccade. Moreover, we do occasionally notice changes. For example, it is not uncommon to detect an occasional editing error in a motion picture. These examples of successful change detection are readily available, whereas, by definition, we do not become aware of those changes that we fail to notice. Given the tendency to judge the frequency of events based on the information that is most available in recollection (Tversky and Kahneman, 1982), estimates of successful change detection are likely to be inflated. Because some changes are noticed, we have the impression that all changes draw our attention, leading to awareness. Evidence for change blindness shows that this impression is false. Unexpected changes do not necessarily draw our attention.

This mistaken intuition can be demonstrated empirically (Levin et al., 2000). In one change detection study (Levin and Simons, 1997), observers viewed a brief motion picture of a lunch conversation in which an intentional change was made every time the camera cut instantaneously to a different angle. For example, a scarf worn by one of the actors disappeared and then reappeared from one shot to the next, plates changed from red to white and then back to red, and objects on the table switched locations. When unsuspecting observers were asked to view this film carefully, they typically did not report any of the changes (Levin and Simons, 1997). That is, they showed complete change blindness for these unexpected changes. To demonstrate the overestimation of change detection abilities, a different group of observers viewed still frames from the film and predicted how likely they would be to detect the various changes (Levin et al., 2000). These observers predicted far greater change detec-

tion for irrelevant changes than actually occurred: for example, approximately 90% of observers thought that they would notice the scarf change, and more than 75% thought they would notice the plate color change when, in reality, no subjects noticed either of these changes.

This massive overestimation of change detection rates reflects the intuitive assumption that important, unusual, or distinctive events will automatically draw attention. This assumption can have important implications, both for theoretical arguments about change detection and for practical applications of evidence for change blindness. Just as observers believe they will detect changes, product designers believe that the subtle change cues they provide will be sufficient to guide attention. One obvious situation in which change blindness can have dire consequences is driving. Brake lights are typically red, and when they come on, they simply brighten. The assumption that the brightening of brake lights will automatically draw attention even if we are focusing attention on some other aspect of the scene (or on other distracting events in the car such as a phone conversation) can have dire consequences. The change from dim to bright is an instantaneous change, and if the change itself does not attract attention, it sometimes will be missed. A more reasonable strategy for ensuring that motorists notice the onset of brake lights would be to have the change occur repeatedly, thereby increasing the probability that observers will be attending to the lights at some point when the change occurs. If drivers are aware of their own poor change detection abilities and the likelihood that other drivers will have mistaken intuitions about change detection of other drivers, then they can adjust. For example, if another car is following too closely and you need to brake, you can lightly pump the brake pedal to cause the brake light to flash repeatedly, thereby increasing the chances that the driver behind you will notice that you are stopping.

Studies of the mistaken belief in the absence of change blindness, something Levin et al. (2000) dubbed *change blindness blindness*, help reveal the potential consequences of change blindness. They also demonstrate that change blindness findings are surprising: not only are we blind to large changes in our visual world, but we remain largely unaware of this fact. This *meta-cognitive* failure might well have more real world consequences than the phenomenon of change blindness itself.

What is retained when changes are not reported?

Findings of change blindness have often been taken as support for the notion that we lack detailed internal representations of the visual world (O'Regan, 1992; O'Regan and Noe, 2001; Rensink, 2000a; Simons and Levin, 1997). Change blindness would be a natural consequence of sparse internal representations. Without an internal representation

of the prechange features, no comparison to the postchange scene would be possible and change detection would fail. However, as noted earlier, the failure to detect changes does not necessitate sparse representations. Observers might well retain much information about the prechange object even if they fail to report a change. Most studies of change detection rely on explicit reports to determine whether or not a change was detected, and many of these reports occur well after the change. Such measures may well underestimate the degree to which changes are detected. For example, in the person-change video described earlier (Levin and Simons, 1997), change detection was measured by obtaining written descriptions of the video after it ended. Observers might have detected a change but then immediately discounted it as implausible and forgotten it. And even if they did not detect the change, they might still have represented the details of the prechange object.

BEHAVIORAL MEASURES OF PRESERVED REPRESENTATIONS
Some behavioral work suggests the presence of preserved representations despite change blindness. In one study (Silverman, 2001), observers viewed letter matrices similar to those used in the classic partial report procedure (Sperling, 1960). On each trial, two matrices were presented in sequence, separated by a briefly displayed gray field. One, two, or all three of the letters in a randomly chosen row were replaced with different letters, and subjects were asked to report whether or not a change had occurred. They were then asked to identify a row of three letters that were degraded by removing 75% of their pixels. The letters were either novel or they were drawn from a changed row or an unchanged row from the previous arrays. Even when observers did not notice the change, they were better able to identify previously viewed letters than novel letters. Furthermore, they were equally good in identifying changed and unchanged rows from the matrices, suggesting that they had a fairly complete representation of the display. These findings are consistent with other work showing preserved representation of visual stimuli that could not be consciously reported (DeSchepper and Treisman, 1996; Mack and Rock, 1998; Moore and Egeth, 1997; Shapiro et al., 1997).

Additional evidence for preserved representations in the face of change blindness comes from a real-world study in which pedestrians were approached by an experimenter who, while carrying a red-and-white striped basketball, asked for directions to a gymnasium (Simons et al., 2002). During this interaction, a group of confederates walked down the sidewalk, and one of them surreptitiously took the ball away. The experimenter then asked the pedestrian a series of questions: "Did you notice anything unusual happen as the crowd of people passed between us? Did you notice anything change? Do you think anything has changed

about my appearance since the crowd went by?" Most observers responded no "to" all of these questions, indicating that they did not consciously detect the change. However, when the experimenter asked "Do you think that I had a basketball before the crowd went by?" more than 60% of the pedestrians responded "yes," and they typically noted something about the ball's unusual appearance when asked (e.g., that it was striped or unusually colored). This "discovered" memory (Schooler, 2001) suggests that observers had represented the presence of the ball and some of its features, but given that the disappearance of the ball did not change their interpretation of the scene or their immediate goal of giving directions, they did not spontaneously compare the current appearance of the scene to their initial representation. Rather, only when cued specifically about the ball did they make the necessary comparison. This finding suggests that change blindness can occur even when observers have an explicitly available representation of the prechange scene (see also Levin et al., 2002).

Together, these findings suggest that observers do form internal representations of some details of the prechange scene even when they do not explicitly report the presence of a change (see also Hollingworth et al., 2001b for evidence that observers sometimes detect changes many fixations after the change occurred). That observers can represent scenes without being aware of their representations is not surprising. Extensive evidence suggests that many aspects of perception occur without awareness (e.g., Chun and Jiang, 1998; Goodale and Milner, 1992; Kihlstrom et al., 1992; Maljkovic and Nakayama, 1994). Moreover, the fact that such representations are potentially accessible to awareness even when observers did not use the representation to detect a change further supports the idea that change blindness often results from a comparison failure (Scott-Brown et al., 2000; Simons, 2000b).

The finding that initial verbal reports of change detection underestimate the amount of information preserved in the face of change blindness raises the intriguing possibility that changes themselves might be detected without awareness. That is, observers might implicitly represent the prechange scene and then implicitly compare that representation to the changed scene. Therefore, a finding of implicit change detection would imply the existence of a representation of the prechange scene. Recent research on change blindness has explored the nature of our internal representations in the face of change blindness by testing whether more sensitive, on-line measures reveal change detection in the absence of awareness. This research has taken several forms. Some studies have relied on behavioral measures such as forced-choice guessing or measurements of response latency to look at change detection without awareness (Fernandez-Duque and Thornton, 2000; Smilek et al., 2000; Thornton and Fernandez-Duque, 2000; Williams and Simons, 2000).

Others have used measured eye movement patterns or fixation durations in the presence and absence of change detection (Hayhoe et al., 1998; Hollingworth et al., 2001b; Ryan and Cohen, 2002). And, in recent years, several laboratories have used neuroimaging measures such as event-related potentials (ERP) (Fernandez-Duque et al., 2002; Niedeggen et al., 2001) and functional magnetic resonance imaging (fMRI) (Beck et al., 2001; Huettel et al., 2001) to explore change detection with and without awareness. Note, of course, that all change detection, whether implicit or explicit, requires both a representation of the prechange scene and a comparison to the postchange scene. The existence of implicit change detection would require that the comparison process occur without awareness (Mitroff et al., 2002). However, if no such implicit comparison process exists, then change detection in the absence of a transient signal must depend on explicit comparisons (Mitroff et al., 2002). Given the dramatically different implications of these two possibilities for theories of change detection, the existence of implicit change detection has become a central question in the change blindness literature. Each of these approaches to exploring implicit change detection is discussed in detail below.

BEHAVIORAL EVIDENCE FOR AND AGAINST IMPLICIT CHANGE DETECTION Most attempts to measure implicit change detection use explicit reports of the occurrence of a change in order to identify detected and missed changes. Presumably, unreported changes were not explicitly detected. Any other evidence for change detection when the change was consciously missed would suggest the existence of implicit change detection and the corresponding representation of the prechange scene. For example, in one study (Fernandez-Duque and Thornton, 2000), observers were given a two-alternative forced-choice decision about which item had changed, and trials were separated into those for which observers did and did not report having seen the change. When observers had not seen the change, they presumably guessed which of the two alternatives had changed. Interestingly, their "guesses" were correct more than 50% of the time.

One concern with this finding, however, is that the observers' reports of change detection might not exhaustively measure all of the explicit mechanisms that could have contributed to their performance (Holender, 1986; Merikle and Reingold, 1992); some unmeasured explicit factors might contribute to the guessing performance for unreported changes. One such mechanism is the explicit elimination of items known not to have changed (Fernandez-Duque and Thornton, 2000; Mitroff et al., 2002). If observers know that some items have not changed, they would guess correctly more than 50% of the time even if they did not see the change itself. In fact, this sort of

elimination strategy adequately accounts for the original data and even predicts performance on a modified version of this task (Mitroff et al., 2002). Thus, although forced “guessing” might provide a more sensitive measure of change detection than verbal reports, current evidence using this task is also consistent with the need for an explicit comparison mechanism for change detection.

Other claims of implicit change detection come from measures of response speed for missed changes. Observers sometimes take longer to respond “no change” when they miss a change than when there is actually no change (Williams and Simons, 2000). Such findings are consistent with the idea that the change was detected by the visual system and affected the response latency even though it did not reach awareness. However, as with forced-choice guessing, such studies do not exhaustively eliminate other explicit contributions to performance. For example, rated confidence in change present/absent decisions accounts for almost all of the increase in response latency for missed changes (Mitroff et al., 2002). To the extent that rated confidence reflects explicit detection, this finding raises doubts about the need to posit an implicit comparison process to explain differences in response latency.

Any study relying on verbal reports to distinguish between detected and undetected changes risks the possibility that criterion shifts can partially explain any implicit effects. Moreover, studies must carefully exclude any effects of explicit strategies that could influence performance even in the absence of change detection. For example, one recent study found evidence that the orientation of a changed item (horizontal or vertical) could influence orientation judgments about another item in a display, even if observers did not report noticing the change (Thornton and Fernandez-Duque, 2000). Observers were more accurate when the orientation of the changed item matched that of the judged item, and they were less accurate when the two were in conflict. This indirect measure of change detection holds promise because it does not require a response about the changed item. However, in this study, the relative positions of the changed item and the to-be-judged item were tightly linked: they were either the same item or diametrically opposite each other. Observers likely were aware of this contingency, and it could affect their strategy in performing the task. This change in strategy might well produce a congruence effect on orientation judgments even if observers did not detect the change. In fact, when the tight coupling of the positions of the changed and to-be-judged items was broken, the congruence effect was eliminated (Mitroff et al., 2002). This finding illustrates the difficulty of verifying the existence of implicit change detection. Not only must the experiment eliminate all explicit change detection, it must also rule out the contribution of other factors, be they implicit or

explicit, that could artificially inflate performance when changes are not reported.

Another example in which an explicit mechanism could account for findings of “implicit” change detection comes from measures of visual search speed in a flicker task (Smilek et al., 2000). Large changes to letter arrays are found more efficiently than small changes (i.e., they have shallower search slopes). Given that attention might be preattentively guided to the target of the search (Wolfe, 1994), the implicitly detected change might guide attention to the change location. Larger changes might exert a greater implicit influence on attention, leading to more efficient search. Although an implicit change detection mechanism could produce differences in search slopes, this difference is also consistent with evidence that larger changes are easier to detect explicitly with focused attention (Mitroff et al., 2002; Williams and Simons, 2000). In fact, when the possibility of implicit guidance is removed by randomizing the positions of each item in the search array for every alternation of the original and changed arrays, observers still show a search advantage for the larger changes (Mitroff et al., 2002). Under these conditions, implicit change detection could not produce the difference in search slopes because there is no stable information available to accumulate in a given location. The presumed basis for implicit accumulation did not exist in this study, but the results were comparable, thereby rendering the implicit accumulation hypothesis unnecessary.

The absence of compelling behavioral evidence for purely implicit change detection supports the intriguing possibility that changes are only detected via an explicit comparison mechanism. This hypothesis is consistent with theoretical frameworks in which the symbol comparison processes needed for change detection require explicit processing (Dulany, 1997). If true, this hypothesis predicts that change detection should never occur without some explicit awareness of the change. This prediction is readily testable: any evidence for implicit change detection in the absence of any explicit contamination will disprove the claim. This theoretical debate—whether or not comparisons of episodic representations can occur in the absence of awareness—is one that might well be aided by other on-line, indirect measures of change detection such as looking time or neuroimaging.

EYE MOVEMENTS AND IMPLICIT CHANGE DETECTION Over the past few years, several laboratories have explored the relationships between eye movements, fixation patterns, and change detection. As previously noted, much of the early work on change detection involved introducing changes during an eye movement. Other studies which measured fixation while introducing changes found that even when observers directly fixated the changed object, they sometimes failed to detect the change (O’Regan et al., 2000). That

is, fixation on the object does not guarantee detection (see also Levin and Simons, 1997; Simons and Levin, 1998). However, changes to the fixation pattern or to the duration of fixations on the changed object might provide evidence for the detection of unreported changes.

If observers implicitly detect changes, then the presence of a change in a scene might affect fixation patterns, regardless of whether or not observers were aware of the change. For example, they might fixate the changed region earlier or for a longer duration. Several studies provide some preliminary support for this sort of implicit change detection hypothesis (Hayhoe et al., 1998; Hollingworth et al., 2001b; Ryan and Cohen, 2002). For example, Hayhoe and colleagues (1998) measured eye movement patterns while participants attempted to recreate a pattern of colored blocks by selecting blocks from a stockpile and placing them appropriately in a workspace. When performing this task, participants often make a stereotyped sequence of eye movements, initially fixating the pattern, then fixating blocks in the stockpile, then returning to the pattern before finally fixating the appropriate location in the workspace. Saccade-contingent changes to the color of a block that was the target of the eye movement led to increases in fixation duration and often to an additional fixation on a neighboring block. Notably, these effects were stronger for saccades to the model pattern after subjects had already selected a block from the stockpile. Thus, eye movements provide a measure of change detection in this task, with longer fixation durations or additional fixations indicating some degree of change detection.

Whether or not increased fixation durations reflect implicit processing is not entirely clear, however. Subjects were only asked whether they had noticed changes at the end of the entire experiment, and postexperiment verbal reports are likely to be less sensitive than on-line eye movement measures. However, it would not be surprising if eye movement patterns were influenced by explicit processes. In fact, even if observers failed to detect the change altogether, they might look longer at a changed display than at an unchanged display. For example, if a subject had a block in hand from the stockpile and then saccaded to the pattern to verify its location, they might well notice that something was wrong when the saccade target was a different color than the held block. Given that they then could not place the held block without determining an appropriate location, they likely would spend more time fixating the pattern than they would have had the block not changed. Their awareness of having looked at the wrong block would influence fixation durations on the pattern even if they never explicitly or implicitly detected the change. Furthermore, even if they failed to notice the change happen, they might infer its occurrence from the fact that they were looking at the wrong color block after a saccade. Their

longer fixation could reflect their awareness of the need to change the focus of their fixation in order to complete the task.

In a more direct exploration of implicit change detection, Hollingworth et al. (2001b) compared fixation durations on a changed object when observers failed to report the change to fixation durations on the same critical region when no change was present. Subjects viewed a scene for 20 seconds in preparation for an upcoming memory test, and a change was introduced during a saccade away from the critical object (ensuring that they had viewed the object before the change). Observers explicitly reported noticing the change only 25% of the time. However, even when they missed the change, they tended to spend more time refixating the changed region. This difference in fixation durations might well reflect implicit detection of the change in the absence of awareness, but as for behavioral measures of implicit change detection, the result could also reflect explicit contributions to looking times. There is no way, given these data, to guarantee that subjects were entirely unaware of the change even though they did not report it (Hollingworth et al., 2001b). Without conclusive evidence for the complete absence of explicit change detection, differences in fixation patterns might well reflect below-criterion explicit detection. In other words, eye movements might simply be a more sensitive measure of explicit detection than are verbal reports or other overt responses.

One final study provides some converging evidence for the sensitivity of eye movement patterns to the presence of changes (Ryan and Cohen, 2002). Observers viewed one image and then, after a delay, they viewed either an identical image or a changed image. The images were counter-balanced such that an image that included a change for one participant was part of a no-change trial for another participant. Thus, by pooling data across observers, differences in the fixation patterns on a single image could be compared for trials with and without changes. When observers reported the change, they showed differences in fixation patterns for the changed scene compared to the same scene in no-change trials. Thus, change detection leads to differences in fixation patterns. Interestingly, several measures of the overall viewing pattern showed a difference between changed and unchanged scenes, regardless of whether or not observers reported the change. (However, measures of fixations to the changed region were different only when observers reported the change.)

Fixation patterns appear to provide a more sensitive measure of detection, but it is unclear whether they reveal implicit change detection. Even though observers did not verbally report the change, they might still have had some degree of awareness of it. Most observers in change detection studies adopt conservative response biases, reporting changes only when they are certain (Williams and Simons,

2000). It is possible that such response biases contributed to the effects for unreported changes in that some of these changes might have been explicitly rather than implicitly detected. This effect could be amplified in this analysis because data for a particular image were pooled across subjects in order to compare identical images from “aware” and “unaware” trials. More precisely, subjects who adopted more conservative biases likely would contribute more data to unaware trials, and those adopting more liberal biases would contribute more data to aware trials. If so, a larger subset of the unaware trials might involve changes that were detected but that did not surpass the subjects’ criterion for an explicit response. Claims of implicit change detection require that the measure of awareness exhaustively eliminate other explicit contributions to performance. Unless explicit reports of the presence or absence of a change are at chance, eye movement measures might reflect contributions of explicit detection rather than purely implicit detection.

Regardless of whether or not these findings indicate the presence of implicit change detection, they do raise a caution about the use of verbal reports as the sole measure of change detection. These findings suggest that observers maintain representations of the prechange scene, and that these representations contribute to fixation patterns even when observers do not report a change. Eye movement patterns do provide some preliminary support for the existence of implicit change detection, and further experiments are needed to determine whether these effects are truly implicit or whether other explicit factors such as criterion differences contribute to performance. In combination with the neuroimaging measures reviewed below, this approach could well serve to provide dissociations that otherwise would be unavailable via overt behavioral responses.

Neuroimaging and change detection

Only in the past few years have researchers begun to use on-line measures of the neural bases of change detection and change blindness. Here we briefly review all of the studies we are aware of—a total of four papers—by highlighting what they tell us about the mechanisms underlying change detection. Like the eye tracking studies, these papers focus on differences in the pattern of activation corresponding to conscious change detection and change blindness, as well as on evidence for implicit change detection. Two of these studies used event-related potentials (ERP), and two used functional magnetic resonance imaging (fMRI).

ERP STUDIES OF CHANGE DETECTION ERPs are a noninvasive measure of the magnetic impulses generated by nerve populations in the brain upon sensory stimulation. ERPs are measured by placing electrodes on the scalp and recording the amplitude of electrical activity at each electrode site.

Theoretically, the time course and regions of activation corresponding to the perception of a display can be inferred from changes in these signals. Of course, given that ERPs rely on a limited number of electrodes, spatial localization of activation requires summation across fairly large regions of cortex.

Although ERPs provide only coarse spatial resolution, in many respects they are optimal for measuring the time course of change detection and for dissociating brain activity in the presence and absence of changes. ERPs have excellent temporal resolution, often signaling the presence of a stimulus within 70 to 80 msec of visual stimulation. Thus, they can provide an on-line measure of neural functioning without any need for the subject to provide an overt response. That is, ERPs allow the measurement of differences in neural patterns of activation in response to changes that otherwise might not be measurable, thereby providing a way to dissociate neural activity in the presence of a change from neural activity in the absence of a change.

Recently, two studies using ERPs have looked at differences in neural activity when observers successfully and unsuccessfully search for changes (Fernandez-Duque et al., 2002; Niedeggen et al., 2001). Niedeggen and colleagues (2001) measured ERPs while observers searched for a change to the position or identity of one letter in an array of letters. They used a flicker task (limited to five cycles) in which the original and changed displays alternated repeatedly (1500 msec each), separated by a blank screen (200 msec). Most of the changes were detected within the five cycles allowed, and observers rarely reported a change when none was present. For the most part, the ERP measurements in this study were closely aligned with the behavioral ones. Averaged ERP traces showed a distinct positive deviation from 200 to 800 msec following the onset of the stimulus presentation during which observers reported the change. This positive deflection was significantly different from the control condition in which no change occurred. The finding that ERP traces differ for trials with a detected change and trials with no change is not terribly surprising. After all, differences in neural activity must exist in order for observers to produce different responses to these two types of trials.

The more interesting question is whether the ERP traces show any difference between trials in which a change is present, but not overtly detected, and trials in which no change is present. Such a difference would suggest that changes could be represented even if they were not overtly detected. However, the results revealed no difference in the ERP trace for undetected and absent changes. The absence of a difference is consistent with the idea that change detection requires at least the potential for an overt response. Of course, even if the ERP traces had differed, the interpretation of the difference would be subject to the same criticisms

and constraints noted earlier in the discussion of behavioral measures of implicit detection. As with any null result, the lack of an implicit effect could also be due to the insensitivity of the measure (e.g., not enough trials with missed changes).

Interestingly, the ERP trace from the image preceding the overt detection response also showed a positive deviation from 200 to 800 msec following stimulus onset. The deviation was somewhat smaller than for the stimulus presentation corresponding to the overt response, but it was present. At least three explanations for this result are possible. The positive deviation could correspond to some form of implicit detection that always precedes explicit detection. Note that it could not correspond to implicit detection more generally because the effect occurred only when observers did eventually make an overt change detection response. If observers failed to report the change, the ERP trace was no different from that in trials in which a change was absent. According to this account, favored by the authors, the brain registers the presence of a change, and the implicitly represented change guides focused attention to the change location, thereby allowing subsequent explicit detection.

A second possibility is that the positive deviations to earlier image presentations correspond to a gradual increase in the confidence of an explicit response. In other words, observers explicitly detect the change earlier, but they have not yet surpassed their criterion for responding. According to this view, the positive deviations to earlier images correspond to explicit but below-criterion change detection. A control experiment reported in the paper provided an initial attempt to eliminate this alternative: observers pressed one key when they “sensed” a change and then a different key when they detected the change. Presumably, if these observers lacked confidence in their change response, they should have reported sensing the change before reporting detection. On most trials, they did not report sensing the change during image presentations prior to the one for which they gave a detection response. However, they did report such sensing on approximately 15% to 20% of trials, which could contribute to the effect.

A related explanation for these positive deviations is that they correspond to explicit detection prior to an overt response and that the final, larger deviation corresponds to change certainty. Given that observers are biased to respond “no change” unless they are certain of the presence of a change, they might try to verify that they detected the change. To do so, they must view an additional image before responding. Thus, the positive deviation on earlier images might correspond to the initial explicit detection of a change, with the stronger positive deviation on the final image corresponding to a combination of detection, focused attention, and response preparation. This detection-plus-verification account is consistent with the lack of evidence

for an implicit effect of the presence of a change and suggests that the pattern of ERP deviations to all of the images corresponds to explicit detection.

Interestingly, this pattern of deviations in the ERP traces corresponds closely to behavioral work exploring change localization prior to overt responses (Mitroff and Simons, 2002). In these localization studies, observers were asked to try to localize a change following each change presentation, with presentations continuing until they succeeded or reached a maximum number of presentations. As in the ERP study (Niedeggen et al., 2001), localization performance was no more accurate in the presence of an undetected change than in the absence of a change; the presence of a change did not affect localization provided that observers never overtly reported the change. Observers showed some improvement in localization performance for the change presentation immediately before the change was explicitly reported. Prior to that, they showed no improvement in localization across consecutive guesses. This pattern is similar to the ERP finding of a positive deviation on the image presentation prior to the overt response. However, this finding can be explained without any need for implicit change detection. As observers search for changes, they likely focus on one area or item. Assuming that no change occurs at that location, they then immediately shift attention to a new location prior to the next presentation. Their change localization response at the end of each cycle likely corresponds to this new guess rather than to the location they have just eliminated as nonchanging. Then, when the change occurs at the guessed location, they report detecting it and localize it correctly. This pattern of guessing and then verifying is consistent with an entirely explicit change detection mechanism. The correspondence of the ERP pattern and the localization data leaves open the interesting question of whether the positive deviations on images prior to the detection response correspond to some form of verification or whether they represent implicit detection. Further exploration of this question, perhaps using both ERPs and localization responses, is needed to determine fully which of the three possible explanations best accounts for this brain activity prior to explicit reports of detection.

A second paper on ERP addressed the question of implicit change detection while exploring the mechanisms underlying search for change (Fernandez-Duque et al., 2002). This study also used a flicker task, but the cycled displays were complex photographs and each trial was separated into five sequential stages for analysis. Initially, observers searched for a change, but none was present for a variable number of cycles (stage 1). A change was introduced (stage 2), and once observers successfully identified the change, they monitored its location and reported when the item stopped changing (stage 3). Next, observers once again searched the display for a change (stage 4). This time,

however, the change occurred on only a small proportion of trials (sometimes it was a new change and sometimes it was the original change), and only the no-change trials were actually analyzed. Following stage 4, observers monitored the original change location and were asked to report if the change recurred (stage 5). Notice that in this paradigm, stages 1, 2, and 4 all involve search for a change, whereas stages 3 and 5 involve focused attention to the change location. This experiment addresses two distinct questions: (1) does searching through a scene differ from focused attention to a single location? and (2) does the absence of a change lead to different activation in the presence of an undetected change?

ERP patterns for focused attention to a single location (stage 5) and search through a scene (stage 4) were comparable, although a bilateral frontal negativity from 100 to 300 msec and a posterior-occipital positive deflection from 150 to 300 msec after stimulus onset were somewhat enhanced by sustained attention to a single location. Given that these differences are unrelated to change detection, they can be used to isolate the effect of change detection from any contributions of sustained attention to the change location. ERP patterns for focused attention on a detected change (stage 3) and search throughout a display for an undetected change (stage 2) were comparable to those involved in focused attention. The 150 to 300 msec negative deflection at frontal sites and the 100 to 300 msec positive deflection at posterior sites were comparable to those found in the comparison of stages 4 and 5. However, ERP traces in stage 3 also showed other differences from stage 2 that might correspond to awareness of the change, such as a greater positive deflection at central sites at delays of 350 to 600 msec. This finding represents one of the first attempts to measure the neural correlates of awareness of a change. Note, though, that differences in activation could also reflect differences in the tasks that subjects perform at each stage. For example, only stage 3 involves search for change removal which requires verification that a change is still present on every cycle. These task differences could induce changes in strategies that might affect ERP traces.

This experiment also considered whether the presence of an undetected change produces a different ERP trace than does the absence of a change (Fernandez-Duque et al., 2002). The design allowed a comparison of activation patterns for the same image when a change is present but not yet reported (stage 2) and when observers search for a change but none is present (stage 4). The presence of a change produced a significant bilateral positive deflection in anterior sites (more medial than lateral) between 240 and 300 msec after stimulus onset, suggesting neural registration of an unreported change. However, further work is needed to demonstrate conclusively that the differences correspond to the implicit registration of changes as opposed to explicit or

strategic influences. As for measures of awareness of the change, the demands of the two stages contributing to the comparison may be somewhat different. In stages 2 and 4, observers are given the same instruction to look for a change, and their subjective experience in both cases is likely that of trying to find a change and sometimes succeeding. However, in stage 2 they have already been searching for 12 to 22 flickers (the duration of stage 1), whereas stage 4 begins at the start of their search. If the initial stages of search differ from those occurring after a period of unsuccessful searching, then differences between stages 2 and 4 could result from changes in the search strategy. Changes also occur less frequently in stage 4 than in stage 2, a factor which might induce a different sort of attentional set. Finally, although subjects in both stages were told to search for a change, in stage 4 they knew that the change would either be the same one they saw earlier or a new one. This knowledge might contribute to the use of different search strategies. For example, subjects might initially devote more attention to the original change location, something they could not do in stage 2. In fact, the act of finding the first change might well influence the nature of the search for a subsequent change to the same image. Given that any of these factors could contribute to differences in patterns of neural activation even in the absence of implicit change detection, further studies are needed to clarify whether ERP measures reveal the existence of implicit change detection.

FUNCTIONAL MRI STUDIES OF CHANGE DETECTION Unlike ERP, fMRI has excellent spatial resolution but somewhat less precise temporal resolution. Consequently, it is better suited to studies of the anatomical locus of the mechanisms underlying change blindness and change detection, but does not provide as precise an estimate of the progression of change detection within a trial. Two published studies have explored change detection in the flicker task using event-related fMRI, one focusing primarily on identifying the anatomical regions involved (Huettel et al., 2001) and the other focusing on differences in activation for detected, undetected, and absent changes (Beck et al., 2001). Huettel and colleagues (2001) looked for brain regions that remained active throughout the search in a flicker task, as well as regions that showed phasic activity as a result of image onsets and offsets in this task. Regions including extrastriate visual cortex, frontal and supplementary eye fields, and inferior/insular frontal cortex in addition to several other regions were all active throughout the search task, suggesting that these areas contribute to visual search for change. This study provided some preliminary estimates of the areas involved in searching for changes, but it did not provide any experimental manipulations to test different aspects of change detection. Future studies can use their initial findings

by determining how activation in these regions varies as a function of changes to the nature of the displays or the task.

Beck and colleagues (2001) used fMRI techniques to address questions similar to those raised in ERP studies of change detection. As in the aforementioned ERP studies, neuroimaging was used to dissociate change detection from change blindness and also to look for differences in neural responses to the presence of an undetected change and the absence of a change (i.e., implicit change detection). This study also manipulated the nature of the changing images, using faces on some trials and outdoor scenes on others. These classes of stimuli typically lead to activity in discrete regions of the ventral visual pathway, faces activating what is now known as the *fusiform face area* (FFA) and outdoor scenes activating the *parahippocampal place area* (PPA) (Tong et al., 1998).

Not surprisingly, detection of face changes produced greater activation in the vicinity of the FFA, whereas detection of changes to outdoor scenes led to greater activation of areas near the PPA. Detection of changes to either type of stimulus also produced more activation in parietal and dorsolateral prefrontal cortex than did missed changes. These regions often are associated with attention and executive control, respectively. The finding of different patterns of activation for detected and missed changes is consistent with other evidence that responses in these regions are heightened by subjective awareness of the stimulus (Tong et al., 1998). Moreover, the finding that the FFA is more active when observers successfully detect a face change and that the PPA is more active when observers successfully detect a place change is consistent with these findings. These findings provide some neurological confirmation that attention is needed for successful change detection.

To examine the evidence for implicit change detection, activation to the absence of a change was subtracted from activation to the presence of an undetected change (Beck et al., 2001). An initial experiment revealed significant activation in the fusiform gyrus, the lingual gyrus, and the inferior frontal gyrus for undetected face changes. However, a second experiment that controlled for eye movement artifacts found no differences between activation in the presence of an undetected change and in the absence of a change. Consequently, these experiments do not provide conclusive evidence that changes are implicitly registered in the absence of conscious change detection. Further studies obviously are needed to verify this null result; however, the basic pattern is consistent both with ERP evidence (Niedeggen et al., 2001) demonstrating the similarity in activation patterns in the absence of a change and in the presence of an undetected change, and with behavioral evidence demonstrating that undetected changes do not influence localization performance (Mitroff and Simons, 2002). Although some of the on-line measures are consistent with implicit detection, none

incontrovertibly demonstrates the need for implicit detection. In fact, the findings described above may well be consistent with the idea that change detection occurs only via an explicit comparison mechanism.

Summary

Existing ERP and fMRI experiments provide contradictory evidence about the possibility of implicit change detection. Both ERP and fMRI results reveal no reliable differences between trials with missed changes and trials with no change (Beck et al., 2001; Niedeggen et al., 2001). However, the search for not-yet-detected changes does produce a different pattern of activation than the search for absent changes. For trials on which a change is subsequently detected, ERP signals to one or two images earlier in the sequence show weaker versions of the deviations that correspond to conscious report of a change (Niedeggen et al., 2001). This pattern is consistent with the idea that if changes are implicitly detected, they guide attention to the change. However, other interpretations that do not require an implicit change detection mechanism can still account for the results. Another study found similar differences in activation during the search for an absent second change to the scene and search for an initial change prior to its onset (Fernandez-Duque et al., 2002). This finding also provides some preliminary evidence for implicit change detection, but further studies are needed to eliminate all the potential explicit and strategic contributions from these ERP trace differences.

Neuroimaging is a useful tool for gaining new insights into the mechanisms of change detection. ERP and fMRI might well dissociate performance for detected and undetected changes in ways that would be impossible using solely behavioral measures, if only because behavioral measures typically require explicit responses. Despite the appeal of these new tools, however, they are still subject to the same assumptions and requirements underlying attempts to demonstrate implicit perception with strictly behavioral tasks. Any convincing demonstration of implicit perception must first confirm that explicit factors and strategies did not contribute to performance. The classic dissociation paradigm used to measure implicit processing requires that the explicit measure of performance show no sensitivity to the presence of a stimulus (Holender, 1986; Merikle and Reingold, 1992). Moreover, the measure must assess all possible explicit contributions to performance. That is, an insensitive measure of explicit change detection might reveal no discrimination of the presence of a change, but that would be unconvincing because stronger or more sensitive explicit measures might reveal discrimination. Only if the explicit measure is optimally sensitive and still shows no explicit discrimination can we be certain that any measured differences in performance

result from implicit processes (Holender, 1986). Given this stringent criterion, it might be impossible to demonstrate implicit change detection using solely direct measures based on subjective reports. Experimenters would first have to demonstrate a lack of explicit sensitivity to the presence of a change while still showing that performance for unreported changes was better than expected. However, if observers show no sensitivity, then aware and unaware trials cannot be distinguished, and it is unclear what trials to compare. In order to measure implicit detection behaviorally, it is necessary to separate trials on which observers saw the change from those on which they missed the change. However, to do so, the task must violate the conservative requirements of the dissociation paradigm.

Both neuroimaging and eye tracking might provide an escape from this catch 22 by dissociating patterns of activation in the presence and absence of a change even for tasks which exhaustively eliminate explicit change detection. To do so, an experiment would need to use a change detection task for which observers showed no explicit sensitivity to the presence of a change. That is, explicit reports of the presence or absence of a change would have to be no better than chance. The critical question, then, is whether looking times or neural activation in the presence of a change would differ from activation in the absence of a change. None of the experiments to date have applied such a stringent criterion, but given that they raise the possibility of an implicit comparison mechanism, strong tests of the hypothesis are needed. A difference in looking or in brain activity as a function of the presence of a change in a study meeting this criterion would provide the necessary evidence for the existence of an implicit representation of the change and would argue against the necessity of explicit comparisons in change detection. Such a finding would also raise the possibility that implicit detection plays a functional role in guiding attention as well as subsequent explicit detection. However, without such a controlled study, current findings of implicit change detection remain inconclusive, and existing results can be attributed to explicit processes and conscious strategies. In the absence of such counterevidence, current studies of change detection are consistent with the strong hypothesis that change detection, in the absence of a transient signal, occurs only through an explicit comparison mechanism.

Acknowledgments

Thanks to Diego Fernandez-Duque, Steve Mitroff, and Ian Thornton for helpful comments on earlier drafts of this manuscript. Thanks also to Neal Cohen, Diego Fernandez-Duque, Michael Niedeggen, Jennifer Ryan, and Ian Thornton for allowing us access to their not-yet-published experiments. Writing of this manuscript was supported

by grants from the NSF (BCS9905578) and the NIH (R01-MH63773-01) and by an Alfred P. Sloan Research Fellowship.

103 The Role of Attention in Visual Cerebral Cortex

JOHN H. R. MAUNSELL

THE DETECTION AND discrimination of sensory stimuli can be profoundly influenced by the amount of attention that a subject directs to them. Neurophysiological studies using a variety of approaches have shown that changes in an observer's state of attention are associated with changes in the processing of sensory signals. The effects of attention on the responses of neurons in visual cerebral cortex is the subject considered here.

Before addressing specific neuronal correlates of attention, it is important to define the type of attention that will be considered. *Attention* is used to refer to a variety of processes, and it is likely that some of these involve different brain mechanisms. For example, attention can refer to a level of arousal or wakefulness, or it can refer to the executive control that guides a task that evolves over the course of days or months. We will restrict our discussion to selective sensory attention: the process of focusing on one signal or stimulus to the exclusion of others. One example is spatial attention, where resources are concentrated on a particular location in visual or auditory space. Attention to particular stimulus features, such as color or orientation, is another form of selective sensory attention. Spatial attention and featural attention have both been shown to modulate the responses of visual neurons (Corbetta et al., 1991; McAdams and Maunsell, 2000; Treue and Martínez-Trujillo, 1999). Although spatial attention may produce stronger effects than featural attention, the two forms have not been shown to differ fundamentally, and they will not be distinguished here.

Although effects of selective attention have been demonstrated in the visual systems of many species, and using many neurophysiological techniques, we focus here on studies of individual neurons in the visual cerebral cortex of macaque monkeys.

Attention modulates the strength of neuronal responses

The most prominent effect of attention on the activity of neurons in visual cortex is a change in the strength of their response to a stimulus. Typically, a neuron's response to its optimal stimulus is stronger when the subject pays attention to it. Most observations suggest that attention alters

the sensitivity of neurons without affecting their stimulus preferences or selectivity, although exceptions will be discussed.

RANGE OF ATTENTIONAL EFFECTS WITHIN AND BETWEEN CORTICAL AREAS Attention has been found to modulate neuronal responses in every visual area examined, from V1 to the latest stages in the cortical hierarchy. However, the magnitude of attentional modulation varies greatly within and between areas and appears to be related to several factors.

Samples of neurons from individual visual areas invariably show a range of modulation by attention, even when the stimulus is optimized for each neuron. Some neurons respond robustly when the stimulus is attended and not at all when it is ignored. Others show no detectable effect of attention. Furthermore, occasional neurons have been found to have significant negative modulation by attention, so that they respond more strongly when a stimulus is ignored.

The reason for this range of effects is not understood. It is possible that neurons with response properties best suited to the current behavioral task are modulated most by attention. For example, when subjects perform a color discrimination task, neurons with greater color selectivity, or with color preferences well matched to the stimuli, might be more modulated by spatial attention than other neurons. However, no such correlation has been described, and the reason for the range of attentional modulations within cortical areas remains an important unanswered question.

Modulation by attention also differs between visual areas. The average strength of modulation is generally stronger in later stages of visual cortex. In V1, the average effect is weak, typically about a 10% increase in response (Crist et al., 2001; Haenny and Schiller, 1988; Luck et al., 1997; McAdams and Maunsell, 1999a; Mehta et al., 2000; Motter, 1993). Stronger effects are found in extrastriate areas. It is difficult to compare modulations from different studies quantitatively because they differ in stimulus conditions and task difficulty (see below), but some investigations have measured attentional modulation in different visual areas in the same subjects using consistent task conditions. Those studies

typically show greater modulations in successive stages of cortical processing. Figure 103.1 plots the averages for attentional modulation from experiments that measured responses in more than one visual area under equivalent conditions. Each symbol represents data from a different experiment. More modulation was found in later levels of visual cortex.

It is not known why attentional modulation should be stronger in later stages of visual cortex. One possibility is that attention acts to insert additional spikes at each level of visual cortex and that this additional activity accumulates, so that attentional modulation is greater at later stages. An alternative explanation is that attention acts to insert activity at the highest levels of visual cortex, and that this activity diminishes as it descends along feedback pathways. While either explanation might account for stronger modulations in later stages of cortex, they seem unlikely because they suggest that signals must grow or diminish uncontrollably as they propagate through cortex. No evidence suggests that sensory signals grow or diminish uncontrollably in this way. It seems more likely that there is an optimal amount of attentional modulation for sensory signals and that different optima exist for earlier and later sensory representations. Whatever the source, the reason for different degrees of modulation in different cortical areas is one of the most important questions to be answered about attentional modulations.

One consequence of the differences in attentional modulation between visual areas is to encourage investigators to focus more on certain areas. For example, area V4 has been extensively examined, in part because it is well positioned. It is early enough in cortical processing that its neurons

FIGURE 103.1. Attentional enhancement of neuronal responses increases as a function of position in the cortical hierarchy. Average attention modulation was taken from experiments that measured responses in at least two cortical levels using the same subjects and the same task. *Open squares* are data from McAdams and Maunsell (1999a); *open circles* are from Treue and Maunsell (1999); *filled squares* are from Ferrera et al. (1994); and *filled circles* are from Cook and Maunsell (2002). The cortical hierarchy levels are spaced according to the levels defined by Felleman and Van Essen (1991). (From Cook and Maunsell, 2002.)

respond well to relatively simple stimuli that are easily controlled and manipulated, such as oriented bars or patches of color. It is also sufficiently advanced in cortical processing that attention modulations are fairly prevalent and easy to demonstrate. However, while V4 is a frequent subject for study in attention experiments, there is little reason to believe that it plays a special role in processes related to attention.

EFFECT OF TASK DIFFICULTY ON ATTENTIONAL MODULATION

Another factor affecting the magnitude of attentional modulation is task difficulty. Stronger responses are generally seen when animals must pay more attention to a stimulus (Spitzer et al., 1988). For example, responses of inferotemporal neurons grow progressively stronger as an animal goes from ignoring a stimulus, to attending it to detect a dimming, to attending it to discriminating its pattern (Spitzer and Richmond, 1991).

Changes in responses associated with task difficulty may be associated with vigilance, and therefore may be less specific than effects seen with attention to spatial locations or stimulus features. However, task difficulty can influence the magnitude of selective modulations associated with spatial attention. Modulation by spatial attention can be much stronger when animals perform a difficult version of a task in which they must detect changes in orientation (Boudreau and Maunsell, 2001).

Differences in a subject's level of effort cannot easily explain differences in attentional modulation between different cortical areas because in most relevant cases the same stimulus and task have been used in both areas, leaving no obvious basis for the subject to devote different levels of effort when recordings were made from different areas. Differences in effort might explain some of the range of modulations seen within areas, because the subject's effort might differ while data are collected from different neurons. However, an experiment that compared neuronal and behavioral effects of spatial attention found that the modulation of individual neurons by attention was uncorrelated with attentional modulation of behavior during the period when the neuron's responses were recorded (Cook and Maunsell, 2002). This suggests that the range of neuronal modulation within areas comes largely from sources other than vigilance.

Because task difficulty affects attentional modulation, the values reported by various studies cannot be taken as absolute, and comparisons between different experiments are problematic. Although the data in Figure 103.1 suggest that different experiments will find comparable average enhancement for a given visual area, those data are not representative of the differences between experiments because they were collected in the same laboratory using tasks of similar difficulty.

The influence of the subject's effort also raises the question of whether much stronger modulations might be seen with particularly challenging tasks. Although some attention experiments have used near-threshold stimuli, many have used stimuli that were unlikely to have required much effort from the subjects. It is notable that particularly strong modulations were found by Mountcastle and his colleagues (1981), who compared responses during a visual task with responses to the same stimuli while the animals sat idle. Little work has been done to explore the limits of attention modulation. For example, responses to a visual stimulus might be much stronger when that stimulus is the subject of a challenging discrimination than to when it is irrelevant and attention is directed to a difficult auditory or somatosensory discrimination.

EFFECT OF ATTENTION WHEN NO STIMULUS IS PRESENT The effects of attention are often examined in terms of responses to visual stimuli, but attention can also affect neuronal activity when no stimulus is present. In early stages of visual cortex, modest increases in the spontaneous activity of neurons have been described when attention is directed to the part of the visual field containing a neuron's receptive field (Luck et al., 1997). This increased activity associated with spatial attention appears equivalent to increases in activity reported in the later stages of visual cortex, which are usually discussed in the context of short-term memory. For example, some inferotemporal neurons maintain an elevated level of activity during periods when the subject remembers a particular form or color, and not during periods when other stimuli must be remembered (Fuster, 1990; Fuster and Jervey, 1982; Miyashita et al., 1993; Yakovlev et al., 1998). Similarly, neurons in the lateral intraparietal area (LIP) remain active when animals pay attention to the motion of a stimulus that is briefly hidden from view (Assad and Maunsell, 1995; Eskandar and Assad, 1999). Thus, attentional modulations apply to undriven activity as well as stimulus-driven activity.

Some studies have not detected changes in undriven activity associated with attention. Because these changes are usually small (typically a few spikes per second), this may be a matter of statistical power. Alternatively, aspects of task design may make these changes less likely. McAdams and Maunsell (1999a) examined attentional modulation of driven and undriven activity in V4 and found that while responses to stimuli were modulated, activity immediately before the appearance of the stimulus was not affected by the location to which attention had been directed. The absence of modulation of undriven activity in this case may have been due to the timing of the stimulus presentations. Because the stimuli always appeared at predictable times and stayed on for relatively long periods, the animal had little motivation to direct its attention to the

cued location until after the stimulus appeared. Consistent with this, average attentional modulations increased during the stimulus presentation. Motter (1994) examined how quickly animals redirected their attention to different parts of the visual field after an instruction was given, and found that neuronal responses changed within a few hundred milliseconds. The dynamics with which attention can shift have not been well characterized, and there is no reason to believe that attention will be fixed during a behavioral trial or even during the course of an individual stimulus presentation.

Attention does not greatly affect underlying response properties

While attention changes the strength of neuronal responses, it does not appear to change profoundly the selectivity of neurons for particular stimuli. Testing whether attention changes the strength of responses can be done using a single fixed stimulus. A range of stimuli must be used to test whether attention affects selectivity. Only a handful of experiments have examined the effect of attention on neuronal selectivity.

EFFECT OF ATTENTION ON TUNING FOR STIMULUS ATTRIBUTES McAdams and Maunsell (1999a) examined how attention affects the orientation tuning of V4 neurons. Each neuron was tested with many orientations in each of two states of attention. Attention to the stimulus increased responses by an average of about 30%, but responses to all orientations were increased proportionally, so that on average there was no sharpening or broadening in orientation tuning. Data from the same study showed that attention increased responses of V1 neurons by a lesser amount, and again with no detectable change in the sharpness of tuning. Treue and Martinez-Trujillo (1999) tested the direction selectivity of neurons in the middle temporal (MT) visual area, and similarly found that attention increased responses without appreciably altering the sharpness of tuning for direction.

Earlier studies suggested that attention narrowed orientation or color tuning for V4 neurons (Haenny and Schiller, 1988; Spitzer et al., 1988). While there are several possible sources for this discrepancy, the most likely cause is the use of different measures for tuning bandwidth between the two sets of studies (McAdams and Maunsell, 1999a). At most, one of the measures could have remained constant across behavioral states. While there is no basis for arguing that either measure is superior, the fact that one measure showed no effect of attention on bandwidth suggests that attention acts primarily to increase sensitivity, not to alter selectivity. An effect of attention increasing the gain of neuronal responses is consistent with studies of attention in humans

using psychophysical methods, ERPs, or functional imaging (Hillyard et al., 1998; Lu and Doshier, 1998).

The variability of neuronal responses also appears to be largely unaffected by attention. When subjects are repeatedly presented with the same stimulus, their cortical neurons characteristically respond with different numbers of spikes on different presentations. The source of this variance is not understood, but the variance of the number of spikes produced is large, typically about the same magnitude as the mean number of spikes (e.g., Geisler and Albrecht, 1997). Although the mean number of spikes produced in response to a stimulus depends on whether the stimulus is attended by the subject, the relationship between the mean and the variance of the spike count is unchanged by attention (McAdams and Maunsell, 1999b). Similarly, no change is obvious in the distribution of interspike intervals.

Attention may change the spiking of cortical neurons in other ways, however. Recent studies have showed that attention is associated with increases in the synchrony of neuronal signals in both the visual and somatosensory cortex of monkeys (Fries et al., 2001; Steinmetz et al., 2000). It remains to be determined how these changes in the timing of neuronal signals interact with increases in the strength of neuronal responses.

EFFECTS OF ATTENTION ON RECEPTIVE FIELDS Attention does change the selectivity of neurons in some situations. Moran and Desimone (1985) found that when two small stimuli are placed within a V4 neuron's receptive field and the subject attends to just one, the neuron responds as if the receptive field had contracted around the stimulus that is the focus of attention. If one preferred and one nonpreferred stimulus are in the receptive field, attention to the preferred stimulus increases responses, while attention to the nonpreferred stimulus reduces responses, relative to attention directed elsewhere. Similar results have since been described in V4, MT, and the medial superior temporal (MST) area (Connor et al., 1996, 1997; Luck et al., 1997; Reynolds et al., 1999; Treue and Maunsell, 1996).

Changes in the efficacy of stimuli in different parts of the receptive field can be viewed as a change in neuronal selectivity. The response of the neuron as a function of position in the visual field (i.e., its receptive field profile) shifts and narrows as attention shifts to different locations. Thus, attention affects selectivity for spatial tuning, even if it has little effect on tuning for attributes like orientation or direction. However, such changes in selectivity may be an indirect consequence of effects of attention that do not alter selectivity directly (Maunsell and McAdams, 2001). Receptive fields large enough to hold two stimuli depend on converging inputs from neurons with smaller receptive fields at earlier

levels in the visual pathway. Imagine that attention acts at a level where receptive fields are sufficiently small that the two stimuli activate different neurons. Additionally, assume that at this level, the only effect of attention is to differentially modulate the strength of response of the two groups of neurons. A neuron in a later stage can have a receptive field large enough to contain both stimuli if it sums inputs from both sets of neurons at the earlier level. While attention does not alter the selectivity of neurons at the earlier level, the changes it causes at that level will change the spatial response profile (spatial selectivity) of the neuron at the later level. Thus, even if attention never changes the selectivity of sensory neurons directly, the convergence of inputs that have been differently affected by attention may lead to changes in selectivity. It should be noted that such changes might be largely limited to shifts in receptive fields, because receptive fields grow progressively larger at later stages in visual cortex. Tuning for stimulus dimensions such as orientation, direction, and color does not appear to broaden greatly in cortical processing and therefore may be less prone to this effect of attention.

ATTENTION AS INCREASED SALIENCE The effects of attention on neuronal responses are reminiscent of the effects of increasing stimulus salience when attention is kept constant. Changes in stimulus contrast or intensity, or other changes that make a stimulus better suited to the response properties of a neuron, typically increase the response of the neuron without altering its tuning for various stimulus attributes (Maunsell and McAdams, 2001; McAdams and Maunsell, 1999a). Most of the reported effects of attention on neuronal responses can be viewed as an effective increase in the intensity of the attended stimulus. For example, the effects of attention described above when two stimuli are in a neuron's receptive field are qualitatively the same as those expected if one stimulus became more intense while the other became less intense. Consistent with this, Reynolds et al. (2000) measured the effect of attention on the responses of V4 neurons using stimuli that covered a range of contrasts, and found that attention was equivalent to increasing stimulus contrast.

Other types of extraretinal inputs to visual cortex also appear to modulate responses without altering underlying selectivity. Signals related to the angle of gaze appear to scale receptive field profiles of neurons in posterior parietal cortex (Andersen et al., 1985). Behavioral differences between reward-associated and unrewarded stimuli scale orientation tuning curves in inferotemporal cortex (Vogels and Orban, 1994). Additionally, receptive field profiles of V4 neurons appear to scale multiplicatively when attention is directed to different points around the receptive field (Connor et al., 1996, 1997).

One of the goals of neurophysiological studies of attention is to understand how the changes it causes in neuronal responses relate to changes in behavioral performance. A general correlation exists in that attention makes neuronal responses to attended stimuli stronger and makes behavioral performance using attended stimuli better. A few studies have tried to relate quantitatively the effects of attention on neuronal responses to changes in behavioral performance.

McAdams and Maunsell (1999b) examined how a subject's attention influenced how well stimulus orientations were discriminated by the responses of individual V4 neurons. They used a d-prime measure, which estimated the orientation difference that would be needed before a neuron's responses to two orientations made it possible to tell which was which with 75% correctness in a two-alternative force-choice task. Attention improved neuronal performance: the median d-prime for unattended stimuli was 26.5 degrees, while that for attended stimuli was 20.4 degrees. The subject's behavioral performance was not measured in this experiment, however.

Recently, Cook and Maunsell (2002) compared neuronal and behavioral performance directly in a motion detection task in which stimuli spanned a range of motion strength and appeared in locations to which the subject directed greater or less attention. In this way, it was possible to assess whether the effects of attention on the neuronal response were commensurate with its effects on behavioral performance. For example, would a weak attended stimulus and a strong unattended stimulus that both produced the same level of neuronal performance also support the same level of behavioral performance?

Figure 103.2 plots average behavioral performance on detecting motion onset against average neuronal responses to the same stimuli parameterized by motion strength. Several motion strengths were tested while the animal attended to the receptive field location (*filled symbols*). One of these motion strengths was also presented in the receptive field when the animal was instructed to attend elsewhere (*open symbols*). Redirecting attention reduced both behavioral performance and neuronal responses. If the effect of attention was equivalent to changing stimulus strength, then the point for this other attentional condition should lie on the function defined by values obtained when the animal was attending to the receptive field location.

The results differed between visual areas. For neurons in MT (Fig. 103.2A, B), the average attentional modulation of neuronal responses was relatively weak, and was too small to explain the changes in behavioral performance associated with shifts in attention. In contrast, the average attentional modulation in the ventral intraparietal area (VIP) was more

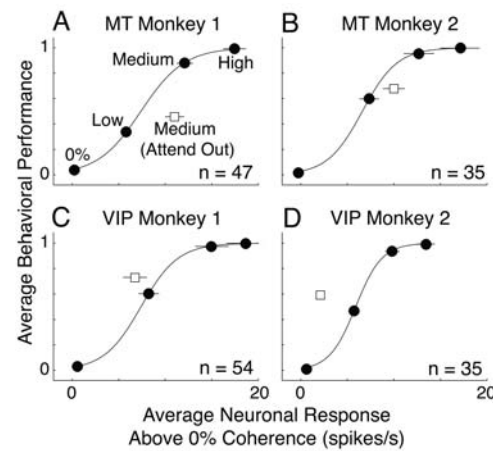

FIGURE 103.2. Average effects of attention on behavior and simultaneously recorded neuronal responses. *Filled symbols* plot behavioral performance and neuronal responses from trials where the animal was attending to the receptive field location. Different points are for stimuli with stronger or weaker motion signals. *Open symbols* plot behavioral and neuronal responses from trials where the medium motion strength appeared in the receptive field, but the animal's attention had been directed elsewhere. If changes in attention were equivalent to changes in stimulus strength, the *open symbols* would lie on the function defined by the *filled symbols*. Instead, for both animals, neuronal effects of attention were too weak in MT (A, B), and too strong in VIP (C, D). (from Cook and Maunsell, 2002.)

than what was needed to account for the changes in behavioral performance (Fig. 103.2C, D).

While there are several plausible explanations for these mismatches, one possibility is that a correspondence between neuronal and behavioral performance exists across attentional states only in those stages of cortex that are best suited for the detection or discrimination being done. As mentioned above, attentional modulations are greater in later stages of cortical processing. Consequently, a shift in attention that produces a particular change in behavioral performance will be associated with different amounts of attentional modulation in different cortical areas. In most visual areas, the average attentional modulation will not match the change in behavioral performance. The results from MT and VIP suggest that the average attentional modulation of neurons in a region intermediate between MT and VIP would be appropriate to account for the behavioral modulation.

More experiments will be needed to determine whether a correspondence between neuronal and behavioral performance persists across attentional states. If a correspondence were found, it would not say anything about the size of the pool of neurons that contributes to the behavior or whether the neurons were confined to a single area. However, it would raise important questions about how different levels of visual cortex contribute to different behaviors. For

example, it would be valuable to know whether neurons showing a correspondence across attentional states for a particular task had the greatest sensitivity for the stimulus attributes that were essential to the task being performed. It would also suggest that manipulating attention might be a valuable tool in exploring how individual neurons contribute to behaviors.

Concluding comments

The results described suggest a basic framework for understanding the function of attentional modulation in sensory processing. Images falling on the retinas activate subsets of neurons throughout visual cortex, with each neuron's activation determined by its more or less hardwired response properties and the content of the retinal image. This pattern of cortical activation is modified by attention. The responses of neurons with receptive fields in parts of the visual scene that are being attended by the subject, or with response properties consistent with stimulus features being attended, would be enhanced relative to others. Perception and behaviors would then be determined by the modified pattern of cortical activity, with the enhancement by attention leading to better discrimination and detection, and faster reaction times, for attended stimuli.

Many questions remain about attentional modulation of neuronal responses in visual cortex. Some of these are readily approachable and will likely be addressed in the near future. Others are more daunting and may need to wait for a more complete understanding of how sensory representations are used in guiding behaviors.

Among the more approachable issues is more information about how attention interacts with the sensory response properties of neurons. We have seen that the primary effect of attention appears to be an increase in sensitivity without much change in selectivity. That notion is based on only a few experiments, however. Other visual areas need to be examined using different tasks and a greater range of stimulus conditions. There is also a need for better information about differences in the amount of attentional modulation in different levels of cortical processing. The data point to a progressive increase in attentional modulation in cortical processing, but this has never been surveyed thoroughly.

Little is known about how selectively attention can act on neurons within visual cortex. For example, studies of spatial attention show that attention can enhance responses of neurons with receptive fields in one location while suppressing responses of neurons with receptive fields elsewhere, but it is not known whether attention can also adjust the enhancement neurons in earlier versus later stages of cortex, depending on task demands. While studies have shown greater modulation at later stages, no attempt has

been made to see whether attention to simpler or more complex stimuli might reverse or exaggerate the differences between levels. It would also be valuable to know whether attention can act differentially on areas in different streams of processing.

In the longer term, we must work toward understanding how attentional modulations of neuronal responses contribute to behavioral performance. It is a reasonable assumption that attentional modulations are optimizing some aspect of neuronal responses, but which one? The stronger responses associated with attention allow better neuronal performance (McAdams and Maunsell, 1999b), but this cannot be the complete explanation. If the performance of individual neurons were the entire story, there would be little reason for modulating responses: why not leave them in the state with better performance all the time? Stronger responses will generally give better performance, so why are neurons not always at the highest possible sensitivity? Presumably sensitivity is set to produce an appropriate balance between false alarms about the presence of a stimulus and failures to detect stimuli that are present. If so, the dynamic, differential modulation of neurons might work to adjust the criterion for neuronal responses in light of current information about the visual scene or the subject's motivation. We will not understand the role of attention in sensory processing until we can answer questions about the specific magnitudes of attentional modulation observed.

The sources of attentional modulation also remain to be determined. Functional imaging studies in humans have suggested that parietal cortex may be a good candidate (Corbetta et al., 1998; but see Duncan, 2001). Recently, Sereno and his colleagues (2001) described topographic maps associated with remembering the locations in the visual field in several sites in parietal cortex. Maps of this sort could provide the input needed to account for spatially selective enhancement of visual neurons with receptive fields in behaviorally relevant locations.

While much remains to be done, considerable progress is being made in understanding the role of attention in sensory processing. The past 5 years have seen the beginnings of a framework for quantitatively relating attentional modulation of neurons' responses to changes in behavioral performance, and the prospects for progress in the near future are excellent. Attention is proving to be among the most approachable cognitive processes for study at the level of responses of single units.

104 Volition and the Prefrontal Cortex

EARL K. MILLER AND JONATHAN D. WALLIS

THE SOPHISTICATED sensory systems of advanced animals—a choice example being the primate visual system—provide a wealth of data about the external world. To take advantage of this, we humans have correspondingly evolved elaborate mechanisms for behavior. While virtually all animals can react to their immediate environment, the rich information we have about the world has allowed us to extend our behavioral repertoire beyond simple reflexive reactions. Primates and other advanced animals can learn to anticipate possible futures and coordinate thought and action in order to direct them toward achieving desired outcomes. This ability is the hallmark of intelligent behavior, and it is called *cognitive control*. A full understanding of visual processing can be achieved only through an appreciation of how the mechanisms for cognitive control can modulate visual processing and how visual information is used to constrain and guide behavior.

Because cognitive control necessarily involves the coordination of many different brain processes, it no doubt depends on circuits that extend over much of the cerebral cortex. However, one cortical region, the prefrontal cortex (PFC), seems to play a central role. It is the area that reaches its greatest elaboration in the human brain and is thus thought to be the neural instantiation of the mental qualities that we think of as “intelligent.” Accordingly, the PFC receives converging information from the visual system and, indeed, all other sensory systems, and it is interconnected with motor system structures needed for voluntary action.

Here we discuss anatomical, neuropsychological, and neurophysiological evidence for, and theories of, the role of the PFC in cognitive control. Much of this discussion will involve visually guided behaviors and other aspects of controlled visual processing such as focal attention, but because cognitive control is by nature supramodal, other modalities will also be considered. We will begin with a discussion of the characteristics of volitional, or controlled, processes, as they can provide predictions about the neural mechanisms likely to underlie them.

Controlled processing

All behavior varies along a continuum from mindless and automatic to willful and purposeful (i.e., controlled) behaviors (Barsalou, 1992). Automatic processes are reflexive. If a

car or a predator is bearing down on us, we leap out of the way before we have even had a chance to form the intention to do so. Automatic processes thus seem to depend on relatively straightforward, hardwired relationships between the brain’s input and output systems. In neural terms, it seems that they depend on strong, well-established neural pathways just waiting to be triggered by the right sensory cue. That is, automatic processes are driven in a bottom-up fashion: they are determined largely by the nature of the sensory stimuli and by whatever reaction they are most strongly wired to.

These relatively simple, hardwired, cue-response mappings are useful in many situations. Because they can simply be fired off by the environment, they are quick and can be executed without taxing the limited capacity of our conscious thoughts. But a creature that is at the mercy of its immediate environment is not well equipped to deal with the ambiguity, and exploit the opportunity, of a complex and dynamic world. Sometimes, the course of action is not obvious because cues are ambiguous (i.e., they activate more than one possible internal representation), or multiple behaviors might be triggered and the one that is optimal for a given situation is at a disadvantage relative to better-established (more automatic) alternatives. In these situations, ambiguity needs to be resolved by our internal states and intentions, by knowledge of possible and desired future outcomes (goals), and by knowledge of what means have been successful at achieving them in the past. This information is used to activate the same basic sensory, memory, and motor processes that are engaged during automatic behaviors. Only now, they are not triggered by cues from the environment. They are orchestrated in a top-down fashion by our expectations about goals and means. So, this mode of behavior is controlled in the sense that we (our knowledge and intentions) are in charge, not the environment.

A tenet of modern studies of behavior is that this knowledge is obtained by learning mechanisms that detect and store associations between cues, internal states, and actions that predict goal attainment (reward) (Dickinson, 1980). Insofar as primates are capable of navigating situations that involve diverse relationships across a wide range of informational domains, it follows that a neural system for cognitive control must have access to information from many brain systems and the ability to encode the goal-relevant relationships between them.

As implied above, the fundamental operation of a cognitive control system is selection, choosing which basic sensory, memory, and motor processes are activated at a given moment. Selection is central because of our very limited capacity to engage in controlled behaviors. This is evident to anyone who has tried to talk on the phone and answer e-mail at the same time; we can only think about a limited number of things at a time. This is in contrast to our high capacity for automatic processes. Because they can be triggered by the environment, any number of them can be fired off at once, as long as they do not come into direct conflict with one another.

It makes sense that brain mechanisms for cognitive control would evolve with this capacity limitation. First, there is the trade-off between amount of information and depth of analysis; focusing processing on a narrow band of information relevant to a current goal allows a much more elaborate analysis of a situation and available options. This single-mindedness also allows us to stay on track; processing information not relevant to a current goal increases the chance for distraction. In fact, in many views of cognition, *control* and *attention* are virtual synonyms. It follows that a neural system for cognitive control must have the infrastructure and mechanisms for selecting goal-relevant, and suppressing goal-irrelevant, processes throughout the cerebral cortex.

Also, as previously implied, the cognitive control system must be highly plastic. Virtually all voluntary, goal-directed behaviors are acquired by experience, and given that humans and other primates are capable of rapid learning of new volitional behaviors, the cognitive control system must have an equal capacity for rapid learning.

The cognitive control system must also have a way to deal with the gaps in time that are inevitable with goal-directed behaviors. Information about predicted goals and means must be brought on-line before the behaviors are executed and maintained until the current task is completed. Also, because goal-directed behaviors typically are extended over time, we often must wait for additional information or for a more opportune time to execute an action. The ability to keep goal-relevant information on-line and available for processing is called *working memory* (Baddeley, 1986). It is less critical for automatic processes because they are immediate: a stimulus triggers an already established circuit.

To bring the role of the cognitive control system into further focus, consider a model proposed by Norman and Shallice (1986). It illustrates a widely accepted view of the architecture of cognition (Fig. 104.1). At the lower level, there are the automatic processes (sensory analysis, memories, details of motor acts, well-learned skills, etc.). The system is in automatic mode when processing flows through the lower level, from input to output, along established pathways without any hindrance or modification: sensory inputs

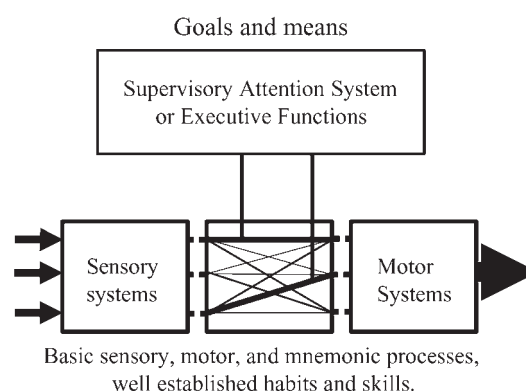

FIGURE 104.1. Two levels of cognitive processes proposed by Norman and Shallice (1986), among others. Represented here is the notion that specialized functions that acquire information about goals and means select and coordinate among innate and well-established routines.

trigger their analysis, which triggers long-term memories, actions, and so on.

A brain that contained only this lower level of processing, however, would belong to an automaton. It would only be capable of reacting reflexively to stimuli that happen to flow into it. To allow the system to engage in proactive, goal-directed behavior, most theories of cognition posit the need for “executive” functions specialized for acquiring and representing goals and means. These functions come on-line when a course of action is uncertain or if a reflexive, automatic reaction associated with a given input would produce an undesirable outcome. They send top-down signals that control the flow of processing through the lower (main) level by favoring goal-relevant processes and suppressing irrelevant ones. Because of this role, Norman and Shallice refer to the executive functions as the *Supervisory Attention System*. Another example of this two-level processing hierarchy is Baddeley’s *Working Memory* model, which posits an executive controller that selects the information that is held in lower-level short-term sketchpads (Baddeley, 1986).

To summarize, we have some expectations about the properties of a neural system for cognitive control. It should be a brain region where diverse information from other brain systems can converge and be synthesized into representations of goals and means. It should have a great capacity to learn from experience. It should have the ability to maintain that information on-line and a means for it to influence other brain systems. A rapidly accumulating body of evidence regarding the PFC suggests that it meets these requirements.

Anatomy of the PFC

The PFC consists of a collection of cortical areas that differ from one another on the basis of size, density, and

distribution of their neurons (Fig. 104.2). Generally, it is divided into 3 subdivisions (dorsolateral, ventrolateral, and orbital/medial), but these can be further subdivided into at least 18 distinct areas.

As we learned above, the theme of cognition (and learning and memory) is synthesis. While the brain's different sensory systems adopt a divide-and-conquer approach to analysis of the external world, it is the job of the learning and memory systems to put the results together to form the big picture. The anatomy of the PFC has long suggested such a role. Like other brain regions involved in learning (such as the basal ganglia and hippocampus), the PFC is a site of convergence of information from many different brain systems.

Different PFC regions have partially unique but overlapping connections with other brain areas. A major difference is between the lateral and orbitofrontal PFC. The lateral PFC is most directly connected with sensory and memory systems that deal with the outside world, while the orbitofrontal PFC is more associated anatomically with medial temporal limbic structures critical for long-term memory and "internal" information, such as affect and motivation (Barbas and Pandya, 1991).

The lateral PFC (dorsolateral and ventrolateral) receives projections from and sends projections to the visual, somatosensory, and auditory areas in the occipital, temporal, and parietal cortices (Barbas and Pandya, 1991; Pandya and Barnes, 1987). There is a good degree of multimodal convergence in these connections. Several lateral PFC areas receive overlapping inputs from at least two sensory modalities. Further, the lateral PFC is interconnected with areas such as the rostral superior temporal sulcus, which has neurons that can be activated by two or three modalities (visual, auditory, and somatosensory). The PFC is not directly connected with primary sensory areas but instead is interconnected with secondary or *association* sensory cortex. This suggests that the PFC operates on highly processed information.

The dorsal PFC (particularly dorsolateral area 46) is heavily interconnected with motor system structures and may be a primary output of the PFC to systems mediating voluntary behavior. It is interconnected with regions important for body and eye movements such as the supplementary motor area (SMA), the pre-SMA, and the rostral cingulate, premotor cortex, cerebellum, superior colliculus, and frontal eye fields (area 8). As with sensory cortex, there are no direct connections between the PFC and primary motor cortex; the PFC is instead connected with premotor areas that, in turn, send projections to primary motor cortex and the spinal cord.

There are also dense interconnections between the PFC and basal ganglia (BG), a set of subcortical structures that are highly interconnected with the motor system. Like the

PFC, the BG receives converging inputs from many cortical and subcortical regions. Unlike the PFC, however, the BG does not project back to the cortical regions that provide it with input; it projects primarily back to the motor cortex and the PFC (Graybiel, 2000; Houk and Wise, 1995). This suggests that the BG influences a wide range of brain functions, although its primary involvement may be with motor output. The anatomical "loops" between the PFC and BG suggest a close functional relationship. Passingham (1993) has suggested that the BG is a major conduit by which reward signals from dopaminergic midbrain ventral tegmental area neurons can influence the PFC.

The orbitofrontal and medial PFC are more strongly connected with limbic system structures than is the lateral PFC. They have direct and indirect (via the thalamus) connections with the hippocampus and associated neocortex, the amygdala, and the hypothalamus. They also have strong connections with olfactory and gustatory cortices, but relatively weaker connections than the lateral PFC to parietal and temporal cortices.

As in other parts of the neocortex, many PFC connections are local; the subdivisions are all reciprocally interconnected, as are their constituent areas (Barbas and Pandya, 1989). Thus, while different PFC subdivisions may have a somewhat privileged relationship with certain brain systems, the PFC also has the intrinsic circuitry to piece together this information as needed. Further, because the PFC is reciprocally connected with many different brain systems, it has the links to influence processing throughout the forebrain. Evidence that this infrastructure is used for cognitive control comes from the pattern of behavior deficits following PFC damage. This is discussed next.

Behavioral effects of PFC damage in humans

PFC damage does not result in simple deficits; there is relatively little overt impairment, at least on superficial examination. Sensory capabilities are intact, patients with PFC damage can remember events and facts, and they appear remarkably normal in casual conversation. Despite the superficial appearance of normality, however, PFC damage devastates a person's life. Patients have trouble staying employed, staying married, or even completing errands. This is due to a constellation of deficits, described next, that seems to reflect a selective loss of cognitive control, that is, a "dysexecutive" syndrome.

GOAL NEGLECT Humans with PFC damage seem to behave without any consideration for future consequences. They become *stimulus-bound*; they engage in whatever habitual behaviors happen to be triggered by cues in the immediate environment; they seem to lack any direction toward unseen goals or any weighing of the consequences of their

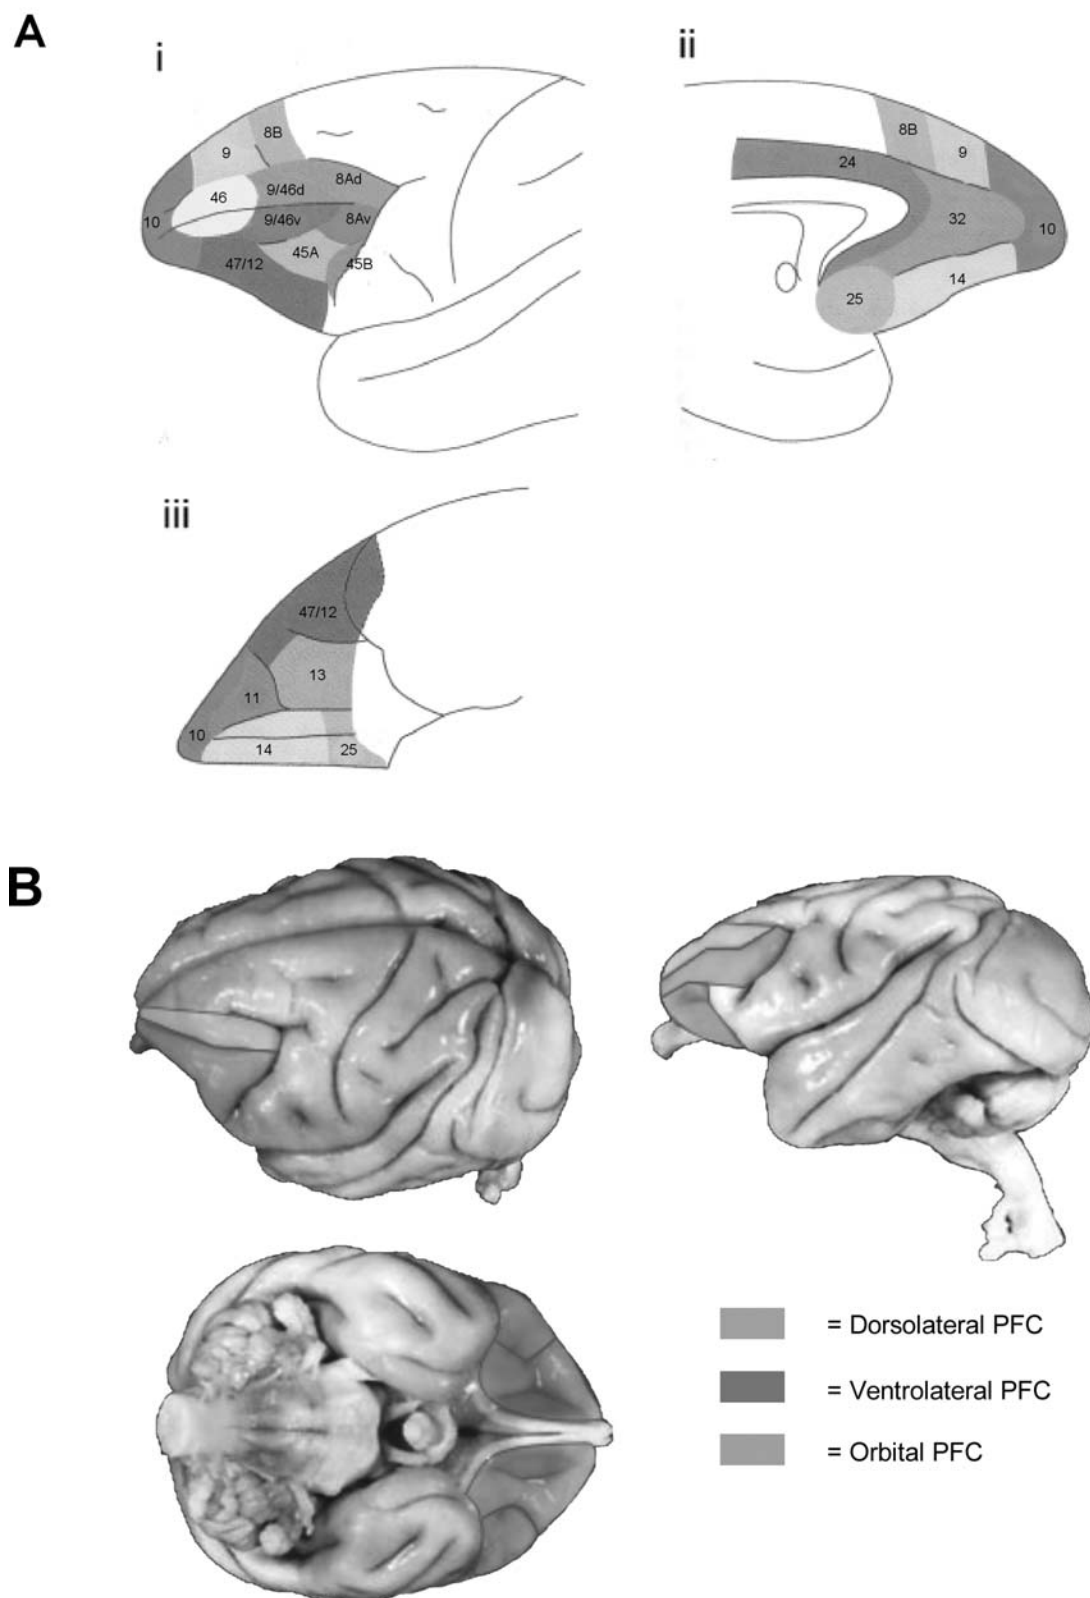

FIGURE 104.2. The prefrontal cortex of the macaque monkey. *A*, Cytoarchitectonic areas of the PFC from Petrides and Pandya

(1994). *B*, Major subdivisions of the PFC. Brain figures obtained from www.brainmuseum.org. (See color plate 77.)

actions. As you can imagine, people in this condition can be easily taken advantage of. There was the case of Elliot, a responsible, successful accountant, who, within a few years after PFC damage, got divorced, married and divorced again, fell in with a disreputable business partner, and lost his business (Eslinger and Damasio, 1985). Elliot became impulsive, lurching from one catastrophe to another based on his momentary whims and, apparently, the selfish suggestions of others who wished to take advantage of him.

This impulsiveness is well illustrated in what is known as *utilization behavior* (Shallice et al., 1989). A patient with PFC damage will habitually pick up and use nearby items. For example, if a doctor leaves a comb on the desk, the patient will pick up the comb and start combing his hair. In (hopefully) one case, the patient made use of a urinal that had been left on a desk. Formal tests of disinhibition include the Stroop Test (Fig. 104.3A), which requires a patient to name the color of the ink in which a word is written rather than read the word. The trick is that the word is the name of another color, and to perform the task it is necessary to suppress the reflexive reaction of reading the word. Following PFC damage, patients have difficulty with this. That is, they have trouble overcoming an automatic, reflexive response in order to emit one that is in accord with the task demand.

This inability to ignore irrelevant distractions and persist toward a goal has been termed *goal neglect* (Duncan et al., 1996). A more everyday example is the Multiple Errands Test of Shallice and Burgess (1991). The patient is required to perform various errands in a shopping center, such as obtaining a copy of the previous day's newspaper. Patients take much longer than control subjects. They habitually enter irrelevant shops just because they happen to be passing them and thus are repeatedly distracted from their principal goal.

PERSEVERATION Difficulties of PFC patients extend beyond overriding strong impulses and highly ingrained reflexes; they even have trouble overriding recently, and therefore weakly, established behaviors. Because other learning and memory systems are intact, they can learn to respond to specific cues in specific ways. But then they become “stuck” in that behavioral rut.

Consider a classic test of PFC impairment, the Wisconsin Card Sorting Test (WCST) (Fig. 104.3B). The patient is required to sort a deck of cards which contains a number of symbols. The cards differ from one another in the color, shape, and number of the symbols, and the patient must learn to sort them by trial and error, with only feedback about whether their responses are correct or not. Patients with PFC damage can learn an initial sorting

FIGURE 104.3. Tasks sensitive to PFC damage in humans. A, Stroop task. B, Wisconsin Card Sort. C, Tower of London task. D, Gambling task. See text for explanation of tasks. (See color plate 78.)

criterion, such as “sort by shape.” However, when the criterion is changed, for example, to “sort by number,” they cannot inhibit the previous rule in order to learn the new one (Milner, 1963). This is called *perseveration*, and it is seen in a wide variety of tasks. It seems that the remaining learning and memory mechanisms can potentiate straightforward responses to certain cues (like color), but without a specialized brain system for quickly figuring out goals and directing behavior toward them, the system can never acquire the experience necessary to draw behavior away from the previously rewarded one.

PLANNING In the examples described above, the basic units of behavior remain intact. What is lacking is the ability to organize them to pursue a goal. One patient, when making coffee, first stirred it and then added milk. Wilder Penfield’s sister had a large tumor removed (by Wilder) from her frontal lobes. She had been an excellent cook, and while her basic

skills remained, she seemed unable to organize the cooking of a meal. She moved haphazardly from preparing one part of the meal to another, so that some parts of the meal were burnt while others had hardly been started.

A formal test of planning is the Tower of London Test; it requires the patient to think several moves in advance (Fig. 104.3C). There are three vertical posts and three colored rings that can be placed on the posts. The three posts are of different lengths such that the first post can accommodate all three rings, the second post two, and the third post just one. From an initial starting position, the patient is asked to move the rings one at a time, from one post to another, to attain a specified goal pattern. This requires patients to use information about the goal state to anticipate which actions will move them progressively closer to it. Patients with PFC damage make many more moves than necessary to reach the final goal position, if they do at all.

EVALUATING CONSEQUENCES Learning new goal-directed behaviors depends on the capacity to evaluate the consequences of our actions so that, in the future, an optimal plan can be chosen. Evidence that certain types of PFC damage impair this process comes from a gambling task (Bechara et al., 1994) (Fig. 104.3D). The patient has to choose cards from four different decks in an effort to win “money.” Some cards win the patient some money, but others cause the patient to lose money. Unknown to the patient, cards from two decks will occasionally win large amounts of money, but they are also occasionally associated with very large losses, and choosing from them will result in a net loss. Choosing from the other two decks results in winning smaller amounts of money, but the losses are also smaller, and choosing from these two decks will result in a net profit. Control subjects quickly learn to limit their choices to the second two decks associated with smaller rewards but a profit, while patients with orbital PFC damage continually choose from the decks associated with large rewards and larger losses until they lose all their money.

WORKING MEMORY It has been suggested that many of the difficulties following PFC damage can be explained, at least in part, by a loss of working memory. This is the kind of short-term memory that one relies on when rehearsing a phone number. It is called *working memory* because the information is forgotten as soon as it is no longer relevant. The hypothesis that PFC damage impairs working memory stems from the observations that PFC damage in monkeys (see below) impairs a spatial delayed-response task that requires them (among other things) to remember the location of a stimulus or behavioral response over a brief delay of several seconds.

At first, an analogous impairment was not detected in humans, possibly because the patients verbalized the remem-

bered location (e.g., “it’s on the left”), which makes the task easier. But studies using abstract patterns that could not be easily encoded verbally revealed that the patient’s nonspatial working memory was impaired (Milner et al., 1985). Also, the *two-back* task has been shown to be sensitive to PFC damage or dysfunction. In this task, humans see a sequence of letters and must respond only if a current letter matches one seen two letters ago. Because this involves matching to a specific stimulus, it may rely on working memory rather than other, more passive, forms of immediate memory such as those that automatically detect repetition (Miller and Desimone, 1994). As will be discussed in the next section, however, PFC damage can impair performance on tasks that have no obvious working memory component.

Behavioral effects of PFC damage in monkeys

The PFC is not a single area, but a collection of cortical areas with unique patterns of inputs and outputs. Because PFC damage in humans happens by accident or illness, it is often diffuse and rarely limited to a specific area or subdivision. This makes it difficult to determine whether different PFC regions are specialized for different functions. The diffuse damage seen in humans can also lead to difficulty in assigning functions to the PFC in general; damage often encroaches on neighboring regions, such as the premotor cortex, the cingulate cortex, and the insular cortex. These problems can be circumvented by experimental induction of precise lesions in monkeys.

DELAYED-RESPONSE TASKS One of the most profound deficits following frontal lobe damage in monkeys occurs during delayed-response tasks. In a spatial version, the monkey sees a reward hidden at one of two locations. Then a screen is lowered and the monkey is made to remember the cued location by discouraging “cheating” strategies such as keeping its hand near the rewarded location. After a brief delay, the screen is raised and the monkey is allowed to choose a location (Fig. 104.4A). Monkeys with large PFC lesions behave as if they forgot where the reward was hidden, even after delays of just a few seconds. Later, it was shown that lesions restricted to the dorsolateral PFC alone could produce the same deficit.

Another type of delayed-response task, object matching, is impaired by damage to the neighboring ventrolateral PFC. In this task, monkeys are shown an object (the sample) and then, after a brief delay of several seconds, must choose the same object (the match) from one or more nonmatching objects (Fig. 104.4B). The most severe deficits are observed when the same two objects are used repeatedly, requiring the monkey to remember which of the two objects it has seen most recently.

FIGURE 104.4. Tasks sensitive to PFC damage in monkeys. Check marks indicate correct choice; Xs indicate incorrect choices. The arrow in *E* indicates the monkey's choice in a self-ordered task. *A*, Spatial delayed response. *B*, Delayed matching-to-sample. *C*, Spatial reversal. *D*, Object reversal. *E*, Object self-ordered search task. (See color plate 79.)

These deficits are often explained by a loss of working memory. There are other interpretations, however. One possibility is that dysfunction is more broad than a specific deficit in working memory; it may reflect the type of goal neglect seen in humans with PFC damage. Consider the spatial delayed-response task. In an often-used oculomotor version, a cue is flashed at one of several possible locations in the visual periphery while monkeys maintain central gaze (Funahashi et al., 1989). After a brief delay, the monkeys are given a “go” cue and must move their eyes to the remembered location of the cue. Monkeys are impaired at this, but unimpaired when the memory delay is removed and they can simply look at the cue when it is flashed on. A loss of working memory to bridge the delay is a reasonable interpretation, but another possibility is that the “no delay” version of the task can be performed by reinforcing a reflexive orienting response to the onset of a stimulus (the cue) in the visual periphery. By contrast, when a delay is imposed,

there is nothing in the environment to indicate the correct response at the time of the action. The monkey's behavior must then be guided by internal information, not only by the memory of the cue but also by the knowledge of the formal demands of the task. In terms of the architecture pictured in Figure 104.1, the no-delay version of the task does not require the higher-order functions because the correct sensory cues can trigger the correct lower-level pathways at the correct time.

In fact, PFC damage in monkeys can impair performance on tasks that have no obvious working memory component. For example, monkeys with lesions of the ventrolateral PFC are impaired on a simultaneous color-matching task. In this task, the monkey is presented with a sample color and two test colors simultaneously. The monkey must choose the test color that matches the sample color. PFC lesioned monkeys were impaired despite the fact that the task involved contains no delays and therefore no working memory requirements. One possibility is that PFC damage produces impairments when, in the absence of a clear signal from the environment, monkeys must follow the logic of a task (e.g., “if the sample color is red, then choose the red stimulus” or “if the cue was on the left, then go to the left after the delay”). Support for this comes from studies showing that PFC damage produces impairments in conditional learning.

CONDITIONAL LEARNING TASKS Conditional learning tasks have been used to test the ability of animals to gain volitional control over behavior. They require learning of associative relationships that are arbitrary and extend beyond the simple one-to-one mappings that underlie reflexive reactions. Whether or not a given response is the correct response to a given cue depends on additional contextual information. For example, reaching for a beer can be rewarding, but only if one takes other information into account; if the beer belongs to another patron, the result could be disastrous. The need to take into account complex relationships in order to decide among alternative actions is presumably the reason cognitive control has evolved.

Monkeys with PFC damage are impaired at conditional learning tasks. For example, monkeys can be trained to learn associations between three distinct visual cues and three directional movements of a joystick. Each cue instructs a specific movement of the joystick. One means “up,” the other “down,” and so on. Bilateral damage to the ventrolateral and orbital PFC impairs this learning. Disconnecting the PFC from its inputs from high-order sensory cortex also results in conditional learning impairments. Humans with PFC damage are impaired on conditional learning tasks analogous to those conducted in monkeys. This deficit may depend on which PFC region is damaged; some studies report no conditional learning deficit following dorsolateral PFC damage in monkeys.

REVERSAL TASKS Perseveration in monkeys following PFC damage has been demonstrated using reversal tasks. In these tasks, reward is alternated between two locations (Fig. 104.4C) or between two objects (Fig. 104.4D), and monkeys must learn to choose the item that had not been rewarded most recently. This requires them to override a prepotent response (one that was just reinforced) in order to follow the task demands. Although deficits in reversal tasks can be seen following damage to several PFC regions, particularly large deficits occur after orbital (ventral) PFC damage. Monkeys perseverate, continuing to choose the location or object under which the reward had first been hidden. This has led to speculation that orbital PFC may be particularly important for inhibitory control (i.e., inhibiting prepotent responses).

OBJECT RECOGNITION TASKS Monkeys with lesions of the orbitofrontal PFC show impairments in visual recognition. This ability is tested using a delayed nonmatching-to-sample task. The monkey is presented with an object and then after a delay of a few seconds, is presented with that same object along with a novel object. New objects are used on each trial so that the monkey can perform the task by recognizing which of the two objects it has previously seen in order to pick the novel object. However, patients with damage to the homologous PFC region do not show this recognition deficit. One possibility for this discrepancy is that the deficit does not lie in recognition per se, but rather in the ability to learn the rules of the task. In particular, it has been suggested that the difficulty lies in making the association between the abstract quality of novelty and receiving a reward. This aspect of the task is not required in human patients, because the patients are explicitly told the rules of the task; monkeys have to learn them by trial and error.

FUNCTIONAL TOPOGRAPHY OF THE PFC A major question concerning prefrontal function is whether different processes can be mapped onto its different areas and subdivisions. The clearest example of a functional difference is the previously mentioned “external” versus “internal” emphasis of the lateral and orbitofrontal PFC, respectively. Observations from neuropsychological studies, such as those discussed above, have naturally led to attempts to assign more specific functions to different PFC areas. For example, the dorsal PFC has been suggested to be responsible for spatial memory, the ventral PFC for object memory, and the orbital PFC for inhibitory control in accord with their preferential connections with the parietal, inferior temporal, and limbic system structures, respectively. As subsequent studies have shown, however, PFC topography is not so simple and straightforward.

It is important here to discuss what constitutes evidence for a functional dissociation between two different brain

areas. In order to conclude that they perform, or at least emphasize, two different functions, it is necessary to demonstrate a double dissociation. A monkey with lesion X must be impaired at process A but not process B, while a monkey with lesion Y must be impaired at process B but not process A. A single dissociation, for example, showing that lesion X impairs process A but not process B, is insufficient evidence since this pattern of results could be achieved simply because the test used to assess process A is more sensitive than the test used to assess process B. It is often the case, however, that monkeys are tested on just one task, and any evidence for a double dissociation can only be inferred across different studies and (often) different laboratories. This complicates the interpretation because any differences in training and testing procedures and in the extent of the lesions are confounding factors. As a result, a clear double dissociation between different PFC regions has been difficult to establish.

Consider the hypothesis that different PFC regions mediate spatial versus object working memory. As mentioned above, some lesion studies have suggested that the dorsolateral PFC mediates visuospatial working memory, while the ventrolateral PFC mediates visual object memory tasks. This suggestion is based on (independent) observations that damage to the dorsolateral PFC impairs spatial delayed-response tasks but not object-matching tasks, while ventrolateral PFC lesions do impair object matching. However, further studies indicated that the story is not so straightforward.

For example, dorsal PFC lesions can impair performance on tasks that do not have a spatial component, such as object self-ordered search tasks. Here, the monkey is presented with three objects covering rewards and must choose each object in turn to get the reward, but after each choice a screen is lowered and the object's positions are shuffled (Fig. 104.4E). Thus, the monkey must continually remember which of the three objects it has already chosen. Also, monkeys with ventral (orbital) PFC lesions are impaired on both object and spatial reversal tasks. Furthermore, ventrolateral PFC lesions impair an auditory task in which monkeys must learn to respond to one tone and refrain from responding to another.

Neurophysiological studies paint a similar picture. There are examples of bias in the distribution of neurons that are sensitive to object identity or location in space (especially for the small population of highly specialized *face cells*) (Wilson et al., 1993). But there is also a good deal of intermixing of object and space (and other types of information). Up to half of lateral PFC neurons have been reported to be selective for both objects and their visual field location; many object-selective neurons have receptive fields just a few degrees in diameter (Rainer et al., 1998). Interestingly, most of the studies reporting integration of these (and other) types of

sensory (and motor) information have been conducted in monkeys trained on tasks in which their integration is needed for the task. By contrast, studies reporting areal segregation of information domains have used tasks in which object and space are separated into different tasks, or paradigms in which monkeys passively experience the stimuli and thus do not engage PFC functions. The great dependence of PFC neural properties on task demands will be discussed in greater detail below.

Likewise, the hypothesis that the orbital PFC is responsible for a monolithic function called *inhibitory control* is not straightforward. If more refined tests are used, inhibitory control deficits can also be observed in monkeys with lesions of the dorsolateral PFC. For example, marmosets were trained on a WCST-like task in which they had to choose stimuli on the basis of a rule, such as “choose by shape” and “choose by color.” When they were required to switch between different rules, monkeys with lesions of the dorsolateral PFC perseverated by continuing to choose on the basis of the previous rule, while monkeys with lesions of the orbital PFC were unimpaired (Dias et al., 1996). However, when the same stimuli were used in an object reversal task, in which the monkeys had to choose one object for a reward and then choose another object, monkeys with lesions of the orbital PFC perseverated by continuing to choose the object that had initially been rewarded. By contrast, the performance of monkeys with lesions of the dorsolateral PFC was normal. This suggests that both the dorsolateral and orbital PFC contribute to inhibitory control, but the dorsolateral PFC may be more engaged by inhibitory control over rules that involve shifts of attention between a stimulus dimension (e.g., color versus shape), while the orbital PFC may be more engaged by inhibitory control over choices based on associations between objects and rewards (Roberts and Wallis, 2000).

In short, the PFC is a complex brain region that cannot easily be split along simple lines. Its functional organization is an active area of research, particularly with the advent of functional imaging in humans. Although a clear picture has yet to emerge, we can make some general predictions. First, although broad categories or gradients of organization may exist, it is unlikely that different classes of information will be represented in a modular, or discretely localized, form. Complex behavior requires that we recognize and respond to relationships across diverse dimensions. Second, learning is likely to play an important role in the information represented in the PFC and hence in its organization.

COGNITIVE ARCHITECTURE AND PFC DAMAGE The pattern of deficits following PFC damage seems to reflect a selective loss of the higher-level functions from the bipartite cognitive architecture pictured in Figure 104.1. Well-established automatic routines on the lower level are intact and available to

be triggered by the appropriate sensory cues. But without the higher-level functions specialized to acquire and represent goals and means, the system would be at the mercy of the environment, ruled by whatever sensory inputs happen to flow into the system and by whatever thoughts, emotions, and actions are strongly associated with these inputs. Thus, behavior would seem impulsive and disinhibited and reactions inappropriate, because they would be emitted reflexively without any consideration of the future. Further, without the influence of predicted goals to continually drive task-appropriate processes, individuals would be distractible and would easily go “off track” when there are temporal gaps between sensory inputs or between those inputs and the individual’s responses. The system might be capable of learning to react to cues, but this learning would be inflexible. Without the ability to predict goals and means, the system would be stuck in a behavioral rut, always reacting to a cue with whatever behavior it was first associated; in other words, the system would perseverate.

To summarize, we have seen that the PFC is a brain area that has access to the diverse range of information that seems appropriate for a region that provides top-down control to other brain processes, and that its damage results in the goal neglect and impulsivity that would be predicted from a selective loss of the higher-order processes in a two-tier cognitive architecture. To begin to understand the neural mechanisms that help the PFC to play this role, we now turn to studies of its neural properties.

Neurophysiology of the PFC

The multimodal nature of inputs to the PFC is reflected in its neural activity. PFC neurons are activated by visual, auditory, tactile, and gustatory cues and by recalled memories, as well as voluntary limb and eye movements. In short, the PFC has access to the diverse informational domains needed to guide goal-directed behaviors. Its neurons have other properties that seem ideal for a system for cognitive control. PFC neural activity can reflect predicted rewards and learned task contingencies (i.e., goals and means) and keep them on-line during task execution.

REWARD-RELATED ACTIVITY Planning goal-directed behavior requires making predictions about goals and the consequences of events and actions. Evidence that PFC neurons participate in this process comes from studies showing that a large proportion of them encode information about expected rewards. For example, some neurons are activated by the delivery of a reward, while others respond when an expected reward is not delivered. After training, many PFC neurons show responses to visual cues that signal whether a reward will or will not be forthcoming and reflect the identity, size, and preference of an expected reward.

RULE REPRESENTATION Rules describe the logic of a goal-directed task. Conditional (if-then) associations (see “Behavioral Effects of PFC Damage in Monkeys”) are prime examples. As mentioned above, they must be acquired mechanisms that detect and store reward-predicting contingencies (associations) between events and actions. Many studies have shown that PFC neurons do just that. Because these studies have typically employed visual cues and either limb or eye movements, most of these studies have focused on the lateral PFC, which is directly connected with the visual and motor systems.

Asaad et al. (1998) recorded from the lateral PFC as monkeys learned associations between each of two visual cues and directional eye movements. Through trial and error, the monkeys learned to saccade to the right after one object was presented and saccade to the left after another object was presented. After this was learned (in about 10 to 15 trials) and practiced (for about 15 more trials), the associations were reversed and the monkeys learned the opposite contingencies: to saccade leftward after presentation of the object that had previously been associated with a rightward saccade and vice versa. Almost half (44%) of randomly selected lateral PFC neurons reflected the learned contingencies; they encoded specific associations between cues and saccades. For example, a given cell might be strongly activated only when object A instructed “saccade left” and not when object B instructed the same saccade or when object A instructed another saccade. This effect is not limited to associations between cues and actions. As noted above, many PFC neurons encode associations between a visual cue and a reward. Lateral PFC neurons can also reflect learned associations between visual and auditory stimuli and between two visual stimuli.

These studies suggest that PFC neurons represent relatively simple task contingencies. Others have shown that they can also encode more complex demands. For example, monkeys can be taught to alternate rapidly between different rules. Following a given cue, they can learn to direct a response to either the cue’s location (spatial matching rule) or an alternative location associated with the cue (associative rule), depending on which rule is currently in effect. When tested in this fashion, many PFC neurons show rule-specific activity (Asaad et al., 2000; White and Wise, 1999). A given PFC neuron might respond to a visual cue when the monkey is using an associative rule but exhibit weak or no activity under identical sensory and attentional conditions that differ only in that the monkey is instead using a spatial rule. Neurons also show reliable shifts in their baseline activity that may reflect a signal that keeps track of which rule is currently relevant.

CONCEPTS AND PRINCIPLES In the examples above, lateral PFC neurons were found to encode learned relationships

between specific cues and/or actions. However, it is not always advantageous for us to take the world so literally. A brain limited to recording each specific behavioral contingency that we encounter would need prodigious storage capacity and would bog us down with unnecessary details. Instead, we have evolved the ability to detect the commonalities across experiences and store them as abstract concepts and general principles. For example, knowing that a gadget is a camera imparts knowledge about parts and functions and spares us the need to learn it anew. Similarly, we have general principles for behavior such as dining in restaurants. This allows the navigation of many different situations with a minimal amount of storage and allows us to deal with novelty. By extracting the essential elements from our experiences, we can generalize to future situations that share some elements but may, on the surface, appear very different. Some recent studies have shown that the capacity of PFC neurons to reflect task demands extends to such abstracted representations.

One example comes from a study of perceptual categorization. Freedman et al. (2001) taught monkeys to categorize computer-generated images as cats and dogs. Three prototypical cats (a house cat, a tiger, and a cheetah) and three types of dogs (a German shepherd, a pointer, and a St. Bernard) were morphed, or blended, into single images that contained both cat and dog characteristics. Some images were 80% cat and 20% dog, or 60% dog and 40% cat. Monkeys were taught that if an image was more than half cat or more than half dog, it should be categorized as a cat or a dog, respectively. As many as a third of lateral PFC neurons reflected the category of the images. In other words, a given neuron might be activated in a similar fashion by all the cat images, even though the exact physical appearance of the different cats varied widely.

It is not only useful to group different sensory stimuli into perceptual categories, it is also useful to group different behavioral experiences according to common themes, that is, as abstract rules or generalized principles for behavior. To explore this, monkeys were trained to use two abstract rules; they indicated whether two successively presented pictures were either the same (match) or different (nonmatch), depending on which rule was currently in effect (Wallis et al., 2001). The monkeys could perform this task with novel pictures, thus demonstrating that they had learned two general principles that could be applied to stimuli that they had not directly experienced. The most prevalent neuronal activity observed in the three major PFC subdivisions (dorsolateral, ventrolateral, and orbital) were those that encoded the match and nonmatch rules. This suggests that rule representation may be a cardinal PFC function.

RAPID LEARNING IN THE PFC Insofar as primates can rapidly learn new behaviors, brain regions guiding them

must also have the ability to quickly change properties. PFC neurons do have this capacity. Monkeys can learn new conditional visuomotor associations in just a few trials, and as they do, PFC neural activity is rapidly modified to reflect the new contingencies. Striking examples of rapid experience-dependent neural plasticity come from studies of the frontal eye fields, part of Broadmann's area 8 that is important for voluntary shifts of gaze (Bichot and Schall, 1999). Normally, neurons in this area are selectively activated by saccade targets that appear in certain visual field locations. Monkeys were also trained to search for a target defined by a particular visual attribute (e.g., red). In this case, the neurons in the frontal eye fields acquired sensitivity to that attribute. Monkeys were also trained to search for a different target every day, and it was found that neurons discriminated not only the current target but also distracting stimuli that had been a target on the previous day relative to stimuli that had been targets even earlier. Monkeys were also more likely to make errors in choosing the distracting stimulus. It was as if the previous day's experience left an impression in the brain that influenced neural activity and task performance.

WORKING MEMORY The first observations that PFC neurons have the capacity to keep information on-line and available over multisecond delays were made in the 1970s by Fuster, Niki, and their colleagues. They demonstrated that during delayed-response tasks, many PFC neurons showed sustained activity that seemed to keep information about a cue or response available over multisecond delays. Goldman-Rakic and colleagues used an oculomotor version of the delayed-response task. In this task, monkeys were trained to maintain central gaze while a cue (a spot of light) was briefly flashed at one of eight locations in the visual periphery. Then, after a delay of 1 or more seconds, the monkeys were signaled to move their eyes to the remembered location of the cue. This allowed them to demonstrate that dorsolateral PFC neurons have precise tuning for memories of particular visual field locations (Funahashi et al., 1989). It also showed that PFC delay activity depends on dopamine (DA) receptors, neurotransmitters implicated in signaling reinforcements and thus central to acquiring and sustaining goal-directed behaviors.

PFC activity sustains brief memories of a wide range of behaviorally relevant cues: objects, colors, the frequency of a vibration to the hand, and forthcoming movements. Similar activity is also evident in the sensory and motor systems. This is not surprising; sustained activity is evident in many brain structures and must play a role in many neural processes ranging from sensory afterimages to holding a motor state. However, what separates more cognitive short-term memory processes such as working memory processes from such lower-level processes is specificity and robustness. Working memory selectively retains task-relevant informa-

tion (rather than just any stimulus) and does so over potential distractions. PFC neurons do have this ability. For example, when monkeys are required to sustain the memory of a sample object across a delay period filled with visual distractors that require attention and processing, sustained activity within the prefrontal cortex can still maintain a memory of the sample object (Miller et al., 1996). By contrast, sustained activity in visual cortical areas seems more labile; it is disrupted by the presence of distractors. Following a distracting stimulus, neural activity reflects the distractor rather than the stimulus the monkey is retaining in working memory. This particular ability is not unique to the PFC. Some neurons in the entorhinal cortex, a region critical for memory, can also maintain sample-specific delay activity across intervening stimuli.

The ability of PFC neurons to "latch onto" a behaviorally relevant input and maintain it robustly has been proposed to depend on gating signals that instruct the PFC network when to maintain a given activity state. This may come from reward-related signals from DA neurons in the midbrain and basal ganglia. These neurons are activated by reward or, importantly, by cues that predict that a reward is forthcoming (Schultz and Dickinson, 2000). In many behavioral tasks, presentation of the cue at the start of the trial is a good predictor that a reward is forthcoming. A burst of DA at this time could strengthen the current PFC representation, protecting it against interference from disruption by distracting information until another DA influx reinforces another representation (Braver and Cohen, 2000; Miller and Cohen, 2001). Local injection of DA antagonists in the PFC does block delay activity in the PFC. Further, the anatomical loops between the PFC and basal ganglia have been suggested to play a role here. Neural activity propagating around the loops may help sustain activity, and the basal ganglia have been suggested to provide a means by which DA signals can influence PFC activity (Passingham, 1993).

Theories of PFC and cognitive functions

The behavioral, anatomical, and neurophysiological observations reviewed above have naturally led to theories of PFC function. There is no model that encompasses all the mechanisms needed for cognitive control. Rather, different theorists have emphasized different aspects of PFC function.

WORKING MEMORY One view of PFC function emphasizes its role in maintaining behaviorally relevant cues on-line over brief (multisecond) temporal gaps (Goldman-Rakic, 1987). The PFC acts like a temporary scratch pad for the inputs it receives from other cortical systems. The importance of such a store for cognition was discussed above but is also appar-

ent to anyone who has tried to do math in her head; intermediate answers and operations must be buffered in a way that allows them to be kept “in mind.” Other deficits following PFC damage are thought to be sequelae of the working memory deficit. Patients may have difficulty planning or appear disinhibited because, without working memory, goal-relevant information is lost over all but the briefest delays, and thus their behavior takes its cue from the immediate environment.

As previously discussed, working memory is essential to controlled processing because goal-directed behaviors extend over time. Support for a role of the PFC in working memory comes from numerous studies showing sustained activity (or correlates of it) in the PFC during working memory tasks. But working memory cannot be the whole picture. It is difficult to explain voluntary behavior without positing additional mechanisms; for example, what determines what enters working memory and what is maintained? PFC involvement in working memory is likely part of a broader role in cognitive control.

SOMATIC MARKER HYPOTHESIS According to this hypothesis the orbitofrontal PFC is responsible for labeling cues or situations with *affective significance* (Damasio, 1994). It associates memories of past affect-laden events with a representation of the state of the autonomic nervous system that the event evoked. This tags the memory of the past event with a *somatic marker* that helps individuals make decisions. Similar events in the future can then evoke a “gut feeling” of the appropriate course of action by recall of the somatic marker. This is particularly helpful in very complex situations where it is difficult to evaluate all the pros and cons and their probabilities. Patients with damage to the orbitofrontal PFC may have difficulty reaching decisions, because no alternative will be obviously more emotionally preferable than others. They may make decisions randomly or impulsively and appear to be disinhibited. Support for this hypothesis comes from impairments on a gambling task (see “Behavioral Effects of PFC Damage in Humans”) following orbitofrontal damage in humans. This task is thought to depend on gut feelings because the probabilities associated with each deck of cards are too difficult to evaluate consciously. In addition, patients with orbitofrontal PFC damage do not show elevated skin conductance responses (a measure of autonomic function) preceding a choice from a risky deck, as normal subjects do.

MULTIPLE PROCESSING LEVELS This view of PFC function posits that there are different levels of cognitive processing that are localized in different PFC regions (Petrides, 1996). The lateral PFC is where information is first received by the PFC and processed. It is involved in simple functions such as maintenance and retrieval (recall) of information from

long-term storage in posterior cortex. For more elaborate processing, information is transferred to the middorsal PFC. This is where multiple behaviors are monitored and information is manipulated. For example, the lateral PFC can rehearse a phone number, but the middorsal PFC would be needed if you had to say it backward. Evidence supporting this hypothesis comes from neuroimaging studies in humans and lesion studies in monkeys. For example, when humans perform tasks that have manipulation requirements, there is greater blood flow into the middorsal PFC compared to the lateral PFC. By contrast, the reverse blood flow occurs if only simple maintenance is required.

RULE ACQUISITION AND REPRESENTATION Because knowledge about goals, means, and consequences is vital to planning and implementing complex goal-directed behavior, several investigators have suggested that the PFC is likely to play a central role in the acquisition and representation of rules. The PFC as a neural system for acquiring task contingencies was first proposed by Joaquin Fuster (1989). He suggested that the sustained and multimodal activity of PFC neurons was used to link together behaviorally associated but temporally separate events and actions.

Others have proposed hypotheses in the same vein. Passingham (1993) suggested that the pattern of deficits following PFC damage results from a loss of the ability to acquire specific types of associations, the conditional if-then rules (see “Behavioral Effects of PFC Damage in Monkeys”) that are used as a test of volitional control. Wise et al. (1996) proposed complementary roles for the PFC and the basal ganglia: the PFC acquires new rules, while the basal ganglia activates already familiar rules. Grafman (1994) suggested that the PFC contains managerial knowledge units (MKUs), sets of basic behavioral rules that can be combined into extended routines. A linked set of MKUs may describe the expected events and appropriate responses for dining in a restaurant, for example.

Miller and Cohen (2001) and their colleagues (Braver and Cohen, 2000; Miller and Asaad, 2002) have proposed models of PFC function that explain how it acquires rules and exerts control over other brain systems. They posit that cognitive control stems from the active maintenance of patterns of activity in the PFC that represent goals and their means. This activity feeds back to posterior cortex, providing bias signals whose net effect is to guide the flow of activity throughout the forebrain along neural pathways that establish the proper mappings between inputs, internal states, and outputs needed to perform the task at hand (Fig. 104.5A).

These representations are developed through the action of reinforcement signals on multimodal PFC circuitry. During learning, when a behavior is successful, reward signals augment the unique pattern of PFC activity evoked

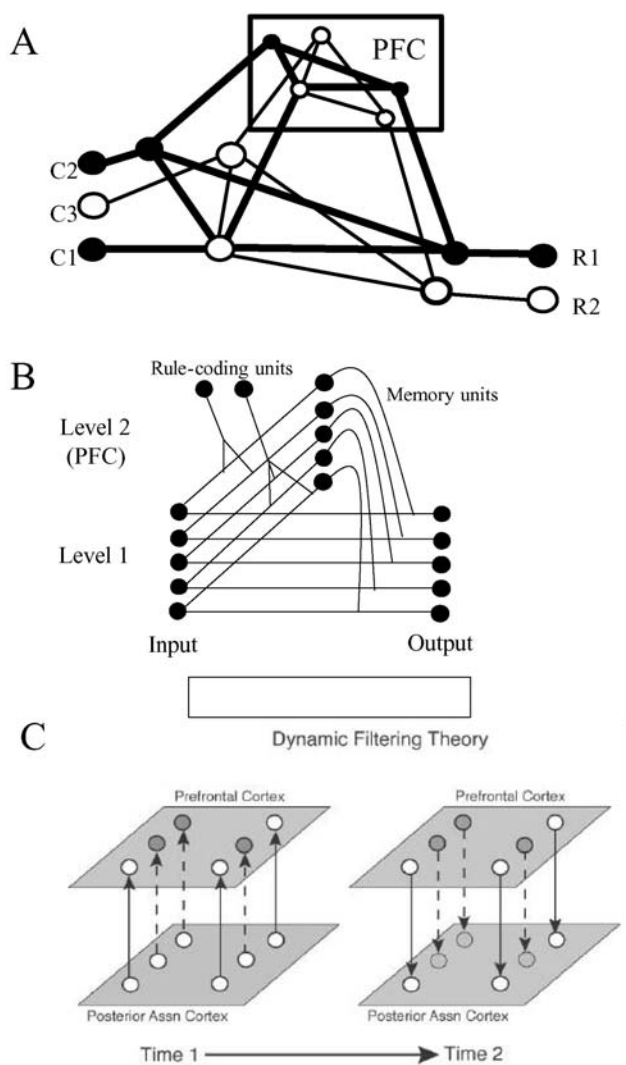

FIGURE 104.5. Models of PFC function. *A*, In the Miller and Cohen model, a task model is formed in the PFC when reward signals link together neurons activated by the events that led to the reward. A subset of cues can then activate the entire representation. Bias signals resulting from the maintenance of this pattern guide the flow of activity along neural pathways that establish the task-relevant mappings between representations of inputs (C1, C2, C3), internal states, and outputs (R1, R2) in posterior cortex. *Thick lines* and *filled circles* denote active processing lines. *B*, The models of Changeux and Dehaene include an executive level (level 2, thought to correspond to the PFC) with rule-coding units and working memory units that gate the flow of activity along lower-level input-output lines. *C*, Shimamura's dynamic filtering model (Shimamura, 2000). At Time 1, a region in PFC is activated by feedforward (i.e., bottom-up) projections from posterior cortex. This activity, along with influences such as task demands, sets up a pattern of activation in PFC (*light circles* = activation, *dark circles* = inhibition). At Time 2, posterior cortex is modulated by PFC via feedback (i.e., top-down) projections that enable both selection of task-relevant and inhibition of task-irrelevant neural activity. (*A* from Miller and Cohen, 2001; *B* modified from Changeux and Dehaene, 1993; *C* provided by Arthur Shimamura, 2000.)

by that situation, action, and consequence by strengthening connections between neurons activated by those events. These representations can begin quite modestly, but with time (and repeated iterations of this process), the PFC representation can “bootstrap” into further elaboration as combinations of events, contingencies between them, and the requisite actions are learned. Midbrain DA neurons have ideal properties for the reinforcement signal. They are activated by rewards and then, after learning, they are activated instead by the cues that predict those rewards and are inhibited when an expected reward is not delivered. As the aim of the organism is to predict the means to achieve a reward, this *reward prediction error* signal is ideal for instructing when the system should learn (Schultz and Dickinson, 2000).

The resulting pattern of PFC activity reflects the task's contingencies and, in neural terms, amounts to a “map” of the neural pathways between inputs, internal states, and outputs needed to perform the task. In short, the intermingling of diverse information in the PFC allows it to quickly plot a map of which neural pathways in the forebrain are successful at solving a task and then holds it on-line so that the rest of the neocortex can follow it. While the PFC may be critically involved in acquisition of this map, its long-term memory may be consolidated in other parts of the brain. The PFC, however, would retain the requisite links to retrieve the appropriate pattern and bring it on-line to guide behavior whenever stimuli are ambiguous (i.e., they activate more than one input representation) or when multiple responses are possible and the task-appropriate response must compete with stronger alternatives.

Similar models of prefrontal and executive function have been proposed. Network models of Changeux and Dehaene (1993) include an executive layer of “rule-coding” units (thought to correspond to the PFC) that controls the flow of information between the input and output layers (Fig. 104.5*B*). Shimamura (2000) proposed a dynamic filtering model of PFC function in which patterns of information sustained by the PFC select and reroute the flow of activity in posterior association cortex (Fig. 104.5*C*).

SELECTION BY BIASED COMPETITION AND SUSTAINED ACTIVITY

To understand how top-down signals from the PFC might select task-relevant neural pathways in other brain regions, consider Desimone and Duncan's (1995) biased competition model of visual attention. In the visual system, neurons processing different aspects of the visual scene (objects or locations) compete with each other for activation through mutual inhibitory interactions. This type of competition seems to occur at every level of the visual system and is thought to be important for enhancing contrast and separating figure from ground. The neurons that “win” the competition and remain active are those that incur a higher level of activity

and thus can suppress their competitors. The biased competition model posits that visual attention exploits this circuitry. In voluntary shifts of attention, a competitive advantage comes from excitatory signals (thought to originate from the PFC) that represent the to-be-attended stimulus. These signals enhance the activity of neurons in the visual cortex that process that stimulus and, by virtue of the mutual inhibition, suppress activity of neurons processing other stimuli.

This notion of excitatory bias signals that resolve local competition in the visual system can be readily adapted to cognitive control in many brain systems (Miller and Cohen, 2001). PFC bias signals can be viewed as the neural implementation of attentional templates, rules, or goals, depending on which brain system is the target of their biasing influence. Because top-down signals from the PFC are multimodal and include information about stimuli, actions, and so on that have become associated through experience, they can simultaneously select goal-relevant inputs, actions, and intervening representations, and thereby dynamically establish a set of neural circuits that would otherwise not exist.

O'Reilly and Munakata (2000) have pointed out that using sustained activation to provide these bias signals has advantages for cognitive control beyond the obvious ability to bridge temporal gaps. As mentioned above, long-term storage of information in the brain is widely thought to depend on structural changes between neurons that either increase or decrease the strength of their connection (i.e., by changing synaptic weights). This hardwiring has advantages for long-term storage and for automatic processes but disadvantages for cognitive control. First, changing synaptic weights has local effects; only the two neurons sharing the synapse are affected, and the information is expressed only when the circuit is fired. By contrast, the goals and means needed for cognitive control must be encoded in a fashion that allows it to influence other brain systems. Second, information encoded by hardwiring is relatively inflexible; well-established circuits will almost always fire off in the same way, and they do not generalize well to novel situations. Encoding the information needed for cognitive control in a pattern of ongoing activation solves these problems. The activity can be propagated across the brain to influence distant circuits, and it allows flexibility; if voluntary behavior stems from a pattern of information maintained in the PFC, changing behavior is as easy as changing the pattern (Miller and Cohen, 2001; O'Reilly and Munakata, 2000).

KNOWING WHEN TO ENGAGE COGNITIVE CONTROL A key question concerning cognitive control that we have not yet discussed is how the system knows when control is needed. Earlier, we noted that cognitive control is necessary when

cues are ambiguous or a reflexive reaction is disadvantageous. Brain systems must therefore exist for recognizing these situations and bringing control functions on-line.

A discussion of these mechanisms is beyond the scope of this review; besides, they are largely unknown. But worth noting here is the work of Cohen, Braver, and colleagues. They posit that the anterior cingulate detects a neural signature of when control is needed—conflict between incompatible representations (Botvinick et al., 2001)—and sends a signal to the PFC. Support for this hypothesis comes from observations of increased blood flow to the anterior cingulate when conflict between two behavioral responses occurs.

Summary

The ability to take charge of one's actions and direct them toward unseen aims is called *cognitive control*. Virtually all theories of cognition posit that cognitive control requires making predictions about available goals and what means might achieve them. This knowledge can then be used to select and coordinate among myriad lower-level, automatic sensory, memory, and motor functions.

The PFC, a brain structure that reaches its greatest complexity in the primate brain, seems to play a central role in cognitive control. It has access to, and the means to influence, processing in all major forebrain systems. Its damage in humans and monkeys results in goal neglect; individuals seem capable only of emitting habitual or innate reactions to the immediate environment, without any consideration or anticipation of future consequences and unseen goals. Neurophysiological studies indicate that PFC neurons seem to mediate the mechanisms essential for a cognitive control system: they are multimodal, they acquire and signal the formal demands of tasks, and they can sustain their activity to keep task-relevant information on-line and available during behavior.

Different theories of PFC function emphasize different contributions to cognitive control: maintenance and/or manipulation of information in working memory, the assignment of affective tags to events and choices, and the acquisition and on-line representation of task rules. None of these theories are mutually exclusive; each may reflect different facets of a system that is necessarily multivariate because of its role in guiding many different behaviors and interfacing with many other brain systems.

XIII THEORETICAL
AND
COMPUTATIONAL
PERSPECTIVES

105 The Evolution of the Visual System in Primates

JON H. KAAS

HUMANS HAVE LONG been impressed with both the similarities and the great differences they see in human behavior and those of the pets and other mammals around them. The obvious differences in behavior have led to interest in and speculation about brain size and structure, brain evolution, and the major functions of brains, especially consciousness. Some of this speculation has not been well informed, leaving the impression that we know little or can know little about brain evolution and that theories of brain evolution are necessarily unsupported and unscientific (for review, see Striedter, 1998). Moreover, we have inherited some misconceptions from the past, especially the belief that evolution is progressive and has a single direction of change (Preuss and Kaas, 1996). This has led to the view that complex human and monkey brains are composed of both old and new parts and that these can be distinguished by appearance. "Old" parts are supposed to look and act old by being poorly differentiated and having crude functions, while "new" parts look new by being well differentiated and having specialized functions (Kaas, 1987). However, evolution does not have a single direction of change, and brains can become smaller; parts can become less differentiated, and parts can be lost (Catania et al., 1999) as well as gained (Kaas, 1989). Old parts can be modified to perform new functions, and new parts modify other parts as they become integrated into existing systems.

Here we consider variations in the organization of the visual system of primates, and the close relatives of primates, as a result of adaptations subserving the differing opportunities and histories of various lines of descent within a framework of inherited and environmental constraints. Brains evolve through a process of "tinkering" with the course of development rather than extensive redesign (Jacob, 1977). Thus, the evolution of the complex human brain is one historical outcome of many possibilities, some of which have been realized by the other primates around us.

The visual system has many subcortical and cortical components, and it would be difficult to discuss them all. As cortex seems to be where mammals are especially variable, and as visual cortex mediates the important function of object vision, we focus here on visual cortex and the pathways leading to it.

How to study brain evolution

The study of brain evolution is a historical science, yet very little about brain evolution can be learned from the fossil record. Brains die and rot, and only the brain case, with luck, remains. Brain cases can tell us something about brain size, brain shape, and sometimes indicate major brain fissures. Brain size is easy to measure, and it is an important variable. Thus, much has been written about brain size (e.g., Jerison, 1973). Moreover, it is especially relevant to consider the implications of observed differences in brain size when studying the evolution of human brains, since our brains have greatly increased in size over the past 3 to 4 million years (Preuss and Kaas, 1999). But the great differences in the internal complexity of brains are not revealed by their external size and shape. Thus, most of what we learn about brain evolution will come indirectly through inferences based on observations made on the brains of the many extant (living) species (Kaas, 1997a). In studying human brain evolution, we have a rich opportunity in that living members of the primate order are highly varied in brain organization, and we have roughly 200 primate species to consider.

The comparative approach to studying brain evolution depends on examining the brains of the most relevant extant species, determining what feature or characters they share, and evaluating the probabilities that features are shared because they were inherited from a common ancestor or evolved independently (see Northcutt, 1984; Preuss, 2000; Striedter, 1998). To obtain a comprehensive understanding of the evolution of the human visual system and those of other primates will take much comparative research, but the approaches and methods of study are known. Fortunately, there has been considerable progress, and this progress allows some of the conclusions that follow here.

The basic premise of the evolutionary or phylogenetic approach is that the brain and other body parts of extant mammals are mixtures or mosaics of features that emerged at various times over the course of evolution. The distributions of any trait across the brains of extant mammals, and the phylogenetic relationships of these mammals, provide the critical sources of information about when a trait in any

particular line of evolution emerged. For example, all placental mammals have a corpus callosum. No other mammals or vertebrates do. Thus, the corpus callosum emerged after the ancestors of placental mammals diverged from marsupials. This cladistic approach (Hennig, 1966) sounds easy, and it is in concept, but the difficulty lies in recognizing brain characters. If current researchers disagree on the existence of V3 in primates, how can we deduce the evolution of V3? As a further complication, even if the existence of a corpus callosum or V3 can be determined with a high degree of certainty, this is only a start, since the features and functions of these structures will vary across and within lines of evolution. A serious problem here is that comparative studies can be time-consuming and costly, and thus the need to be practical will often compromise the plan of investigation. Finally, many relevant species are either unavailable for study or can be studied only after natural death. This includes most of the 200 or so species of primates that are potentially available for study. Fortunately, much can be learned from histological studies of the brains of a few available specimens, and interpretations of comparative studies can be guided by more extensive information from more fully studied species. Other important insights will come from our emerging understandings of the mechanisms of brain development and the “rules” of brain scaling (Finlay and Darlington, 1995; Kaas, 2000).

The origin and radiation of primates

Applying the comparative method to the study of brain evolution depends on knowing the phylogenetic relationships of the species under investigation. Molecular studies and statistical techniques have helped sort out such relationships over the past few years and have pushed back the probable times of divergence of major mammalian groups (e.g., Murphy et al., 2001). Early mammals arose from mammal-like reptiles approximately 200 million years ago and separated into six major lines that fractionated into the 20 or so orders of living mammals now commonly recognized (Fig. 105.1). Two early branches led to the present-day monotremes and marsupials. A third branch of placental or eutherian mammals divided into four major groups or superorders. The oldest of these superorders (Afrotheria) includes the surviving insectivore-like tenrecs of Madagascar, but also elephants and armadillos. Another early branch (Xenarthra) contains armadillos and sloths. The third group of placental mammals (Laurasiatheria) includes shrews and moles as well as bats, carnivores, pigs, and whales. The fourth superorder (Euarchontoglires) is the most relevant here, as it includes humans and the other primates, as well as the closest relatives of primates. Our closest nonprimate relatives are tree shrews (Scandentia) and flying lemurs (Dermoptera), which are included with primates in the

higher-order taxon, Archonta. Bats (Chiroptera) were once included in Archonta, but recent molecular evidence places them in the superorder Laurasiatheria. Although megachiropteran bats have well-developed visual systems that seem primate-like, humans are more closely related to rats, mice, and rabbits (Rodentia and Lagomorpha). To the extent that primates share brain traits with tree shrews and flying lemurs, these traits probably emerged before the time of divergence some 65 million years ago. Traits shared with rabbits and rodents evolved even earlier, perhaps 85 million years ago, while features shared with bats and cats go back even further (except for similar but independently evolved traits).

Early primates soon diverged into three main lines: a prosimian line leading to present-day lemurs, lorises, and galagos; a tarsier line with only a few surviving species; and a highly diverse line of anthropoid primates that split into New World monkeys, Old World monkeys, and apes. One line of apes gave rise rather recently (about 5 to 6 million years ago) to hominids and present-day bonobos and chimps. As the only remaining hominid, *Homo sapiens* appeared only within the past 200,000 years.

While much of what we infer about the organization of the human brain comes from studies on macaque monkeys, it is important to remember that we have evolved independently of Old World monkeys for at least 30 million years and that our brains have expanded by three to four times over those of our closest living relatives, the great apes, in less than 6 million years. Besides the great change in size over that time, what changes in structure, organization, and function occurred? Comparative studies of chimpanzee and human brains will help address this question, but much is beyond the scope of a comparative approach, as the intermediate brains that would bridge this huge gap are long gone.

What features of the visual system do primates share with other mammals?

The record of fossil brain endocasts (e.g., Jerison, 1973) indicates that early mammals were rather small and small-brained, with proportionately little neocortex. Such small-brained mammals remain in all four superorders of placental mammals, as well in the marsupial and, to some extent, monotreme groups (Krubitzer, 1998). Features that distantly related mammals share are those that were likely retained from the very first mammals (Kaas, 1995). If we consider hedgehogs and shrews from Laurasiatheria, rats and rabbits from Euarchontoglires, armadillos from Xenarthra, tenrecs (Fig. 105.2) from Afrotheria, opossums from Marsupialia, and perhaps the platypus from Monotremata, we find small eyes without a highly specialized area centralis, retinal projections to a dorsal lateral geniculate

Phylogeny of Living Mammals

FIGURE 105.1. The evolutionary history of mammals. Recent molecular studies of mammalian phylogeny (e.g., Murphy et al., 2001) have reorganized the phylogenetic tree into four superordinal groups or superorders (1–4) of Eutherian (placental) mammals. Prototherian (A: Monotremes) and Metatherian (B: Marsupials) mammals diverged even earlier from the ancestors of placental mammals. Recent evidence is also pushing back the times of diver-

gences, so the values indicated here, in millions of years ago (mya), are approximate and controversial. Humans are placed with other primates in the superorder Euarchontoglires, with our closest relatives being tree shrews (Scandentia) and flying lemurs (Dermoptera). Rodents and lagomorphs (rabbits) are somewhat more distant.

FIGURE 105.2. A dorsolateral view of the brain of a Madagascan tenrec (*Echinops telfairi*) showing the location of primary visual cortex (V1) and other sensory areas. A second visual area (V2) is presumed (dashed line along V1) from studies in other mammals. Note that there is very little neocortex and little space for visual areas (V?) in addition to V1 and V2. Tenrecs are distantly related to primates (Fig. 105.1). As mammals with little neocortex that are distantly related to each other have a V1 and a V2 but little room for other visual areas, we conclude that early mammals had V1 and V2 but few other visual areas. For reference, primary motor (M1) somatosensory (S1), and auditory (A1) areas are indicated. S2 is the second somatosensory area. (Based on Krubitzer et al., 1997.)

late nucleus (LGN) that is histologically rather uniform but with some segregation of inputs from the two eyes (Kahn and Krubitzer, 2002), and a superior colliculus that receives input from the entire retina of the contralateral eye and sparse but variable input from the temporal retina of the ipsilateral eye (Kaas and Preuss, 1993; Kahn and Krubitzer, 2002). A pulvinar (or lateral posterior) region of the thalamus is not large, and it does not have histologically distinct subdivisions, but portions do have inputs from the superior colliculus and visual cortex. In neocortex, there is a distinct but poorly differentiated primary visual area, V1 or area 17, with a retinotopic representation of the contralateral visual hemifield. The lateral border of V1 is largely formed by a strip-like second visual area V2 (Rosa and Krubitzer, 1999), and more laterally in temporal cortex there is a small amount of additional visual and multimodal cortex. The lack of a V2 and temporal visual cortex in the smallest of extant mammals, a 3 gram species of shrew, appears to be a consequence of an extreme reduction in body and brain size (Catania et al., 1999). A small strip of cortex medial to V1, area prostriata, may have visual functions, but this

subdivision of cortex has not been well studied. In brief, early mammals had poorly developed visual systems with only two to four subdivisions of visual cortex.

The visual system of early primates

The brains of early primates resembled those of the smaller present-day prosimians in approximate size and shape (Conroy, 1990). The temporal lobe was not as expanded as it is in living anthropoid primates, and the posterior parietal cortex was not as large. Since these regions of cortex are predominantly visual in function in primates, early primates had not yet expanded these regions of higher-order visual processing. Features of the skull suggest that early primates were nocturnal visual predators living on small prey and some fruit in the tropical rain forests. There would have been an emphasis on brain systems for visually detecting insects and other prey, and for visually guided reaching with the hand to grasp prey. Later, some prosimian primates and the newly emerged anthropoid primates shifted to diurnal life, with more emphasis on eating fruit (Ross, 1996, 2000). The ancestors of present-day tarsiers appear to have moved to a diurnal niche, which was then abandoned as they readapted to nocturnal life by evolving enormous eyes and a rod-dominated retina while retaining the diurnal adaptations of a fovea and two types of cones (Hendrickson et al., 2000; Ross, 1996). Present-day tarsiers have become such extremely specialized visual predators that they apparently eat no plant food. Primary visual cortex is proportionately large and exceptionally well differentiated into layers and sublayers in tarsiers (Collins et al., 2001a), much like the optic tectum of predatory birds.

We can make further deductions about the visual systems of early primates by comparing extant primates and determining what features they have in common (Weller and Kaas, 1982). Further comparisons with our closest nonprimate relatives, especially the closely related tree shrews and flying lemurs, will help indicate features that evolved with the first primates and those that evolved earlier.

An important change from related mammals as early primates emerged was forward rotation of the eyes. This created a larger binocular field and a shift of the retinal region of highest ganglion cell density near the margin of the temporal retina centrally toward the optic disc (Kaas and Preuss, 1993). Tree shrews have a binocular field of about 70 degrees, somewhat less than that of many mammals, but all extant primates have much larger binocular fields (Ross, 2000), and early primates probably had binocular fields of 130 degrees or more. The retina had the three major classes of ganglion cells that are found in all extant primates, the K, M, and P cells (Casagrande, 1994; Hendry and Yoshioka, 1994), named after the sizes of their target cells in the LGN (Kaas et al., 1978). Detailed vision depends greatly on the P-cell projections, and

in all primates most of the ganglion cells are P cells that project to the LGN. The fewer M cells may be important in motion detection. M cells relay to the LGN and superior colliculus, as do the smaller K cells that comprise 10% or so of the total in diurnal primates. K cells are more common in nocturnal primates, judging from the well-developed K-cell region of the LGN in nocturnal owl monkeys and the K-cell layers of the LGN of nocturnal prosimians (see below). Thus, early nocturnal primates likely had proportionately more K cells. These three basic classes of ganglion cells appear to have emerged earlier in mammalian evolution than with the first primates, but more comparative studies are needed.

The projections of the retinas to the superior colliculus in all examined primates (e.g., Lane et al., 1973) differ from all nonprimate patterns in that only the “hemiretinas” that are devoted to the contralateral visual hemifield project to each superior colliculus. In other mammals, the complete retina of the contralateral eye projects to the superior colliculus (Fig. 105.3). This pattern must have been present in the first primates, but not much before, because tree shrews, rats, and rabbits (close relatives of primates) all have the more generalized condition (Kaas et al., 1973). It was once thought that megachiropteran bats also had the primate pattern, and this was considered evidence that these bats might actually be

FIGURE 105.3. All primates share a unique type of retinotopic organization in the superior colliculus. In all primates, the left superior colliculus receives superimposed inputs from the nasal hemiretina of the right (R) eye and the temporal hemiretina of the left (L) eye, resulting in a representation of the right hemifield that is largely binocular. The right superior colliculus (SC) has a comparable pattern of inputs from the left and right eyes. In other studied mammals, the complete retina of the contralateral eye projects to the superior colliculus, even though the temporal retina also projects ipsilaterally to the LGN, as in primates. The temporal retina may also project weakly to the ipsilateral superior colliculus in a species-variable manner. Note that in nonprimate mammals, the superior colliculus represents the complete visual field of the contralateral eye, including the binocular part of the ipsilateral hemifield. LD, line of decussation of retinal projections to the two hemispheres.

primates (Pettigrew, 1986), but further study did not support this conclusion (Thiele et al., 1991). For other reasons, bats are no longer considered to be closely related to primates (Fig. 105.1). This primate specialization of only representing the contralateral hemifield in each superior colliculus likely relates to the emphasis on binocular vision that occurred in early primates. How this change altered superior colliculus function is uncertain.

The other major target of the retina, the dorsal LGN, also became specialized with the first primates. All primates have a laminated LGN that reflects a basic pattern of four main layers (Fig. 105.4). The two thinner ventral layers of large cells (the magnocellular layers) receive inputs from the M cells of the retina, while the two thicker dorsal layers of smaller cells (the parvocellular layers) receive inputs from the much more numerous P ganglion cells. The outer (external) layers of each pair receive inputs from the contralateral eye, and the inner (internal) layers receive inputs from the ipsilateral eye. However, there is some evidence for a modifica-

tion of this pattern in tarsiers so that the external magnocellular layer receives inputs from the ipsilateral eye (Pettigrew et al., 1989). The K cells project to a distinct pair of koniocellular layers of small cells in prosimian primates and to a scattering of small cells between layers in other primates. The P-cell layers divide to form additional sublayers in some of the New World monkeys, all of the Old World monkeys, and the great apes and humans. The closest relatives of primates, the tree shrews and flying lemurs, also have laminated LGNs, but with different arrangements of inputs from the two eyes than in primates. In addition, LGN layers in tree shrews segregate inputs from classes of ganglion cells in a different way than primates. Thus, distinctly laminated LGNs evolved independently and differently in tree shrews, flying lemurs, and primates. The early primates must have evolved a basic four-layer pattern from a more generalized LGN, with some segregation of inputs by eye of origin and little segregation by type of ganglion cell. Specialized layers for K-cell inputs were probably part of this early pattern,

FIGURE 105.4. Laminar patterns of the dorsal LGN in primates. The schematics are of the laminar patterns in brain sections cut across layers that are stacked like slices of bread from ventral (or along the optic tract) to dorsal (near the pulvinar). Early mammals had a simple pattern of LGN lamination that segregated inputs from the ipsilateral retina in a central region between outer regions with inputs from the contralateral retina. All primates have a more elaborate pattern of four basic layers that evolved with the first primates. Close relatives of primates, tree shrews and flying lemurs, evolved different patterns of lamination. In flying lemurs, layers have been identified histologically and by having inputs from the contralateral (contra) or ipsilateral (ipsi) eye (Pettigrew et al., 1989). In tree shrews (Norton, 1982), microelectrode recordings suggest that M- and P-cell (termed Y and X) inputs are mixed in the same layers, unlike primates, while ON and OFF ganglion cell inputs are

segregated in different layers (Norton, 1982), unlike in primates. Other layers appear to have K-cell inputs. The basic primate pattern of lamination includes two parvocellular (P) and two magnocellular (M) layers, with the longer (for the monocular field) outer (external) layers receiving from the contralateral retina (PE, ME) and the shorter inner or internal layers (PI, MI) from the ipsilateral eye. Present-day tarsiers may have a modified pattern, as there is evidence that the two M layers have a reversed pattern of input in regard to eye of origin, so that ME receives input from the ipsilateral retina (Pettigrew et al., 1989). All prosimians have an extra pair of koniocellular layers (KE and KI). In other primates, K cells are scattered between layers where they do not form distinct layers. In many anthropoid primates, the parvocellular layers divide to form sublayers and leaflets of sublayers. (Based on Kaas et al., 1978.)

but these layers were lost as diurnal primates emerged. Tarsiers did not regain K layers with a return to nocturnal life, as tarsiers and the only nocturnal monkey, the owl or night monkey, evolved a thick K-cell region, but not distinct K-cell layers, between the P and M layers. In anthropoid primates, the emphasis on diurnal vision resulted in a great increase in the proportion of the LGN devoted to P-cell inputs. These layers became thicker, especially in parts representing central vision, and they subdivided to form four or more P “layers” (actually partial layers).

In all primates, the pulvinar complex appears to contain the major inferior, lateral, and medial divisions that interconnect with early (inferior and lateral pulvinar) and later (medial pulvinar) levels of the processing hierarchy in visual cortex. In anthropoid primates, the inferior pulvinar has distinct chemoarchitectonic subdivisions, two of which receive dense inputs from the superior colliculus (Stepniewska et al., 2000). All these subdivisions are not as obvious in prosimian primates, but at least some subdivisions of the inferior pulvinar exist (Symonds and Kaas, 1978). The pulvinar complex of tree shrews is quite differently organized (Kaas et al., 2000). Thus, a distinctive differentiation of pulvinar nuclei is part of the specialization of the visual system that occurred with early primates.

Visual cortex in early primates

Early primates were characterized by a large expanse of visual cortex that was divided into a number of visual areas, although the exact arrangement of the visual areas is uncertain. All primates have a large primary visual area, V1, which is rotated from its common position in other mammals to occupy the caudal pole of the hemisphere with much of the area on the ventral surface and medial wall, and in the calcarine sulcus, a fissure found only in primates. Primary visual cortex in extant primates is approximately two to three times larger than would be expected for mammals of a similar body size, but V1 is smaller in prosimian primates than in simian primates of similar size. Primates tend to devote a third to a half of V1 to the first 10 degrees of central vision, with this expansion of central vision being more pronounced in diurnal primates (Rosa et al., 1997). All primates have a similar projection pattern from LGN layers to V1 so that inputs from M layers terminate in a sublayer of layer 4 that is external to the sublayer with P layer inputs (Casagrande and Kaas, 1994). All primates appear to have modular subdivisions of layer 3, the dot-like pattern of cytochrome oxidase (CO) dense “blobs,” which receive afferents from the K cells of LGN (Casagrande, 1994), and the nonblob surrounds. Tree shrews do not have the CO blob pattern, although myelin stains reveal a dot-like pattern of myelin-poor blobs (Lyon et al., 1998). Both primates and tree shrews have orderly arrangements of orientation-selective

neurons in V1 (Humphrey et al., 1980). The major cortical outputs from V1 in all studied primates (Lyon and Kaas, 2002a, 2002b, 2002c) are in decreasing magnitude to V2, V3, MT, and DM (Fig. 105.5). Most of the projections to MT are from deep layer 3 (3C, incorrectly termed *layer 4B* in most studies; see Casagrande and Kaas, 1994, for review), while the middle of layer 3 (3B) provides most of the projections to the other cortical targets (Casagrande and Kaas, 1994).

In summary, early primates differed from their ancestors in having a large, rotated V1 that was disproportionately devoted to the central 10 degrees of vision. K, P, and M inputs from the LGN were already segregated into modules or sublayers. Outputs to MT and other extrastriate visual areas were largely from different sublayers of layer 3.

Most of the outer border of V1 is formed by the narrow belt-like second visual area, V2 in all extant primates. Most of the outer border of V1 represents the line of decussation of the retina (the vertical meridian), which corresponds to the full extent of the V1/V2 border. The rest of V1, corresponding to the temporal margin of monocular vision, is

FIGURE 105.5. Subdivisions of visual cortex in a prosimian galago. Visual areas identified here likely emerged with the first primates. Visual areas include a primary area, V1, with CO dense modules (*dots*) and a second visual area, V2, with band-like CO dense (*bars*) and CO light modules with different connections and functions. V2 is bordered by a narrow third visual area, V3, with separate dorsal and ventral halves. A middle temporal visual area, MT, is found in the middle of the upper temporal lobe. Other visual areas include the dorsomedial visual area, DM, the dorsolateral visual area, DL (also known as V4), the fundal area of the superior temporal sulcus (FST), and the medial superior temporal area (MST). Posterior parietal cortex (PP) and inferior temporal cortex (IT) contain additional visual areas, but they have not been fully defined. In the frontal lobe, the frontal eye field (FEF) has visuo-motor functions. For reference, other areas common to all studied primates are included. Motor: SMA, supplementary motor area; PMD, dorsal premotor area; PMV, ventral premotor area; M1, primary motor cortex. Somatosensory: areas 3b (S1), 3a, and 1 (possibly 1 and 2), second area (S2), and parietal ventral area (PV). Auditory: A1, primary auditory area; R, rostral auditory area; AB, auditory belt.

bordered by a small, poorly understood area, the prostriata (Rosa et al., 1997). Nocturnal prosimians, and therefore early primates, devoted less of V1 to central vision. As a result, they devoted less of the border of V1 to the vertical meridian and a shared border with V2 (Rosa et al., 1997). Thus, V2 was less elongated than in diurnal primates. In monkeys, V2 is characterized by a modular organization that is revealed by stains for CO as alternating CO-dense and CO-light bands crossing V2. The CO-dense bands appear to be of two types, “thick” and “thin,” and each of the three types of bands is thought to have different connections with V1 modules and sublayers and with other visual areas (Krubitzer and Kaas, 1990). Such a pattern of modular organization is less apparent in prosimian primates, although CO-dense bands may be weakly apparent in favorable material (Preuss and Kaas, 1996; Preuss et al., 1993). However, modular differences in connections of V2 suggest that an anatomical framework for bands exists (Collins et al., 2001b). Tree shrews also have a banding pattern of V1 connections in V2, but the functional significance of this segregation is not clear (Lyon et al., 1998; Sesma et al., 1984). These observations suggest that V2 already had modular subdivisions in early primates, but the modules may have been less regular and distinct than in present-day simians. Nevertheless, a pattern of modular processing in V2 was part of the visual specialization of the primate branch of mammalian evolution.

The existence of V3 as a visual area in primates has long been in question (Kaas and Lyon, 2001). The dorsal half of V3 (V3d), representing the lower visual field, was defined by projections from V1, but the ventral half (V3v) appeared to have no such connections. This allowed for other interpretations of the V3 region. Some (e.g., Kaas, 1997b) favored the view that V3d was actually part of a larger area, the dorsomedial (DM) area, representing both the upper and lower visual quadrants. Alternatively, V3d was considered by others to be an incomplete visual area representing only the lower visual quadrant (e.g., Felleman and Van Essen, 1991). More recently, we have been able to demonstrate with injections of tracers in the less accessible ventral part of V1 that this part of V1 does project to the ventral V3 region in a range of primate species and that the overall projection pattern of V1 corresponds to that predicted for V3 (Lyon and Kaas, 2001, 2002a, 2002b, 2002c). Thus, compelling evidence exists for V3 in prosimian galagos, several species of New World monkeys, and Old World macaque monkeys. Given this broad distribution, early primates undoubtedly had a V3. However, there is no clear evidence yet for a V3 in tree shrews (Lyon et al., 1998), or in rodents and rabbits (Rosa and Krubitzer, 1999), so V3 does not appear to have been present in much earlier mammals that led to both primates and sister groups. This leads to the conclusion that V3 in primates and cats evolved

independently. This conclusion should be held cautiously, however, as further study could provide evidence for V3 in tree shrews and other mammals.

A similar conclusion relates to the evolution of the middle temporal (MT) visual area. This distinctive visual area has been found in galagos (Allman et al., 1973) and in all other studied primates, including humans, but not in tree shrews, rodents, or rabbits (Kaas, 1997b). MT is easily identified in primates by its projection pattern from V1, dense myelination, retinotopic organization, and neurons that are dominated by a relay of the M-cell pathway through V1 (Casagrande and Kaas, 1994). Because of this distribution, MT appears to be a visual area that first evolved with the early primates. Thus, cats are unlikely to have a homolog of MT, as is sometimes postulated.

In all primates, the dorsomedial (DM) visual area remains as a smaller area after its posterior border has been redefined to include a narrow V3d between DM and V1 (Fig. 105.5). Injections of tracers in different locations in V1 reveal a complete representation of the visual field in DM in addition to a separate representation of the lower field in V3d (Lyon and Kaas, 2001, 2002a, 2002b, 2002c). Because of its wide distribution in present-day primates, DM would have been present in the first primates. As yet, there is no obvious homolog of DM in tree shrews or rodents.

All primates have visual areas in addition to V1, V2, V3, MT, and DM, and some of these areas are likely to be widely shared and thus inherited from a common ancestor. There is already considerable evidence that this is the case for the dorsolateral visual (DL) area, which actually appears to consist of two parallel areas, one posterior to the other, in at least some primates (Stepniewska and Kaas, 1996). Likewise, there is good evidence for MST and FST (FST contains dorsal and ventral subdivisions; Kaas and Morel, 1993) in a range of primate species. The frontal eye field of monkeys and humans has been demonstrated in prosimian galagos (Fig. 105.5; Wu et al., 2000), suggesting that all primates have this visuomotor area. Other shared visual areas are likely to be identified in posterior parietal cortex, where regions have connections with other areas of visual cortex and with the superior colliculus, as well as premotor areas in all examined primates, and in inferotemporal cortex, which receives a massive input from the DL region in all examined primates (Weller and Kaas, 1987).

Evolution of the human visual system

Less is known about how the human visual system differs from that of the first primates. This is partly because it is not yet clear how much the visual systems of prosimians, New World monkeys, and Old World monkeys differ from each other (Kaas, 1997b). In addition, we are only in the early

stages of fully describing the organization of the human visual system, and we know little about the visual systems of apes. Members of the major branches of primate evolution cover a range of body and brain sizes (Fig. 105.6), and they are specialized in various ways, so we can expect variation within as well as across their groups. In Old World monkeys, over 30 visual areas have been proposed (Felleman and Van Essen, 1991), and these primates have greatly expanded regions of visual cortex in the temporal and parietal lobes compared to most New World monkeys and all prosimians. Quite possibly, Old World monkeys have more visual areas than New World monkeys. Further increases in overall brain size and the total extent of visual cortex undoubtedly occurred in the apes leading to our early hominid ancestors. Possibly there was a further increase in the number of visual areas, but this is uncertain. What is clear from the fossil record is that our ancestors of only 3 million years ago had brains only slightly larger (600 to 800 cc) than those of present-day African apes (Preuss and Kaas, 1999), and these brains may have resembled those of African apes in general organization. From that time, the brains of our ancestors increased rapidly in size to the present volume of about 1400 cc, but we know little about the structural changes in brain organization that occurred over that time. What is known from comparing human brains with those of apes and monkeys is that the easily identified primary visual area increased considerably in absolute size while occupying proportionately less of the total neocortex. This observation is consistent with the theory that the number of cortical areas, including visual areas, has increased.

The functions of cortical areas are altered as they increase or decrease in size due to distance constraints on single-

neuron capacities (Kaas, 2000). Small areas have intrinsic connections that cover more of the area and make them more suitable for global comparisons of receptive field centers with surrounds. While large areas are good for considering local detail, smaller areas are more broadly useful. This may be why the large human brain is not simply a larger version of a monkey brain. V1 and at least several other areas did not increase proportionately in size as brains became larger and new areas were likely added. As the complex human body has been made possible by the addition of gene copies that subsequently evolved new functions (Ohno, 1970), the addition of new cortical areas allowed both new and original areas to differentiate, specialize, and mediate new capacities (Allman and Kaas, 1974; Kaas, 1989).

Finally, understanding of brain evolution is still in its early stages. Much more can be learned about the evolution of complex visual systems from theoretical approaches that examine scaling issues related to brain size, as well as from our growing understanding of the modes of brain development and how development can be altered in evolution. Most important, much more can be learned about the brains of the living apes. As a recent example, the histochemistry of primary visual cortex of monkeys, apes, and humans has been compared, leading to the conclusions that some ancestral features of V1 were lost with the evolution of apes, while new features emerged after our ancestors diverged from the apes (Preuss et al., 1999). More specifically, humans do not show the band of dense CO staining of monkeys and apes that marks the outer (4A) stratum of P-geniculate afferent terminations. Furthermore, humans have a unique mesh-like pattern of dendrites and cells that appear to relate to the M-cell system in this sublayer. These observations suggest that the processing of P-cell information has been reduced and M-cell processing enhanced. As M cells respond well to motion and contrast in dim light, the human visual system may function better at dusk.

Presently, we know that human brains are about three times as large as those of the African apes, but we still know very little about how human and ape brains differ structurally. Histochemical and traditional architectonic approaches can help identify nuclei and cortical areas that apes and humans have in common (Hackett et al., 2001), specialized features of those areas (Preuss et al., 1999), and possibly nuclei and areas unique to humans. The goal of determining the similarities and differences in cortical organization across primates has been expressed from the time of Brodmann (1909), but now we have powerful modern methods to add force to such studies.

FIGURE 105.6. Size differences in primate brains. Our early primate ancestors were small, with small brains with few fissures, such as the mouse lemur brain (*lower left*). Smooth-brained members of the Euarchontoglires radiation (Fig. 105.1) gave rise to early primates with shallow lateral and calcarine fissures. The brain size and number of fissures increased dramatically in the course of evolving the human brain. The caudal regions of the lemur and human brain that are devoted to vision are shaded.

106 Gestalt Factors in the Visual Neurosciences

LOTHAR SPILLMANN AND WALTER H. EHRENSTEIN

It is now almost generally acknowledged that psychological facts have “correlates” in the biological realm. These correlates, the so-called psychophysical processes, are events in the central nervous system.

Wolfgang Köhler (1940)

A brain theory of visual perception

Gestalt psychology, best known for its richness of perceptual phenomena and rigor of observation, was more than just a school of phenomenology. It was an early and systematic approach to infer brain processes from percepts. In his seminal article on apparent motion between two successive stimuli, Max Wertheimer (1912) writes: “Es handelt sich um bestimmte, zentrale Vorgänge, physiologische ‘Querfunktionen’ besonderer Art, die als das physiologische Korrelat der Phi-Phänomene dienen” (We are dealing with certain, central processes, physiological lateral interactions of a special kind that serve as the physiological correlate of the phi phenomena). Accordingly, apparent motion was thought to be based on interactions between two brain states, resulting in a perceptual filling-in of the unstimulated interspace (*Felderfüllung*), not unlike an electrical short circuit. Thus, far from being content with his discovery of phi motion, Wertheimer was interested in the way in which it originated in the brain.

In 1923, using simple dot and line figures, Wertheimer further investigated the rules of perceptual organization, that is, the *Gestalt factors* or principles inherent in the visual system. Both of his papers had a lasting impact. They showed that our perception cannot be understood on the basis of stimuli alone, but also requires active mechanisms by which they are processed. More than 80 years later and notwithstanding passionate debates on linking propositions (Teller, 1990), we are now witnessing a physiology that aims to understand these principles in terms of interactions within neural networks.

Inspired by Wertheimer’s approach, Wolfgang Köhler (1920, 1923) systematically addressed the neural implications of the Gestalt concept. He postulated that the neuronal processes at the psychophysical level (*psychophysisches Niveau*), at which neuronal activity becomes conscious experience,

have isomorphic structural properties to perceptual *Gestalten*. Consequently, perceptual organization was assumed to rely on neuronal rather than on stimulus properties.

Although Gestalt psychologists studied perception in general, they often selected phenomena demonstrating that we are not free to perceive as we choose. No matter how hard we try or how often we look at a given stimulus pattern, we are always the victims of the constraints that the visual system imposes on us. The principles that determine why we see the way we do (Koffka, 1935) have become known as *laws of vision* (Metzger, 1936/1953). They are the reason why, in a multitude of possible “solutions,” only one percept typically materializes. When there are several solutions, the task for the visual system becomes a challenge (Fig. 106.1).

Instead of providing a full historical account of Gestalt factors (Spillmann, 1999a), we concentrate in this chapter on select examples to examine where we stand and where the future might lead us. Excellent treatises of visual perception within a Gestalt psychological context may be found in the handbook chapter of Teuber (1960), in the handbook volume edited by Metzger (1966), and in subsequent books and chapters by Hochberg (1971), Kanizsa (1979), Kubovy and Pomerantz (1981), Beck (1982), Rock (1984), Spillmann and Ehrenstein (1996), and Palmer (1999). Readers will also enjoy the recent papers by Sekuler (1996) and Westheimer (1999), which focus on Max Wertheimer’s early contributions and interpret them within the context of modern neuroscience.

Basic concepts of Gestalt psychology

What do we mean by *Gestalt*? According to the Austrian philosopher Christian von Ehrenfels (1890), the term *Gestalt* applies to perceptual unit formation and is characterized by two criteria: *Übersummativität* (superadditivity) and *Transponierbarkeit* (transposability). *Superadditivity*, denotes that the whole is different from (or more than) the sum of its parts and is perhaps best illustrated by Wertheimer’s (1912) phi motion, as already described. Two orthogonal lines presented briefly in the proper sequence will show phi motion (pure motion without object displacement) or appear as a single bar

FIGURE 106.1. With prolonged inspection, continuous changes in perceptual grouping may be experienced. New “flowers” arise spontaneously from the “meadow” and disappear again, testifying to the instability of figure-ground segregation. (From Robinson, 1972; see also Spillmann and Ehrenstein, 1996.)

moving through a right angle (optimal motion). The perceived movement, including its direction and speed, cannot be reduced to the two static line events. It is an experience of its own (*sui generis*, Wertheimer, 1912; see also Steinman et al., 2000), “an emergent property that does not correspond with the piecemeal features of the stimuli” (Sharps and Wertheimer, 2000).

Another well-known example of superadditivity is a gray ring that lies on a ground half red, half green. As long as the ring is perceived as a whole, it looks uniformly gray (Koffka, 1935). However, if the two halves are separated by a thin border, simultaneous color contrast due to the red and green hemifields induces a distinct greenish and reddish color in the two semicircles. Koffka concluded that an intact, unified figure (*Gestalt*) will look uniform, while two semicircles produced by the same stimulus will look different. Thus, the whole has properties that are different from those of its parts.

The second Ehrenfels criterion, *transposition*, implies that the whole is preserved even if there are large changes to its components. What counts are the relations between stimuli rather than the specific stimulus attributes. A square may be small or large, black or colored, outline or surface, fully delineated or just defined by its apices: as long as there are four right angles connected by equilateral sides, it is a square. Transposition enables perceptual constancy or invariance (see the section “Perceptual Invariance Mechanisms” on page 1577).

In addition to these two criteria, *Gestalten* are distinguished by possessing an *equilibrium* that depends critically on the structural role of their components. For this reason, the same stimulus may appear differently, depending on the way in which it is embedded in a larger context. Conversely, different stimuli may elicit similar percepts as long as they have

similar structural properties. These observations were at the core of Köhler’s (1920) hypothesis that our perception does not depend on firm anatomical wiring (*Konstanzhypothese*), but rather on *dynamic self-organization* that aims at an energetic equilibrium.

Wertheimer (1923) proposed that this equilibrium expresses itself in the *Prägnanztendenz*, or the tendency toward a “good” *Gestalt*. The term implies that the simplest, most regular, and balanced organization “wins” in our perception. To account for *Prägnanz*, the Gestaltists assumed a number of *autochthonous* (i.e., inherent) factors responsible for grouping and figure-ground segregation. These factors determine the way in which we see.

PERCEPTUAL CONSTRAINTS Gestaltists considered perceptual organization as an active process, adding to rather than merely reflecting the stimulus. Typically, perceptual organization generates wholes and parts as well as groups and group members. Perception seems to us direct, undeniable, and veridical, helping us to get around in the world. But it is not always that simple.

This may be illustrated by three examples. (1) Sometimes we see what actually is not there. Take the Ehrenstein figure (Ehrenstein, 1941, 1954) or the Kanizsa triangle (Kanizsa, 1955, 1979), both of which stand out because of illusory contours and illusory surfaces for which there is no physical correlate in the stimulus (amodal contours; Fig. 106.2A, B). (2) At other times, we may be blind to what is actually in full sight. For example, a figure may require great effort to be discerned, because it is embedded (hidden) in a larger context that produces “wrong” figural groupings (Gottschaltdt, 1926; Fig. 106.2C). (3) Finally, we may see the properties of a stimulus but not as they really are. This is evidenced by so-called geometric-optical illusions (Oppel, 1855; Hering, 1861; Fig. 106.2D, E). Shapes may appear distorted, and sizes, angles, and orientations may differ from their actual geometry and will remain this way, despite better knowledge of their true alignment. Such mismatches between stimulus and percept were taken by the Gestaltists as evidence of how the brain processes visual information. In this sense, illusory phenomena may be used as noninvasive tools to study the neural mechanisms underlying visual perception. Perceptual illusions thus reveal the limitations as well as the creative abilities of the visual system.

FIGURE-GROUND SEGREGATION AND PERCEPTUAL GROUPING A central issue of the Gestalt approach to perception is the distinction between figure and ground. The first person to address this distinction systematically was the Danish psychologist Edgar Rubin (1915), a student of G. E. Müller. His descriptions of the properties characterizing figure and ground are summarized as follows:

FIGURE 106.2. Demonstrations of Gestalt phenomena. *a*, Ehrenstein figure and *b* Kanizsa triangle displaying brightness enhancement, illusory contours, and amodal completion. *c*, Hidden figure by Gottschaldt; the hexagon on the left becomes nearly imperceptible when embedded in the parallelogram on the right. *d*, Geometric-optical illusions by Oppel; the “short” and “long” lines (on the top and bottom) are actually identical in length. *e*, The two “bowed” lines in the figure by Hering are, in fact, straight and parallel.

A figure possesses “Ding (thing) character;” it is spatially cohesive, delineated and appears to lie slightly above the ground. It is enclosed, i.e., demarcated by a contour, and fills the entire surface inside the border. A figure possesses a shape (frequently symmetrical) and is surrounded by a background, on which it rests. In contrast, the ground possesses *Stoff* (stuff, material) character, it appears farther away and is partially occluded by the figure. It is open (not delineated) and extends behind the figure. It has no conspicuous shape (e.g., a patch of sky between the clouds) and typically is larger than the figure.

The question of how we manage to parse a large stimulus field into figure and ground goes back to the Gestalt psychologists’ proposal that figures emerge on a ground due to so-called grouping factors (Wertheimer, 1923; see also

Bahnsen, 1928; Morinaga, 1941). Among these, similarity and common fate stand out as especially powerful for the formation of extended surfaces: sections of a stimulus pattern that have the same brightness, color, texture, or depth tend to become a surface in perception. Similarly, sections that move together in the same direction and with the same velocity assume surface properties. Taken together, these factors describe the lawful transformation of retinal stimuli into neural object representations. In the following subsections, we give a brief description of each of these factors (see also Palmer, 1999).

Symmetry. If faced with symmetrical and nonsymmetrical stimuli, perception follows symmetry as a figural organization principle. For example, spaces that are delineated by wavy, mirror-symmetric contours are perceived as figure, asymmetrical spaces as ground (Fig. 106.3A).

Parallelism. Similarly, undulating lines that are parallel and maintain their width (e.g., *Ebenbreite*) achieve the status of figure, whereas their nonparallel interspaces are delegated the role of ground (Fig. 106.3B).

Smooth (or “good”) continuation. Collinear stimulus parts tend to be linked together, whereas parts exhibiting sharp bends or corners are not (Fig. 106.3C). This observation calls for neurons sensitive to collinearity (see the section “Perceptive Neurons” on page 1579).

Closure. A closed stimulus is more readily organized into a figure than an open one (Fig. 106.3D). Closure also manifests itself in a tendency to complete perceptually a partly occluded object.

Proximity. All other factors being equal, closely adjacent stimuli are more likely to be grouped into perceptual units than are stimuli that are farther apart. An example is shown in Figure 106.3F, where neighboring dots are readily organized into pairs of dots. In comparison, the more widely spaced dots are almost impossible to group together. Proximity wins.

Similarity. Stimuli sharing the same brightness or color are more likely to be grouped than dissimilar stimuli. The same applies to size, shape, and orientation (Fig. 106.3G–I), as well as texture and depth.

Common fate. Stimuli that move simultaneously at the same speed and approximately in the same direction are seen as a group (Fig. 106.3J). This factor, common fate, ties together stimuli that are widely distributed in the visual field, producing the perception of coherent motion. Common fate is possibly the strongest of all classical grouping factors, overriding proximity and similarity. Stimuli that would not

FIGURE 106.3. Schematic demonstration of Gestalt factors determining figural segmentation according to (a) symmetry (Bahnsen, 1928), (b) parallelism (Morinaga, 1941), (c) smooth continuation, (d) closure; and grouping of elements according to (f) proximity, (f–i) similarity, and (j) common fate. All but the first two factors are from Wertheimer (1923). (Adapted from Palmer, 1999.)

normally be grouped together in stationary displays will emerge as a group as soon as they begin to move in unison (i.e., covary in time and space).

Little was known at the time about the neuronal mechanisms underlying these perceptual segregations. However, recent psychophysical and neurophysiological studies have shed light on the processes that may be responsible for figure-ground organization. Among these, the spread of brightness and color information from an edge by long-distance filling-in are the best understood (see the sections “Surface Filling-in” on page 1582 and “Large-Scale Color Effects” on page 1583).

SUBJECTIVE FACTORS Although Gestalt psychologists were primarily concerned with the sensory (bottom-up) factors underlying figure-ground segregation and grouping, they also recognized that subjective (central or top-down) factors

FIGURE 106.4. Demonstration of set (*Einstellung*) and past experience as factors in amodal completion. The meaningless assembly of lines on the left becomes a mirror-symmetric E after the capital letter E is discerned on the right. (From Ehrenstein, 2001.)

could modify perceptual organization. Such factors are an observer’s set (*Einstellung*) and past experience.

For example, the three pieces in Figure 106.4 (*left side*) may appear, at first glance, as a meaningless geometric arrangement of lines. However, when flipped over (Fig. 106.4, *right side*), they will—given appropriate knowledge—be easily recognized as a capital E with the missing contours amodally completed. Now, having the *Einstellung* of an E, if one looks back on Figure 106.4 (*left*), one immediately sees a mirror-symmetric E rather than a mere assembly of lines (Ehrenstein, 2001). Another example of the effect of past experience is the well-known Dalmatian dog (photographed by Ron C. James) which is perfectly hidden on a spotty surface due to its broken body lines, but once it has been discerned, it will be instantaneously visible on subsequent exposures.

In a natural setting, incomplete objects are the rule, rather than the exception, due to partial occlusion. Nonetheless, we have little difficulty seeing an incompletely given stimulus as complete because of the Gestalt factors of smooth continuation, closure, and completion. In this sense, it may be said that we perceive a stimulus correctly due to *active processes* in our brain. These processes complement and transform the visual input thereby producing percepts that match corresponding objects in the real world. Memory helps, but cognitive processes (e.g., unconscious inferences; Helmholtz, 1909–1911) are not needed. Figure 106.5 demonstrates that even impossible solutions are perceptually accepted, such as René Magritte’s rider on a horse (*Le blanc-seing*).

GESTALT FACTORS IN DYNAMIC DISPLAYS In addition to the (dynamic) factor of common fate, each of the other Gestalt factors has an equivalent in the realm of motion (Metzger, 1936/1953). For example, the factor of proximity finds its correlate in the factor of least displacement (*geringste Verschiebung*), while the factor of smooth continuation corresponds to the factor of a steady and uncrossed trajectory (*stetige Bewegungsbahn* and *kreuzungsfreier Verlauf*). Metzger (1935) showed that we can reconstruct depth from the trajectories of a cluster of vertical bars rotating on a platform and—when backprojected—casting their shadows on a two-

FIGURE 106.5. Magritte's rider on a horse requires scrutiny to appreciate the impossibility of the figure and scene. (*The Blank Signature*, 1965. National Gallery of Art, Washington, DC, Collection of Mr. and Mrs. Paul Mellon 1985.64.24; see Wenzel, 1998.)

dimensional screen. Despite different velocities and directions, as well as continuous transformations of the relationships between the shadows, the observer perceives a rigid three-dimensional assembly of bars—even monocularly—according to the Gestalt tendencies of persistence in shape and time (*Tendenz zur Formbeständigkeit, Gesetz der geringsten Veränderung*). The perceptual extraction of a moving shape in depth known as *kinetic depth effect* (Musatti, 1924; Wallach and O'Connell, 1953) is due to the same factors. Recent findings on depth from motion and motion transparency studies in the monkey place the neural mechanism of this phenomenon at the level of area MT (Bradley et al., 1998) (see Chapter 81).

Metzger's (1934, 1935) findings, together with earlier observations by Ternus (1926) on *phenomenal identity* (group vs. element motion), provided the basis for Michotte's (1946/1963) observations on *phenomenal causality*, where two moving stimuli are perceived to interact in various ways: entraining and launching, collision, traction, and passing each other. They may also be considered forerunners of Johansson's (1973) *biological motion*, showing that human figures dancing in the dark will be veridically perceived although the stimulus pattern consists of no more than a

small number of (coherently moving) lights attached to their joints. Neurons mediating biological objects from such motion have been found and studied in detail in monkey temporal cortex (Oram and Perrett, 1994).

GESTALT FACTORS IN THE ANIMAL KINGDOM Are Gestalt factors in visual perception unique to humans or do they influence the behavior of other species as well? In her pioneering work, Mathilde Hertz (1928) demonstrated that the perceptual organization of jaybirds' vision is similar to that of humans. Metzger (1936/1953) further showed in a variety of species (insects, birds, fish, mammals) that the same principles that make objects more conspicuous in human vision are used by nature to provide camouflage and concealment. Camouflaged animals blend in with their environment and may be perfectly hidden from even the most inquisitive eye. Camouflage reduces visibility by counteracting the very Gestalt principles that govern figure-ground segregation and grouping. Particularly effective in this regard are blobs and textures that interrupt existing boundaries or create new boundary contours and offset surfaces by suggesting "wrong" perceptual entities. If the animal remains still (or moves in unison with its surround), it becomes an integral part of its environment. On the other hand, a camouflaged animal will *pop out* as soon as it moves relative to its surround (factor of common fate).

Certain fish use countershading thereby being less visible against the water surface from below. Ramachandran et al. (1996) studied the mimicry of a bottom-dwelling flat fish (*Bothus ocellatus*) and found an amazing adaptability to the prevailing environment to minimize visibility from above. This species can even simulate on its skin a checkerboard pattern on which it is placed by the experimenter and will follow changes of check size with little delay. From such findings, we may conclude that the factors rendering an animal invisible are the same in predators and human observers, as they operate similarly and are equally effective in both.

The same assumption applies to geometric-optical illusions (Zöllner, Ebbinghaus, Ehrenstein) which have been demonstrated in goldfish, domestic chickens, starlings, finches, and guinea pigs (Dücker, 1966), thereby narrowing the number of possible explanations to one that is common to all.

PERCEPTUAL INVARIANCE MECHANISMS In addition to analyzing the figure-ground factors inherent in perception and perceptual processing, Gestaltists posed what is perhaps an even larger question: that of perceptual constancies (*Wahrnehmungskonstanzen*). Invariance mechanisms are of doubtless evolutionary survival value. Unless the retinal image of a stimulus that moves to and fro, translates, tilts, and rotates is attributed to the same object, we cannot derive experiences, as there is no object identity under different

stimulus conditions (Gibson, 1950). Furthermore, different illumination must be discounted in order for us to remain oriented in an ever-changing world (Neumeyer et al., 2002). Size, shape, and color constancy are thus fundamental perceptual mechanisms in human and nonhuman species, probably from birth on, as without them survival would be tenuous (Lorenz, 1959). The perceptual constancy of the ongoing stream of glimpses needed whenever we move our eyes (position constancy) and the distinction between object and subject movement (Ebenholtz, 2001) are genuine—but even less understood—problems of Gestalt psychology. Tentative answers to these basic questions concerning the underlying invariance mechanisms are just beginning to emerge from neurophysiological studies (Sary et al., 1993; for a review, see Spillmann, 2001).

Although we rely on invariance mechanisms all the time, they must be seen within the proper context (Spillmann, 1997). For example, in the case of color constancy, correct hue perception depends on the relational change of the entire scene acting as a reference system (*Bezugssystem*). A striking example is the well-known *Gelb effect* (Gelb, 1929). A black disc suspended in the dark is illuminated by the beam of a spotlight—it appears white. However, when a piece of white paper is placed on it, the disc immediately turns black. The Gelb effect demonstrates the importance of appropriate “anchors” (Gilchrist et al., 1999) for achieving and preserving color constancy and hence veridical perception. Relational perception (in the sense of Wertheimer and Köhler) is crucial not only for correctly perceiving brightness and color, but also for the transposition of paired differences between test and reference stimuli. For example, in Figure 106.3*F*, the widely spaced pairs of dots might group if surrounded by dots with even larger interspaces. Thus, a simple explanation of the Gestalt factor of proximity in terms of adjacency within localized receptive fields may not apply without also considering the context.

Although color constancy has been shown behaviorally in several species (e.g., bees and goldfish; Neumeyer, 1980; Ingle, 1985; Neumeyer et al., 2002), we know of only one study reporting color constancy neurons in area V4 of the primate (Zeki, 1980). Here neurons responded to a red patch in a multicolored Mondrian pattern regardless of changes in spectral illumination, suggesting that they were mediating invariant color. More studies of this kind are needed.

ISOMORPHISM A key concept of the Gestalt theory of brain processes is *isomorphism*. In the context of current neuroscience, isomorphism refers to the assumption of a structural resemblance between the proximal stimulus (retinal image) and its representation on the cortical surface.

Studies using radioactive tracers as well as functional magnetic resonance imaging (Tootell et al., 1982, 1998) have established a retinotopic but not isomorphic representation

of the stimulus on the surface of the cortex. Neighboring loci in the retinal image remain neighbors, although there is a complex logarithmic transformation between retinal and cortical images, as well as anisotropies along the horizontal and vertical meridians (Tootell et al., 1982; Schwartz, 1994; Wood and Schwartz, 1999). The cortical magnification factor (*M*) demonstrates that the size of receptive fields is inversely related to their spatial extent in the visual cortex. Stimuli of different eccentricity that are *M*-scaled therefore occupy the same space on the cortical surface (Wilson et al., 1990). For area V1 at least, *M* scales are the biologically correct perceptual metric. Numerous other areas are also concerned with visual processing, but none of them have the high magnification factor and high degree of retinotopic regularity of the primary (striate) cortical area. Understanding their role within the context of Gestalt psychology takes us to the forefront of neuroscience research today.

A second meaning of isomorphism, central to Gestalt theory, has received much less attention. It concerns the hypothesis according to which the experienced order in space is structurally identical to the functional order in the distribution of underlying brain processes (Köhler, 1947). Using metal electrodes applied to the back of the head, Köhler and Held (1949) set out to find the neuronal representation of a percept on the surface of the occipital cortex. For example, they tested the hypothesis by Köhler and Wallach (1944) that the figural aftereffect (an apparent displacement of a test pattern following prolonged exposure to an adaptation pattern) affected nearby stimulus contours more strongly, because their neural representations lay closer to each other on the cortical surface. The idea that perceptual as well as stimulus properties are the correlational counterparts of brain processes is now gaining acceptance as researchers begin to focus on the issue of conscious perceptions in the absence of stimulus correlates (e.g., Spillmann, 1999b; Engel and Singer, 2001; Kanwisher, 2001; see Chapter 114).

Gestalt concepts and neuroscience

In the past 40 years, neurophysiological research has produced a wealth of results that are obviously linked to Gestalt theory (Spillmann, 1997, 1999a, 2001). In the second half of this chapter, we will discuss these results because they not only advanced the field, but also promoted our understanding of the neural mechanisms underlying visual perception.

As to Wertheimer's (1912) apparent motion, it has been shown that movement-sensitive neurons in the frog respond to a pair of stimuli separated in space and time (apparent motion) as though they were responding to real motion (Grüsser-Cornehls, 1968). Meanwhile, single-cell recordings

in the monkey suggest that the neuronal substrate for apparent motion may be distributed over multiple cortical areas (V1, MT), in which neuronal responses depend critically upon the temporal and spatial intervals of the stimuli (Newsome et al., 1986). For high apparent speeds, physiological data from MT, but not V1, corresponded closely to the psychophysical data.

In today's field of neuroscience, we distinguish between three kinds of neuronal interactions: convergent/divergent (feedforward), horizontal (corticocortical), and reentrant (feedback from higher to lower areas). Wertheimer's (1912) *Querfunktionen* (lateral processes) would sensibly fall within the middle category, whereas the other two are now called *bottom-up* (sensory input) and *top-down* processes (attention, motivational states). Less tangible terms that have become popular over the years include *early* or *low-level*, *intermediate* or *mid-level*, and *late* or *high-level vision*.

RECEPTIVE FIELDS AS A FUNCTIONAL MICRO-GESTALT A concept now firmly established by single-cell neurophysiology is the *receptive field* (Kuffler, 1953) of a neuron, which includes excitatory and inhibitory regions of various shapes suited to encode different attributes of the physical stimulus. This concept has been used to support the idea of a hierarchical system for feature extraction by arguing that one class of neurons drives another, and as a consequence, stimulus selectivity and complexity of receptive field shapes increase from lower to higher levels of processing (Hubel, 1988). This concept was enthusiastically embraced by vision researchers but left Köhler incredulous (Teuber, 1967), as it was counter to his holistic theory of brain function based on electrochemical fields in the cortex. It also seemed to reintroduce atomism by dissecting the stimulus (and the subsequent percept) according to its local parameters (e.g., contrast, orientation, disparity).

Research has shown that there is a considerable degree of functional specialization—for example, cells in area V4 dedicated to color and cells in area V5 to motion (Livingstone and Hubel, 1987; Zeki, 1980, 1993, 2001). However, there is also evidence of multipurpose cells (Schiller, 1996) allowing for flexible and efficient interaction within distributed systems. Receptive field organization, with its various forms of center-surround antagonism and selective spatial and temporal sampling properties, integrates the initial receptor inputs in a superadditive way, thereby allowing for transposition of stimulus properties. In this sense, the receptive field may be considered a functional *micro-Gestalt* for processing visual stimuli (Spillmann and Ehrenstein, 1996). The extended wiring diagram of Felleman and Van Essen (1991) tracing hundreds of individual connections between a great many centers should not distract us from the obvious: that the visual brain is a highly interactive system of feedforward, feedback, and lateral loops that approaches a sort of func-

tional continuum despite (or even because of) the multitude of discrete pathways.

A major distinction between two processing streams (Mishkin et al., 1983), one to the temporal lobe ("what") and the other to the parietal lobe ("where"), is now generally accepted. According to this distinction, areas processing the shape of an object, including its brightness, color, orientation, and depth, are separated from cortical areas concerned with processing direction of motion and location in space. The question thus looms: how do all these attributes come together?

PERCEPTIVE NEURONS In 1970, Jung and Spillmann introduced the term *perceptive field* to denote the psychophysical correlate of the neuronal receptive field. Perceptive fields were understood to be organized analogously to receptive fields (i.e., center-surround), but to subserve many more neurons to achieve a percept (e.g., the Hermann grid illusion) or mediate a threshold response (the Westheimer paradigm). The sizes of *perceptive* fields defined and measured in this manner increased from the fovea to the periphery in close agreement with the size of single-cell *receptive* fields (Spillmann et al., 1987) (Fig. 106.6).

Twenty years later, Baumgartner (1990) proposed the term *perceptive neuron* for cells that respond as though they mediated the perception of illusory contours in Kanizsa-type figures. The Zurich group had found that neurons in area V2 responded to an *illusory* contour stimulus—the aligned top and bottom parts of a bar separated by an empty gap in the middle—in a way similar to a bar without a gap (Baumgartner et al., 1984; von der Heydt et al., 1984; Peterhans and von der Heydt, 1991). Since there was no physical stimulus activating the (local) receptive fields of

FIGURE 106.6. Comparison of receptive and perceptive field centers in the rhesus monkey. The sizes of the receptive field centers refer to retinal broadband cells and were taken from DeMonasterio and Gouras (1975). The sizes of the perceptive field centers were obtained using the Westheimer paradigm and are averages from the temporal and nasal retinas of two monkeys (Oehler, 1985). (From Spillmann et al., 1987.)

these neurons due to their location inside the gap, the authors inferred that there must have been an influence from a larger (global) response field in the outer surround, bridging the gap. When a thin orthogonal stop was attached to the inner end of each inducer, the neuronal response was abolished, as was the illusory contour. Since there was no physical stimulus activating the receptive fields of these neurons (as defined by bars and edges), the authors inferred that there must have been an influence from *beyond the classically defined receptive field*.

To account for the responses of these higher-order V2 neurons (or neuronal representations of the illusory contours), a gating mechanism was assumed that groups the signals of endstopped cells, each one detecting an attribute of the stimulus (line end or corner) (Peterhans et al., 1986). Stimulus alignment was critical: lines and corners that were out of register (or moved out of synchrony) no longer produced a response, a result that seems to follow from good continuation and collinearity (Peterhans and von der Heydt, 1991). Similarly, in psychophysics, it was found that a slight misalignment between the inducing stimuli and the test spot failed to reveal the subthreshold summation hypothesized to underlie the perception of illusory contours (Dresp and Bonnet, 1995). It is now known that context dependency of the neuronal response is not a privilege of area V2, but is already found in visual area V1 (see the section “Context-dependent Boundary Formation” on page 1582).

FACE CELLS Nowhere is the assumption of global rather than local processing more obvious than in face perception. The face is the most important visual stimulus in social interaction. Faces are global percepts that cannot be derived from individual features. Only holistic perception reveals the individuality of a face, as is evident from the clinical syndrome of *prosopagnosia*, or face blindness (Spillmann et al., 2000). Face-blind patients complain that they see the eyes, nose, mouth, ears, and hair but that “they don’t add up.”

In view of the biological preeminence of the facial stimulus, it should not be surprising that cells have evolved in the brain to encode faces. Such neurons have indeed been found. The early reports on neurons in the inferotemporal lobe (Rolls, 1984, 2000; Perrett et al., 1982, 1992) responding to intact faces more strongly than to their constituent parts have now been confirmed. “Face neurons” would be expected to allow for a certain amount of transposition and invariance for us to be able to recognize faces irrespective of illumination, distance, and viewpoint (Grüsser and Landis, 1991). Indeed, they must be capable of preserving the configural information of the face despite large transformations of the stimulus. Global or holistic perception enables perception of the identity as well as the physiognomic properties (emotional salience) of a face. However, as of yet, no type of neuron has been found to signal the facial expres-

sions of happiness or sadness, surprise or fear, anger or disgust, although brain lesions in the amygdala have been found to result in impaired recognition of fear and disgust (Calder et al., 2001). To show how the perception of emotional salience of a face is neurally encoded will be a major task of future research.

BINDING BY SYNCHRONIZATION: A MECHANISM FOR GESTALT FORMATION In the outside world, parts that belong to one object are situated next to each other. However, there are exceptions when it comes to the perception of groups and group members. Here the question arises of how we link up distant parts of a stimulus moving in the same or similar direction. The most widely discussed answer is: by response synchronization in cell assemblies. Neurons stimulated in a similar manner are hypothesized to adjust their firing patterns so as to discharge in unison (Eckhorn et al., 1988; Gray et al., 1989). Synchronization would then bind stimuli together in different loci by virtue of their common properties (e.g., orientation, color, size) and in this way achieve grouping. The advantage of such coupling by synchronized neuronal activity is obvious: it would enable cells and cell groups to change partners with which they share activity when the stimulus configuration changes. Binding by synchronization thus provides a flexible efficient neuronal mechanism for figure-ground segregation (see Chapter 113).

In addition to local features, binding plausibly underlies the detection of coherent motion according to the factor of *common fate*. How common must common fate be? Uttal et al. (2000) found that as few as 4 collinearly arranged dots moving on a random dynamic noise field of 100 dots suffice to be seen as a group. This low signal-to-noise ratio is astonishing, but even more remarkable is the fact that a similarly low ratio was found behaviorally in trained, alert monkeys and also when recording from individual neurons (Newsome et al., 1989; Britten et al., 1992).

Gestalt psychologists such as Köhler (1940) would have liked the idea of temporal binding because it generates percepts from the interaction of many neurons in different areas of the brain and because the same neurons can serve different percepts. Köhler wrote “A given visual field, for instance, is biologically represented by a certain distribution of processes in the occipital lobes of the brain; the correlates of other perceptual facts are located in various other lobes; and many psychological events are likely to concern the brain as a whole.” This foresight from the foremost theoretician of the Gestalt movement has proven to be remarkably close to today’s findings using neuroimaging methods. These findings suggest parallel stimulus processing within several retinotopically organized visual brain areas and cross-talk between these and nonvisual areas (Engel et al., 1997; Heeger, 1999; Kastner et al., 2000; Van Essen et al., 2001).

Examples of current Gestalt research

FIGURE-GROUND CORRELATES To account for stimulus integration and figure-ground segregation, new terms have emerged to convey the notion that a contour typically is unilateral: *belongingness* (Nakayama and Shimojo, 1990) and *border ownership* (Zhou et al., 2000). As a rule, the contour delineates the figure, not the ground. When figure and ground switch, as in bistable (reversible) figures, the assignment of the contour switches as well. This asymmetric assignment was central to Gestalt psychology and was referred to as the law of the inside (*Gesetz der Innenseite*; Metzger, 1936/1953).

Neurophysiological studies in monkey area V1 (Lee et al., 1998) as well as V2 provide evidence for this kind of figure-ground polarity. For example, neurons have been found that are selective for figure-ground direction (1) at illusory contours like those produced by Ehrenstein- or Kanizsa-type figures (Baumann et al., 1997; Heider et al., 2000; Peterhans and Heitger, 2001), (2) at luminance edges in overlapping squares and rectangles (Zhou et al., 2000), and (3) at stereo edges in random-dot stereograms (von der Heydt et al., 2000; Heider et al., 2002). This kind of neural activity would plausibly contribute to the perceptual segregation of figure and ground at these contours.

SMOOTH (OR “GOOD”) CONTINUATION In a series of experiments, contour processing was tested psychophysically by using a surface of Gabor patches with random orientations. Collinearly oriented but disconnected patches were added to

form a perceptual contour (Field et al., 1993; Kovács and Julesz, 1993). Figure 106.7 shows that these patches can easily be seen as a curvy line despite the fact that the distance between aligned patches is larger than the length of each patch and the elements in the background have a smaller average separation than those along the contour. This *popout* effect is even stronger when the patches form a closed circle. These results may be taken as evidence for a neuronal mechanism that perceptually connects individual stimuli with an *association field* (Field et al., 1993) according to the Gestalt factors of good continuation and closure. If one of the elements was rotated out of alignment, the chain broke up and a circle was no longer perceived. Kovács and Julesz (1994) also found that local contrast sensitivity within the virtual circle of orientated patches was enhanced relative to that on the outside, suggesting that the elements constituting the figure are privileged. Neurons coding collinearity (Peterhans and von der Heydt, 1991) may be involved in this task (see Chapter 70).

Stimuli beyond the classic receptive field have been shown to facilitate the response to a central bar in cat visual cortex when they are cooriented and coaxially aligned with the central stimulus (Nelson and Frost, 1985). In fact, when a jumbled target/background pattern was used for a stimulus, the response in area V1 of the alert monkey to an optimally oriented target bar increased when the immediately adjoining bars at either end of the target were rotated to become collinear with the central stimulus (Kapadia et al., 1995, Fig. 12). The combined response could even be higher than that

FIGURE 106.7. The figure of a circle in a random arrangement of Gabor patches becomes visible according to the Gestalt factor of good continuation. *a*, Partial curve; *b*, complete circular figure. Note that the number of patches and the overall distribution of

their orientations are equal in *a* and *b*, but the brain's response is not. (From Kovács and Julesz, 1993. Copyright 1993 National Academy of Sciences, USA.)

to the central bar alone. This increase suggests that surround inhibition was eliminated and replaced by collinear facilitation. Anatomical studies have shown that tangential connections in the primary visual cortex predominantly link neurons responding to contours that have similar orientation preferences and are aligned collinearly (Bosking et al., 1997; Schmidt et al., 1997). Together with neurophysiological evidence showing that these connections can mediate collinear facilitation, these results suggest that the neuronal circuitry underlying contour integration and perceptual salience is already present in area V1 (Löwel and Singer, 1992; Crook et al., 2002). The psychophysics of good continuation may thus find its neurophysiological correlate in the functional architecture of these connections (Palat and Sagi, 1994).

CONTEXT-DEPENDENT BOUNDARY FORMATION Boundaries typically result from stimulus differences at the edge between homogeneous but differing surfaces. Such differences may be luminance, wavelength, orientation, texture, motion, and depth contrast (Nothdurft, 1993; Bach and Meigen, 1997; for a review, see Regan, 2000). Even a phase lag (Leonards et al., 1996; Kandil and Fahle, 2001) or a difference in flicker frequency is sufficient to define an edge, and an edge owned by a space segregates figure from ground. Here it was found that the contour delineating a figure fuses at a flicker frequency as low as 4 to 5 Hz, whereas the enclosed surface area fuses at a much higher frequency (van de Grind et al., 1973). We may conjecture that this difference reflects processing by the parvo- and magnocellular systems, (Livingstone and Hubel, 1987): parvo-cells having low temporal and high spatial frequency resolution (edges); and magno-cells having high temporal and low spatial frequency resolution (surfaces).

Lateral neuronal effects of context-dependent contrasts were first reported by Nelson and Frost (1978) in area V1 of the cat and thereafter by others in the monkey (for a review, see Allman et al., 1985). Orientation and motion contrast were the phenomena most thoroughly studied (e.g., Knierim and Van Essen, 1992; Sillito et al., 1995; Sillito and Jones, 1996). Figure 106.8 shows that the response to a single orientation is best when there is a suitable center stimulus, and it becomes significantly weaker when flanker stimuli of like orientation are presented in the surround (Kastner et al., 1999; Nothdurft et al., 1999). Conversely, orthogonal stimuli restore the response. This result explains why a hatched square elicits a strong response when presented on a differently oriented background but a reduced response when the orientation contrast is eliminated (Lamme, 1995; Zipser et al., 1996). Thus, figure-ground segregation is likely to involve orientation-selective, context-sensitive neurons. A similar conclusion holds for neurons responding to motion and texture (see Chapter 45).

FIGURE 106.8. Neuron responses reflect orientation contrast in cat striate cortex. The response to the optimal stimulus (0) is much higher than to the same stimulus surrounded by like elements (1) but only slightly higher when surrounded by orthogonal stimuli (2). Little response is obtained when the orientations of the bars are rotated by 90 degrees (4–7). (From Kastner et al., 1997.)

SURFACE FILLING-IN While the neural representation of boundaries is fairly well understood, the cortical representation of surfaces is still a matter of conjecture. How do we account for the perception of uniform brightness, color, and texture on extended areas? As pointed out above, cortical neurons respond poorly to uniform stimuli. The question therefore arises of why and how we perceive a bright, colored area enclosed by a contour. Grossberg and Mingolla (1985) advocated two processing systems: a *boundary processing system* and a *feature processing system*. The latter produces perception of a uniform surface by diffusion of stimulus information extracted from the edge.

More specifically, Spillmann and Werner (1996) and Gilbert (1998) proposed that excitation (i.e., active filling-in) via horizontal connections accounts for area contrast and other large-scale effects. Indeed, when a large yellow disc is surrounded by an achromatic annulus and the luminance of the annulus is increased beyond that of the disc, the yellow color will change to brown and ultimately black: Hering's (1874) *Schwarzverhüllung*. This is definitely a surround effect, which requires that the luminance change is extracted at the contour and transmitted to the center of the disc.

These hypotheses are now receiving support from psychophysical experiments, suggesting that brightness and texture originate at the border and spread onto the delineated area until stopped by a black barrier (Paradiso and Nakayama, 1991). In this way, a homogeneous surface is created representing a figure on a ground (for a review, see Spillmann and DeWeerd, 2003).

LARGE-SCALE COLOR EFFECTS Filling-in of color represents a particular challenge to any explanation, as this is a large-scale effect driven by a small-cell input: color is processed predominantly by the parvocellular system, which is characterized by small receptive fields. Yet, a wide, uniform spread of perceived color has been evident at least since Goethe's (1810) description of colored shadows. Here subjectively saturated colors are induced and perceived on a large achromatic area when it is flanked by a chromatic surround. Recently, Kallmann et al. (2002) measured the induced color of these shadows and found in all cases a hue shift toward the complementary color of the surround. The effects were strongest for blue and yellow surrounds and under conditions where the luminance of the surround exceeded that of the "color-shadowed" area. This is a striking phenomenon that up to now has eluded physiological explanation, although results suggest involvement of the larger koniocellular or S-cone receptive fields.

There may be a relation to chromatic induction mechanisms. In an experimental setup similar to that producing colored shadows, Valberg (1974) measured the colors induced into an achromatic center by chromatic surrounds. The dependence of the induced colors on the hue and saturation of the inducing colors points to lateral processes within color opponent mechanisms. The finding that steady surrounds, remote from the receptive field center, affected the activity of parvocellular neurons in the macaque lateral geniculate nucleus (Valberg et al., 1985) further supported this suggestion. It thus appears that the global response field, far beyond the classical receptive field, controls cell response by means of simultaneous contrast, and it does not wait until the highest visual centers to do so. As daylight changes from dawn to dusk, these mechanisms presumably drive global gain control mechanisms and cause sensitivity shifts that ensure color and lightness discrimination for the objects encountered in a natural environment.

FIGURE 106.9. The watercolor effect as an example of large-scale color assimilation arising from thin color boundaries. A purple border flanked by an orange fringe produces a uniform orange coloration on the enclosed white surface area. The orange regions are segregated as figure from the other spaces, which are ground. (From Pinna et al., 2001.) (See color plate 80.)

A novel *watercolor effect* (Pinna et al., 2001) exhibits large-scale properties similar to those of Goethe's colored shadows, except that it is induced by a narrow fringe and is more subtle in appearance. Figure 106.9 shows a wavy line pattern consisting of a dark purple contour lined by an orange fringe. Clearly, the orange color is seen spreading uniformly over the entire surface area. This process is seemingly instantaneous and covers visual angles of up to 45 degrees. The watercolor effect may serve to enhance figure-ground segregation by imparting surface color to the enclosed area. It may also promote grouping between distant stimulus elements (Fig. 106.10). While diffuse and subtle, the color is not weak: when pitted against the classical Gestalt factors (see the section "Figure-Ground Segregation and Perceptual Grouping" on page 1574), watercolor invariably wins as the figural determinant (Pinna et al., 2003). The assimilative color spreading from the narrow fringe may arise in two steps: first, weakening of the contour by lateral inhibition between differentially activated edge cells (local diffusion); and second, unhampered flow of color onto the enclosed surface area (global diffusion).

Another spreading phenomenon that can fill-in large areas is *neon color spreading* (Bressan et al., 1997), where a veil of color covers the area of illusory brightness enhancement in the Ehrenstein and Kanizsa figures. Simple inducing stimuli, such as four short black lines connected by a colored cross, are sufficient to elicit the effect: a delicate glow in the color of the cross. However, spreading is not unique to color. Figure 106.11 demonstrates that spreading is also observed for texture (Watanabe and Cavanagh, 1991), suggesting that filling-in is a general mechanism by which the

FIGURE 106.10. The watercolor effect is superior to the classical Gestalt factors (here, proximity) in conferring figure status on one space in preference to another. In this well-known variant of Rubin's (1915) sectored disc (or Maltese cross), the narrow sectors are normally seen as the figure. However, if colored fringes are used for the figure's contours, then the watercolored sectors are seen as figures, regardless of whether their boundaries have proximity or not. (Courtesy of B. Pinna; see also Pinna et al., 2003.) (See color plate 81.)

visual system creates figures on a ground from sparse information.

GESTALT COMPLETION ACROSS SCOTOMATA The principles governing visual perception under normal circumstances would also be expected to be effective as a repair mechanism. From the work of Kaas et al. (1990) and Gilbert and Wiesel (1992), it appears that holes in the retina resulting in visual scotomata are compensated for by a massive reorganization of cortical receptive fields. The authors found that a deafferented cell quickly resumed firing when light fell on adjacent regions of the retina. One way to explain this reactivation is by assuming that collateral signals are fed to deafferented neurons through horizontal long-distance connections. Accordingly, patients rarely notice a dark spot in their visual field after laser coagulation of the retina. Instead, they report that the percept in the area of the lesion is largely undisturbed and complete, with color, brightness, and texture. There are limits, though, when the area to be bridged is too large and when the parts to be connected are

nonrelatable, for example, because of different orientation (Kellman and Shipley, 1991). In this case, no perceptual filling-in takes place. The interpolation required to bridge a scotoma, including the physiological blind spot (Fiorani et al., 1992; Durgin et al., 1995), may be analogous to that taking place in the formation of illusory contours in Ehrenstein- and Kanizsa-type figures (see the section “Perceptual Constraints” on page 1574).

APERTURE MOTION Preceded by Stumpf’s early observation in 1911 (see Todorovic, 1996), Hans Wallach (1935) was the first to analyze systematically the direction of perceived motion when moving contours are viewed through an aperture or a window (Wuerger et al., 1996). Here one observes a striking change in apparent motion direction dependent on the shape of the aperture. Normally, the perceived motion direction of a line with invisible end points would be at right angles to the line’s orientation. In a window, however, the direction of motion typically appears parallel to the contour of the window. For example, oblique lines viewed through a vertical rectangular slit are always seen to move vertically (*barber pole effect*). With an L-shaped aperture, the apparent direction of the moving lines changes from vertical to horizontal when the lines reach the base of the L. The *aperture problem* refers to a fundamental question of motion perception: how are local motion signals integrated to provide coherent motion percepts in a complex visual scene? The visual system itself faces the same difficulty: an aperture problem arises from the limited receptive field size of a single neuron (Adelson and Movshon, 1982; Hildreth, 1984).

To account for this problem, Movshon et al. (1985) proposed a two-stage model of motion processing. The information from first-order, direction-sensitive simple or complex cells of areas V1 and V2 is integrated in second-order *component* and *pattern* cells in area MT, whose neurons have large receptive fields and receive direction-selective inputs from areas V1 and V2. Component cells provide signals about the local motions of individual contours, similar to cells found in area V1. Pattern neurons, however, reflect integrated information about coherent motion that results from combined inputs of local motion signals from several different contours or orientations (Movshon et al., 1985). They occur only in area MT.

Recently, Grossberg et al. (2001) extended Movshon’s model, assuming directionally tuned transient short-range cells that respond to local image transients. Long-range cells in area MT pool their signals (multiple orientations, opposite contrast polarities, and depths). MT cells further activate a directional grouping network, proposed to occur within the adjacent cortical area MST, within which motion directions, generalized across space, compete to determine a local winner: coherent motion signals typically win over incoher-

FIGURE 106.11. In addition to producing an illusory contour delineating a surface having illusory brightness, the brain is capable of filling the space with illusory texture. Illusory spreading of texture within the Ehrenstein pattern is shown for *a* hatched and *c* dotted crosses bridging the central gaps. *b*, *d* Crosses in isolation. The spreading effect is best observed in peripheral version; fixate at the center of the pattern. (From Watanabe and Cavanagh, 1991.)

ent ones. The winning direction coded by MST cells is fed back to MT cells, which enhance directionally consistent cell activities and suppress inconsistent activities.

Wallach's (1935) demonstrations of perceptual organization in seen motion have thus served to demonstrate local edge effects on whole-surface motion, and to inspire research and modeling of neuronal mechanisms in areas MT and MST that cast light on integrative mechanisms in motion perception.

Outlook

Gestaltists considered Gestalt factors in vision essentially as bottom-up mechanisms built into the visual system through evolution of the organism as it interacted with stimuli in a natural setting. In this sense, it may be said that illusory contours have evolved to support contour integration and contour completion in partially occluded stimuli (Dresp, 1997). In the words of Michael Wertheimer, "Gestalten are real phenomena in the natural world, not the whimsical, arbitrary creations of a mind" (Sharps and Wertheimer, 2000, p. 324). Today's attempts to match the visual features in natural scenes with the properties of known neuronal mechanisms will show how well we are equipped for the task: to encode the world around us (see Chapter 70).

Another question being asked today focuses on the relationship between vision and action. Gestalt psychologists restricted themselves to the study of perception (*reine Anschauung*). Yet, our sensory systems developed in close correspondence with our motor systems (Weizsäcker, 1947). Thus, one would expect that what we see has direct bearing on the way we act, and vice versa. Modern theories of visual function distinguish between different though interactive visual systems, one for the perception of objects, the other for the guidance of actions directed at those objects (e.g., Goodale and Humphrey, 1998). Evolutionary history suggests that these systems are based on the ventral stream (vision as a basis of cognition) and the dorsal stream (vision leading to motor control), respectively.

Perceptual constancy occurring despite translation and rotation of the eye, head, and trunk has now been added to the study of vision, as have changes of observation distance. Selective attention (Treue, 2001; see Chapter 103), fixation, guided saccades, and pursuit movement (Ebenholtz, 2001) have also been included. From these must emerge an understanding of how we construct maps of the space around us that are sufficiently accurate and stable for us to walk through them. Finally, cross-modal studies, already present in the older literature (e.g., Goldstein and Rosenthal-Veit, 1926; Schiller, 1932) are reentering the field (e.g., Ehrenstein and Reinhardt-Rutland, 1996; Stein, 1998; Lewald et al., 2001). They show, for example, that the direction of gaze

can influence the perceived auditory direction, an effect which can be linked to the (incomplete) transformation of spatial coordinates within auditory and visual neural representations in the primate midbrain and parietal cortex. Cross-modal sensory integration affords coherent space perception to enable proper action.

By its very nature, Gestalt psychology as a theoretical approach to vision and perception required the assumption of neural networks even before the term became ubiquitous. Perception is organization. It is implicit in every perceptual demonstration due to laterally interacting networks. Given today's knowledge, we realize that the questions then asked were far ahead of their time. Eighty years later, a biological basis for higher perceptual factors appears to be within our grasp. Seemingly effortlessly, our brains pick up information, process it, and enable us to maneuver in a complex environment. We negotiate our world far better and faster than any robot without stumbling. Why? Because Gestalt factors, the interface between the world and the percept, guide us along. A large number of neurons is not decisive, nor is the speed of processing. Gestalt-like interaction makes the difference.

Acknowledgments

Preparation of this chapter was supported by DFG Grant SP 67/6-2 (to LS) and DFG Grant Eh 91/4-4 (to WHE). Jerry Nelson helped with the conceptualization, and Ilona Kovács, Sigrid Löwel, Galina Paramei, Esther Peterhans, Viktor Sarris, Arne Valberg, John S. Werner, Mimsey West, and Michael Wertheimer provided valuable comments. Ute Lobisch prepared most of the figures. Baingio Pinna and Frank Stürzel assisted with the electronic data transfer. Simon and Anna cheered us up. We thank them all.

107 Neural Mechanisms of Natural Scene Perception

JACK L. GALLANT

AN IMPORTANT GOAL of visual neuroscience is to understand the neural mechanisms mediating vision in the natural world. Natural vision is a difficult problem for two reasons. First, natural images are exceedingly complex, and their structure is not well understood. Second, natural visual behavior reflects the influence of a dynamic system controlling eye movements and attention and operating simultaneously at many levels of visual processing. These factors make it difficult to perform controlled experiments that isolate the specific attributes relevant to particular hypotheses about visual function. Therefore, most experiments in visual neuroscience address natural vision indirectly, using simple stimuli and tightly controlled visual behavior.

The degree to which theories developed from simple experiments can generalize to natural vision hinges on the linearity of visual neurons. In a linear system, the response to a complex stimulus is equal to the sum of the responses to its simpler constituents. This property is called *superposition*. If the visual system were linear, responses to complex stimuli such as natural scenes could be predicted based on a combination of responses to simple stimuli. However, the visual system does not generally obey superposition; responses to the sum of two simple stimuli often do not equal the sum of responses to each alone. The failure of superposition becomes markedly more pronounced at higher stages of visual processing. For example, neurons in the inferior temporal cortex often respond only to complex configurations of specific stimulus features and give no responses to the constituent parts. In such cases, experiments using very simple stimuli are likely to have limited utility.

A second common assumption of linear systems analysis is that the response to each stimulus is unaffected by previous stimuli. This is related to a property called *stationarity*. A stationary system does not change its characteristics over time and is therefore easy to analyze experimentally. However, nonstationary processes, such as visual adaptation, attention, learning, and memory, operate at all stages of visual processing and depend on the history of visual experience. To avoid the complexities of nonstationarity, conventional experiments are usually designed so that the system is held in one mode of operation. If this is not the natural mode of the system, then the results may not generalize to natural vision.

It is clear that the visual system at least partly violates the assumptions underlying many conventional neurophysiological experiments. This complicates both the conduct and the interpretation of experiments that use simple stimuli, especially for studies of higher visual processing. At the same time, the difficulty of quantifying and controlling natural vision limits our ability to address it directly using standard experimental procedures. Thus, the most difficult part of studying natural scene perception is developing appropriate experiments.

This chapter reviews current research on the neural mechanisms of natural scene perception. We begin with a brief review of the statistical properties of natural scenes insofar as they are currently known. Second, we review theoretical and experimental studies aimed at determining whether and how the visual system is optimized to process natural scenes. These studies have examined neural coding of natural scenes in retina, the lateral geniculate nucleus (LGN), and primary visual cortex (area V1). Third, we summarize recent experiments that use natural scenes to objectively characterize filtering properties of neurons in area V1 and in higher, extrastriate visual areas. Finally, we describe recent neurophysiological experiments on natural vision. These studies investigate both eye movements, which control how a natural scene is sampled, and attention, which affects how information is represented at various stages of visual processing. The review focuses on the ventral visual pathway and does not address natural scene perception in other visual subsystems (e.g., parietal cortex, frontal eye fields). The review also does not address perception of natural color images, an important area of current research.

Scene statistics

Natural images are obviously quite complex and may appear almost impossible to characterize. Fortunately, several reasonable assumptions simplify analysis of natural scenes. A *natural scene* can be broadly defined as any scene that is likely to be experienced in the normal evolution or development of an organism. This excludes many of the simple stimulus patterns, such as gratings and white noise, often used to study vision but rarely encountered in nature. It is also useful

FIGURE 107.1. *A*, White noise. This stimulus has a flat power spectrum and no correlations between pixels. *B*, $1/f$ noise. This stimulus has a $1/f^2$ power spectrum like that of natural images but no correlations between pixels. *C*, A natural image. *D*, The natural image

shown in *C*, with a normal power spectrum and a scrambled phase spectrum. The image appears similar to the $1/f$ noise pattern shown in *B*. *E*, The natural image shown in *C*, but with a whitened power spectrum and a normal phase spectrum. The image is recognizable.

to ignore the structure of any single, specific image and focus instead on characterizing the statistical distribution of a large ensemble of scenes. Any specific regularities in this distribution could, in principle, be exploited by the visual system. Another simplifying assumption is *viewpoint invariance*, which reflects the fact that the camera (or eye) could observe a scene from any vantage point. Finally, it is useful to consider the spatial and temporal statistics of natural scenes in isolation insofar as this is possible. The spatial statistics of the scenes are determined by the structure of the world, while the temporal statistics are determined by several factors: the motion of objects in the world, the motion of the observer through the world, and the observer's eye movements.

The first-order spatial and temporal statistics of natural images are relatively well understood (Olshausen and Field, 2000; Ruderman, 1994). They describe the distribution of luminance values that might appear in any image. The second-order spatial statistics are more interesting; they describe the correlations between pairs of pixels. These correlations can be obtained from the spatial autocorrelation or from its Fourier transform, the power spectrum. Analysis of the autocorrelation matrix of the distribution of natural scenes reveals that nearby pixels tend to have similar bright-

ness values and that the strength of this correlation falls off with distance. Correspondingly, analysis of the power spectrum of this distribution shows that power decreases as $1/f^2$ (where f is spatial frequency; note that the power spectrum is the square of the amplitude spectrum). In other words, low spatial frequencies in natural scenes tend to have the most power, and power decreases with increasing spatial frequency (Field, 1987) (Fig. 107.1). These second-order statistics may reflect both scale invariance (Field, 1987; Ruderman, 1997) and the distribution of one- and two-dimensional image features such as edges, curves, line terminations, and so on (Balboa et al., 2001).

Natural scenes contain rich statistical structure beyond the two-point spatial correlations described by the power spectrum. Edges and lines, textures, surface patches, and objects all can contain correlations higher than second-order. A simple demonstration illustrates the importance of higher-order structure for natural scene perception: if the power spectrum of a white noise pattern is adjusted to match the $1/f^2$ spectrum of natural scenes, the resulting image will look like shapeless clouds (Fig. 107.1). This indicates that the appearance of a natural scene is not entirely (or even predominantly) determined by its power spectrum. Conversely,

if we weight the Fourier coefficients of a natural scene so that all frequencies have equal power (a process called *whitening*), the resulting image still contains substantial identifiable structure. Thus, the appearance of the scene is not determined solely by its power spectrum. Finally, it is easy to discriminate between scenes whose power spectra have been shuffled (i.e., the amplitudes of the spatial frequencies have been shuffled randomly). In contrast, it is impossible to discriminate between images whose phase spectra are randomized. This implies that much of the information about the meaning of specific natural scenes is carried in the spatial phase spectrum (Piotrowski and Campbell, 1982; Tadmor and Tolhurst, 1993; Thomson and Foster, 1997).

It is difficult to quantify the higher-order spatial statistics of natural scenes (Krieger et al., 1997; Thomson, 1999; Wegmann and Zetsche, 1990b) and their phase characteristics (Thomson, 2001). This is partly due to the common occurrence of surface and volume occlusions in natural scenes. Occlusion in natural images is a fundamentally nonlinear process, and few methods are available for quantifying the resulting distributions (Lee et al., 2001). Even so, useful image models can be obtained by using established statistical methods that do not explicitly consider occlusion.

One of the most useful statistical methods for discovering important structure in natural scenes has been independent components analysis (ICA) (Hyvarinen et al., 2001). Assume that each natural image reflects the combined influence of many independent factors that represent the structural elements of the image. Instead of identifying these elements according to some explicit theory, ICA extracts them directly from a large sample of images. ICA finds the independent factors that can be linearly combined to create any image from a distribution of natural scenes.

The theoretical importance of independent components (ICs) for image coding can be understood by considering the probability density function (PDF) of pixel correlations in natural images. If the PDF is Gaussian, then there are no privileged directions in correlation space and all linear coding strategies are equally efficient. However, if the distribution is not Gaussian, then image codes that are aligned with the most kurtotic dimensions will be most efficient. ICA allows one to discover these important non-Gaussian dimensions, even if they reflect image correlations beyond second-order.

Several different studies have now used ICA to characterize natural scenes (Bell and Sejnowski, 1997; Hyvarinen and Hoyer, 1999; Olshausen and Field, 1997) and have produced remarkably consistent results. In all cases the ICs are spatially localized, bandpass functions tuned for orientation and spatial frequency. Taken together these ICs can represent any natural scene, but very few of them appear in any specific scene. This form of representation is known as a *sparse code*.

The ICs of natural scenes are very similar to Gabor wavelets (each wavelet is a sinusoid weighted by a Gaussian envelope) that have been used as computational models of neurons in primary visual cortex (Daugman, 1988; Field, 1994; Navarro et al., 1996). When ICA is applied to videos of natural scenes containing moving objects (Szatmary and Lorincz, 2002; van Hateren and Ruderman, 1998), the ICs are localized in space-time, bandpass in spatial and temporal frequency, tuned for orientation, and direction selective. The close correspondence between the ICs of natural scenes (or movies) and the tuning properties of V1 neurons suggests that this area is optimized to process the sparsely distributed features in natural scenes. We discuss this issue more fully below.

Independence, as used in ICA, has a specific meaning: the presence of one IC predicts nothing about the presence or absence of any other element. However, there is no guarantee that the estimated ICs will indeed be completely independent. The ICA algorithm only ensures that they will be as independent as possible, given the data. The actual degree of independence is important; if the ICs of natural images are not entirely independent, further processing could recover additional information. The nonindependence of Gabor wavelet filters has been examined directly in theoretical studies by examining their responses to natural images (Simoncelli and Schwartz, 1999; Wegmann and Zetsche, 1990a; Zetsche et al., 1999). The filters are not completely independent; when one wavelet filter is triggered by an image, another filter is also likely to respond. These correlations reflect higher-order structure in natural images that might be exploited by further nonlinear processing.

Optimization

The question most commonly addressed in studies of natural scene perception has been whether the visual system is optimized to process natural scenes, and if so, what sort of optimization is involved. All species evolved in environments with specific physical properties and selective pressures should have favored those individuals that could most efficiently perceive their environment. Conversely, there is no reason to believe that natural selection would favor adaptation to arbitrary visual environments never experienced by an organism.

Theoretical considerations of signal processing suggest a clear strategy for optimally processing the information contained in natural scenes (Barlow, 2001; Zetsche and Krieger, 1999). First, the visual system should discard information that is not useful for processing a specific scene. Because the second-order correlations reflected in the $1/f^2$ power spectrum of natural scenes provide little useful information, the early stages of visual processing (retina, optic nerve, LGN, and possibly V1) might therefore reduce or eliminate them.

Second, the visual system should exploit the information remaining after decorrelation. This information is vital for identifying and processing the shapes in each specific scene. The Gabor-like sparse ICs of natural scenes represent one early aspect of information exploitation. More complex information is likely to be processed at later stages of processing in the inferior temporal processing stream (V1, V2, V4, and the inferior-temporal complex).

OPTIMIZATION IN RETINA AND LGN A basic form of decorrelation is to whiten the signal. Whitening produces a more efficient representation of the image because information is distributed more equally across the available channels (e.g., LGN afferents tuned to different spatial frequencies). Early studies on natural image processing concluded that spectral whitening is indeed implemented in the eye of the fly (Srinivasan et al., 1982). The contrast-response function of the fly eye effectively whitens the contrast distribution of natural scenes. This process is implemented by means of lateral inhibition between interneurons, which removes local spatial correlations. Theorists have argued that mammalian retinal ganglion cells and LGN neurons, both of which have a clear center-surround organization, might also decorrelate photoreceptor responses (Atick, 1992; Dong and Atick, 1995a; also see Barlow, 1961).

Because natural images vary over time, it is also likely that LGN neurons also whiten temporally varying signals (Dong and Atick, 1995a). The hypothesis that LGN whitens the temporal spectra of natural images has been tested directly in neurophysiological experiments (Dan et al., 1996). The experiments compared LGN responses obtained with movies of natural stimuli to those obtained with white noise. These two stimulus classes have substantially different temporal power spectra: natural movies have a complex $1/f^n$ power spectrum, while the power spectrum of white noise is flat. Thus, temporal decorrelation was assessed by comparing the power spectra of LGN responses obtained with the two stimulus classes. The temporal spectrum of LGN responses to natural movies was flat, even though the input had a complex temporal spectrum. This indicates that the LGN decorrelates natural temporal stimuli. In contrast, the power of LGN responses to white noise increased with temporal frequency. This shows that decorrelation is achieved by suppressing low temporal frequencies and enhancing high temporal frequencies. Taken together these results show that the LGN removes second-order temporal correlations in the input and that this whitening process is matched to the temporal statistics of natural vision.

OPTIMIZATION IN AREA V1 If V1 is optimized for processing natural scenes, then the receptive field properties of V1 cells should efficiently exploit information remaining after decorrelation by earlier stages of processing. We have

already seen that the ICs of natural scenes are spatially localized, tuned for orientation and spatial frequency, and sparsely distributed in each natural image (Bell and Sejnowski, 1997; Hyvarinen and Hoyer, 1999; Olshausen and Field, 1997; van Hateren and van der Schaaf, 1998). If primary visual cortex is optimized for processing such scenes, then V1 neurons might display these same key characteristics. This would permit efficient representation of natural scenes because the neural code would be aligned with the privileged axes of the stimulus space (Field, 1994; Zetzsche and Krieger, 1999). Many neurophysiological experiments conducted over the past 25 years have confirmed that V1 neurons are spatially localized bandpass filters tuned to orientation and spatial frequency (for review, see De Valois and De Valois, 1990). Thus, it appears that V1 cells are indeed optimized to detect the sparse components of natural scenes.

Several theoretical and experimental studies have investigated whether primary visual cortex uses a sparse code. The issue has been addressed by estimating *coding density* across the cell population (Barlow, 1961; Field, 1993; Vinje and Gallant, 2002). Coding density describes the fraction of neurons within a given visual area that participate in the representation of a natural scene. If a code is maximally dense, then information about a scene is completely distributed across all neurons and the decoder must integrate information from all cells to make sense of a scene. For this reason, dense codes tend to be robust to damage but difficult to decode. In contrast, a maximally sparse code represents each scene by the activity a single cell (e.g., one's grandmother would be represented by a single "grandmother cell"). Maximally sparse codes are easy to decode, but they are fragile and require enormous numbers of neurons.

The optimal coding density for representing natural scenes probably depends on both external (stimulus statistics) and internal (developmental and metabolic) factors. If the primary visual cortex is optimized for representing the sparse components of natural scenes, then the distribution of neural filters should match these components (Field, 1994; Olshausen and Field, 1996). Field (1987, 1994) first showed that when Gabor wavelets are adjusted to maximize their sparseness, they are most consistent with measured receptive field properties in primary visual cortex. Gabor wavelets are not the only type of filter that can form a sparse image representation. Many schemes that decorrelate pixels will produce a rather sparse code (Krieger and Zetzsche, 1996). It has been argued, however, that this representation produces an optimally sparse distribution for natural scenes (Field, 1987; Zetzsche and Krieger, 1999), consistent with the optimization hypothesis.

One open issue is how such a representation could come about, either through evolution or through learning.

Olshausen and Field (1996, 1997) demonstrated that an unsupervised neural network algorithm implementing ICA could learn a sparse distributed code for natural images. The resulting network elements were localized, oriented, and bandpass, much like the receptive field profiles of V1 simple cells (De Valois et al., 1982; Jones and Palmer, 1987). An important control condition demonstrated that the resulting elements did not look like V1 receptive fields when the model was trained on much simpler patterns (e.g., sinusoidal gratings). This result suggests that evolutionary and developmental processes could, in principle, have optimized area V1 to process natural scenes.

These theoretical studies demonstrate that Gabor wavelets can efficiently represent the sparse components of natural scenes. As noted above, such filters are not completely independent. They still possess significant correlations that reflect higher-order structure in natural scenes (e.g., corners and local curvature: Simoncelli and Schwartz, 1999; Zetzsche and Barth, 1990). This information is implicit, however, and can only be extracted by further, nonlinear processing (Krieger and Zetzsche, 1996; Zetzsche and Barth, 1990), which might occur within the nonclassical receptive field (nCRF) of neurons in primary visual cortex (Schwartz and Simoncelli, 2001; Simoncelli and Schwartz, 1999).

In a series of neurophysiological experiments, Vinje and Gallant (2000, 2002) investigated several hypotheses regarding sparse coding in primary visual cortex. Their stimuli simulated the stimulation neurons receive during free viewing of static natural scenes, including both fixations and saccadic eye movements. (This ensured that stimuli contained realistic spatial and temporal statistics.) They confirmed that natural stimulation of the nCRF increases kurtosis of the response distribution and decorrelates the responses of pairs of V1 neurons that receive similar stimulation (Vinje and Gallant, 2000). Using information theoretic analyses, they further found that nCRF stimulation also increases the information rate, the information per spike, and the efficiency of information transmission in individual neurons (Vinje and Gallant, 2002). Taken together these physiological results demonstrate that the nCRF increases the sparseness of the stimulus representation in V1, consistent with the hypothesis that the nCRF tunes V1 neurons to match informative components of the natural world.

Representation

The studies cited above confirm that vision scientists have achieved a good basic understanding of how shape is represented in primary visual cortex. Area V1 represents the visual world by means of a large bank of Gabor-like filters designed to match the sparse components of natural scenes. Much less is known about shape representation in the con-

stellation of over 30 extrastriate areas that make up the rest of the visual cortex (Gallant, 2000; Van Essen and Gallant, 1994). It is presently unclear if statistical analyses of natural scenes will provide new insights into scene structure beyond what is already known. Thus far, theoretical studies of shape have provided few clear, testable hypotheses about its potential neural representation.

Given these limitations, most neurophysiological experiments on shape coding in extrastriate cortex have sought to characterize neural responses along only a few specific stimulus dimensions (Desimone et al., 1984; Fujita and Tanaka, 1992; Gallant et al., 1993; Gross et al., 1972; Kobatake and Tanaka, 1994; Pasupathy and Connor, 1999). These studies suggest that higher visual areas implement banks of nonlinear, multidimensional filters for complex shape attributes. However, the fundamental principles of shape coding are still unknown. Experiments that use restricted stimulus spaces to test specific hypotheses are inevitably limited by the choice and size of the stimulus set. It is impossible to know, from these experiments alone, whether observed shape selectivity represents a fundamental coding property or merely reflects tuning along some other, unknown dimension. Therefore, some researchers have begun to address shape coding using natural scenes. Because a large sample of such images should include most relevant shape attributes, the stimulus selection bias can be minimized.

METHODS FOR INVESTIGATING SHAPE REPRESENTATION USING NATURAL SCENES Neurophysiological recordings can be made from single cells for only a limited time, usually a few hours at most. This constraint severely limits the number of images that can be used as stimuli in a real experiment. Under the best of circumstances, only a few thousand images can be sampled from the enormous universe of potential natural scenes. On the other hand, natural scenes are quite complex and contain rich statistical structure to which extrastriate neurons are presumably sensitive. These considerations suggest that the success of neurophysiological experiments will depend critically on procedures for data analysis and interpretation.

Despite the fact that many visual neurons are nonlinear, some insight can still be gained by the application of linear system identification methods. The fundamental idea behind linear system identification is that any system (in this case, a neuron) can be modeled as a filter that operates on the input and produces some output (DeBoer and Kuyper, 1968; Marmarelis and Marmarelis, 1978). This is conceptually equivalent to regression analysis. Instead of testing a specific hypothesis about shape coding, responses to complex stimuli are analyzed to determine how each stimulus component influences responses. These relationships are then summarized mathematically using a framework that describes both linear and nonlinear terms of the function relating

stimuli to responses. System identification uses a rich stimulus set and so requires few a priori assumptions about which specific stimulus attributes a neuron might encode.

In visual neurophysiology the mapping function that relates stimuli to responses is called the *spatiotemporal receptive field* (STRF). It describes both the spatial tuning of a cell and the evolution of tuning over time (Theunissen et al., 2001). STRFs are usually estimated by reverse correlation of recorded action potentials against preceding stimuli (DeAngelis et al., 1995; DeBoer and Kuyper, 1968), and several different algorithms have been proposed for performing this computation (Marmarelis and Marmarelis, 1978; Ringach et al., 2002; Theunissen et al., 2001). System identification methods have also been applied to other sensory systems (DeBoer and Kuyper, 1968; deCharmes et al., 1998; DiCarlo et al., 1998; Klein et al., 2000; Theunissen et al., 2001).

STRF estimation works best when two conditions are satisfied: the stimulus is spectrally unbiased, and response nonlinearities can be described accurately. White noise is unbiased and so is theoretically optimal for such studies (Marmarelis and Marmarelis, 1978). However, white noise is an inefficient stimulus for characterizing neurons selective for complex shapes. One way to overcome this problem is to characterize cells with natural scenes rather than noise (Theunissen et al., 2001). Because the visual system evolved to process natural scenes, these stimuli should elicit robust responses from visual neurons. The disadvantage of this approach is that the STRF must be corrected to remove bias introduced by natural stimulus statistics, such as the $1/f^2$ spatial power spectrum and local spatiotemporal correlations. Procedures have recently been developed for removing these biases and for characterizing response nonlinearities, such as rectification, that have posed problems for previous system identification studies (David et al., 1999; Nykamp and Ringach, 2002; Ringach et al., 2002; Stanley et al., 1999; Theunissen et al., 2001).

One important decision that must be made before STRF estimation concerns which dimensions to use to characterize responses. Many studies using linear systems identification have simply performed reverse correlation in the spatial domain (i.e., pixel gray-scale values; DeAngelis et al., 1995; Jones and Palmer, 1987). However, some nonlinear neurons, such as complex cells in area V1, cannot be analyzed this way; the phase-invariant behavior of complex cells masks the structure of the spatial kernel. For this reason, researchers have computed STRFs using other parameter spaces such as the Fourier domain (Theunissen et al., 2001), the second-order response covariance matrix (Touryan and Dan, 2001), or nonlinear feature spaces (Ringach et al., 2002). Any decision about which parameter space to use during STRF estimation must inevitably reflect some spe-

cific hypothesis about the nature of visual coding and nonlinear responses. When the chosen parameter space effectively linearizes the nonlinear response, it can significantly improve STRF estimates (Mazer et al., 2000; Theunissen et al., 2001).

STRF ESTIMATION IN AREA V1 System identification methods have been most often used to examine coding in the early visual system. The goal has usually been to determine whether computational models developed using simple stimuli account for responses to natural scenes. If the visual system is linear, then models developed using simple stimuli should generalize to natural vision. To the extent that the visual system is nonlinear, this may not occur. The practical influence of nonlinear processes is an empirical question that can only be investigated by comparing responses obtained using simple stimuli with those observed during natural vision (Theunissen et al., 2001). System identification provides a quantitative method for characterizing and comparing neural responses obtained under these different stimulus regimes.

One recent attempt to examine this issue compared STRFs of area V1 neurons in response to rapid sequences of random gratings and movies that simulated the stimulation received during natural vision (including the stimulation that occurs during eye movements; David et al., 1999; Theunissen et al., 2001) (Fig. 107.2). Each stimulus class was used to generate a separate STRF, giving two (potentially different) filter estimates per neuron. The accuracy of estimated STRFs was assessed by evaluating how well each one predicted neural responses. In general, STRFs generated from each stimulus class best predicted responses to the same class. For example, STRFs estimated from naturalistic stimulation best predicted responses to novel natural scenes (on average accounting for about 25% of the total variance in responses). These results demonstrate that area V1 is sensitive to the prevailing stimulus statistics. As these statistics vary, nonlinear mechanisms place the visual system into different operational modes.

To investigate what specific filtering properties were modulated by stimulus statistics, these experimenters examined the tuning profiles of recorded cells (David et al., 1999; Theunissen et al., 2001). Dynamic gratings evoked STRFs with simpler temporal responses and narrow tuning for orientation and spatial frequency. Natural stimuli tended to evoke STRFs with complex temporal profiles and broader spatial tuning for orientation and spatial frequency. STRFs obtained with natural stimuli were also less space-time separable than those obtained with dynamic stimuli (Mazer et al., 2002). These differences (and other data from the same study) indicate that temporal stimulus statistics have a substantial effect on both the temporal and spatial response properties of neurons in area V1.

A. Dynamic Grating Sequence

B. Natural vision movie

FIGURE 107.2. *A*, STRF of one V1 neuron obtained with a dynamic grating sequence. Each panel shows the Fourier power spectrum of the STRF at a single response latency (14 msec frame rate). The grating stimulus reveals good spatial tuning for left diagonal orientations and a simple temporal response with a latency of

about 40 msec. *B*, STRF of the same cell shown in *A*, obtained with a movie simulating natural vision. Although the spatial tuning of the STRF is relatively unaffected by stimulus statistics, the temporal response profile is quite different from that shown in *A*. (Adapted from Theunissen et al., 2001.) (See color plate 82.)

Eye movements and attention

Natural vision is an active process that operates in the context and service of behavior. Therefore, a complete description of natural vision must also address intention, attention, eye movements, and scene interpretation. These topics have been studied extensively using both behavioral and computational methods (for review, see Itti and Koch, 2001). Neurophysiological studies have been more limited and have tended to study specific components of natural vision (e.g., eye movements or attention) in isolation.

MODELS OF ATTENTION, EYE MOVEMENTS, AND CONTROL
Several computational models of how the visual system might function during natural vision have been proposed, and they share several core features (Deco and Zihl, 2001; Koch and Ullman, 1985; Lee et al., 1999; Niebur and Koch, 1996; Rao and Ballard, 1997; Schill et al., 2001; Sheinberg and Zelinsky, 1993). All treat sensory neurons as multidimensional filters. Within a given visual area, these filters collectively make explicit certain information about a visual scene. Other information is implicitly available and can be obtained by further processing. Although these neural filters have relatively stable tuning profiles, they are dynamically modulated by top-down attentional processes. These top-down influences reflect both immediate goals and prior knowledge about the structure of the visual world. By modulating filters appropriately, attention optimizes the visual system for a specific task.

As new stimuli are encountered, the neural filters respond in parallel. Because their responses are influenced both

bottom-up and top-down, they simultaneously represent both the structure of a scene and its behavioral relevance. In extrastriate areas that are retinotopically mapped, such as V4, the responses collectively form a saliency map indicating which spatial locations are most likely to contain behaviorally relevant patterns. Subsequent eye movements are then directed toward the point on the saliency map that is most active. Simultaneous with this, incoming neural responses are used to update continuously internal representations of the world.

There is ample behavioral evidence supporting this general model of active vision. Behavioral studies have shown that both humans (Binello et al., 1995; Mannan et al., 1995; Rao et al., 1996; Reinagel and Zador, 1999; Yarbus, 1967) and nonhuman primates (Burman and Seagraves, 1994; Gallant et al., 1998; Keating and Keating, 1982; Wilson and Goldman-Rakic, 1994) systematically sample complex scenes by moving their eyes toward points of interest. Indirect behavioral evidence suggests that selective attention is tightly coupled to these eye movements (Binello et al., 1995; Hoffman and Subramaniam, 1995; Kowler et al., 1995; Motter and Belky, 1998; Schill et al., 2001; Sereno, 1992).

There is also substantial neurophysiological support for the individual components of this model. Top-down attentional effects have been reported in most visual areas (for review, see Colby, 1991; Desimone and Duncan, 1995; Schall, 2001). It is clear that these attentional effects reflect task demands and internalized behavioral constraints (Chelazzi et al., 2001; Miller et al., 1993). Attention can modulate both the magnitude of neural responses to stimuli

at attended locations (spatial attention: McAdams and Maunsell, 1999) and selectivity for attended features or patterns (object attention: Motter, 1993, 1994; Olson and Gettner, 1996). It is also critical for scene segmentation (Desimone and Duncan, 1995; Moran and Desimone, 1985). In most cases, attention seems to alter the gain of neural filters (McAdams and Maunsell, 1999) or to gate inputs from earlier areas to facilitate scene analysis (Desimone and Duncan, 1995). However, it can also shift the spatial tuning profiles of V4 neurons somewhat (Connor et al., 1996, 1997). Other neurophysiological experiments support a close coupling between shifts of attention and eye movements, particularly in parietal areas 7a and LIP (Ben Hamed et al., 2002; Gottlieb et al., 1998; Steinmetz and Constantinidis, 1995). Eye movements and attention also appear to be coupled in area V4 (Mazer et al., 2001; Tolias et al., 2001).

NEUROPHYSIOLOGICAL STUDIES OF NATURAL SCENE PERCEPTION Neuroscientists have only recently begun to investigate the neural mechanisms mediating natural vision as an integrated system. In primary visual cortex, neural activity is substantially reduced during free viewing of natural scenes relative to what might be expected from studies using simple stimuli (Gallant et al., 1998). This effect appears to be due to two factors. First, natural scenes typically span the entire visual field and so drive suppressive mechanisms in the nCRF (Vinje and Gallant, 2000, 2002). Second, natural eye movements induce parasaccadic suppression, reflecting the combined influence of an efference copy of eye movements and direct suppression by high-velocity saccadic stimulation (Diamond et al., 2000; Judge et al., 1980).

Recent experiments have examined V4 activity during free viewing visual search of natural stimuli (Mazer et al., 2001). Animals were trained to search for a natural image patch (3 to 10 degrees) hidden in a large array of similar patches (Fig. 107.3). Eye movements were permitted during search; both eye position and neural activity were recorded continuously. Search arrays were arranged so that whenever the animal fixated a patch, the receptive field of the recorded cell would be centered over a different patch. Several different modulatory effects were observed that were clearly related to the task. First, the overall activity of many V4 neurons was modulated by the search target. Some cells showed a persistent target-dependent enhancement or suppression of their activity throughout a trial, including during saccades. Others showed a target-dependent multiplicative enhancement or suppression of responses, consistent with a gain control mechanism. These effects occurred throughout each fixation and were independent of the image patch falling within the receptive field at any time. Therefore, they likely reflect top-down object-related attention. This suggests that V4 may contain several different classes of neurons that

participate in different aspects of natural vision. Second, some V4 neurons showed target-dependent modulation of their STRFs. In particular, Fourier domain STRF tuning profiles were modulated by the search target. This effect suggests that attention optimizes V4 neurons for a particular task by direct top-down modulation of spatial frequency and orientation tuning of individual cells. Finally, the activity of many neurons predicted the direction of subsequent eye movements: the larger the response of the cell, the more likely it was that the next saccade would place the fovea at the spatial location of the neuron's receptive field. Given that V4 neurons are affected by both task demands and stimulus properties, this suggests that V4 functions as a saliency map.

All of these observations are qualitatively consistent with the computational models of visual search reviewed above. Neurons in area V4 collectively implement a parallel bank of spatially localized multidimensional filters. The sensitivity and tuning profiles of these filters can be modulated by top-down influences to optimize performance in a specific task. During natural vision, the filters respond to local features in the scene according to their match with the stimulus characteristics. The output of the filter bank is then used to drive subsequent eye movements.

Natural vision experiments have also been used to examine object coding in the inferior temporal cortex (IT) during free viewing visual search for natural targets embedded in natural scenes (Sheinberg and Logothetis, 2001). Animals were required to locate a target in one of several images within which it might be embedded and were free to make eye movements as necessary to evaluate each image. IT cells were remarkably silent during the search task. However, they tended to give a burst of action potentials when animals recognized that a target was present in a particular image. Population analyses showed that these bursts tended to occur immediately before a saccade to the target item, consistent with the idea that IT activity correlates with recognition. Furthermore, larger bursts predicted faster response reaction times. Taken together these data indicate that IT activity encodes the probability that a behaviorally relevant target is present in a natural scene. These data also suggest that many aspects of visual processing, such as scene segmentation and grouping, are already completed by this stage of processing. IT cells may therefore be most involved in behavioral control and judgment.

Natural scene perception has also been examined using neurophysiological recordings in the frontal eye fields (FEF), which occupy a relatively late stage of visual processing. Neurons in this area form a representation of visual space but are also directly involved in the generation of eye movements to specific retinal coordinates (Schall, 2001). During free viewing of natural scenes, FEF neurons respond to natural scene patterns when they are the target for subse-

quent eye movements (Burman and Seagraves, 1994). However, these neurons do not respond to the same scenes when animals are required to follow a moving spot that retraces previous eye movements. Instead, during this rescan condition, neurons respond only to the target spot. Thus, during natural vision, FEF neurons appear to encode salient stimuli that are the targets for upcoming eye movements.

Future directions

Although vision is one of the oldest topics in systems neuroscience and psychology, study of the neural mechanisms mediating natural scene perception is quite young. Conventional experiments have been most productive in studies of the early stages of visual processing, where the system is quasi-linear. Experiments using natural scenes could provide a useful supplement to such studies, allowing us to evaluate current models and account for nonlinearities in early vision (Vinje and Gallant, 1998).

Computational and experimental neuroscientists are actively pursuing several lines of inquiry that are likely to reveal fundamental new functional and organizational principles of vision in the coming years. Most importantly, they are beginning to focus on characterizing the higher-order statistical structure of natural scenes (Schwartz and Simoncelli, 2001; Thomson, 1999; Zetsche and Krieger, 1999). One important component of this research may be to develop nonlinear models of the way natural images are formed on the retina to account more accurately for occlusion and self-occlusion in natural scenes (Lee et al., 2001).

Better models of complex scene structure could substantially aid experimental studies of intermediate and late stages of visual processing. Because these neurons are highly nonlinear, conventional experimental methods employing simple stimuli and strong behavioral control may miss important functional characteristics. Linear system identification methods incorporating additivity and stationarity

assumptions may also have limited utility in these regions. Quantitative statistical analysis of natural scenes could simplify efforts to investigate these areas by enabling researchers to focus on their most important structural attributes.

Neural responses at higher stages of visual processing also depend strongly on behavioral state (Desimone and Duncan, 1995). Attention, learning, and memory are all increasingly influential at higher processing stages. Experiments designed to exploit natural visual behaviors can ensure that responses reflect the behavioral dependencies that actually occur during perception of natural scenes (Mazer et al., 2001).

Acknowledgments

James Mazer, William Vinje, Kate Gustavsen, Kathleen Bradley, and Stephen David provided extensive help in preparing this manuscript. In addition, James Mazer and Stephen David kindly allowed their data to be used in Figures 107.2 and 107.3. Bruno Olshausen, David Field, and Christoph Zetsche also contributed many ideas about neural coding of natural images and about natural vision. Preparation of this chapter was supported by a grant from the NEI.

FIGURE 107.3. *A*, Free viewing visual search task. On each trial, one patch was designated as the target and the remaining patches were distracters. The target patch was presented at the center of the display and could be inspected freely. After a brief interval a grid of patches was presented, arranged so that each time a patch was fixated, another patch would appear in the receptive field of the recorded V4 neuron. (Several sample grids could appear sequentially on a single trial; only one grid is shown here.) The animal had to respond when the target patch was identified among the distracters. *B*, Top-down attentional modulation. The top row compares mean responses recorded during trials when patch A was the target with those obtained when B, C, or D were targets. The bottom row compares responses when patch B was the target with these when A, C, or D were targets. The left column shows data from one V4 neuron displaying persistent top-down attentional modulation. The middle column shows data from a different cell

with multiplicative modulation. The third column shows data from a cell with no attentional modulation. *C*, V4 activity predicts the direction of the next saccade. The bottom panel shows the average response of one V4 neuron during fixation (fixation onset at 0 msec). The time course of the response is typical of such cells: parasaccadic suppression followed by a transient response and then a lower sustained response. The upper panel breaks down responses according to the direction of the upcoming saccade. Upcoming saccades that will be directed toward the receptive field are at 0 degrees (center line in each box), while those that will be directed away are at –180 and +180 degrees (edges of box). Boxes represent different response epochs (noted above each box). Activity of this V4 neuron clearly predicts the direction of the next saccade; when activity is high, the next saccade is most likely to be directed toward the receptive field. (See color plate 83.)

108 Principles of Image Representation in Visual Cortex

BRUNO A. OLSHAUSEN

THE VISUAL CORTX is responsible for most of our conscious perception of the visual world, yet we remain largely ignorant of the principles underlying its function despite progress on many fronts of neuroscience. The principal reason for this is not a lack of data, but rather the absence of a solid theoretical framework for motivating experiments and interpreting findings. The situation may be likened to trying to understand how birds fly without knowledge of the principles of aerodynamics: no amount of experimentation or measurements made on the bird itself will reveal the secret. The key experiment—measuring air pressure above and below the wing as air is passed over it—would not seem obvious were it not for a theory suggesting why the pressures might be different.

But neuroscience cannot simply turn to mathematics or engineering for a set of principles that will elucidate the function of the cortex. Indeed, engineers and mathematicians themselves have had little success in emulating even the most elementary aspects of intelligence or perceptual capabilities, despite much effort devoted to the problem over the past 40 years. The lack of progress here is especially striking considering the fact that the past two decades alone have seen a 1000-fold increase in computer power (in terms of computer speed and memory capacity), while the actual “intelligence” of computers has improved only moderately by comparison.

The problem: pattern analysis

Although seldom recognized by either side, both neuroscientists and engineers are faced with a common problem: the problem of *pattern analysis*, or how to extract structure contained in complex data. Neuroscientists are interested in understanding how the cortex extracts certain properties of the visual environment—surfaces, objects, textures, motion, and so on—from the data stream coming from the retina. Similarly, engineers are interested in designing algorithms capable of extracting structure contained in images or sound—for example, to identify and label parts within the body from medical imaging data. These problems at their core are one in the same, and progress in one domain will likely lead to new insights in the other.

The key difficulty faced by both sides is that *the core principles of pattern analysis are not well understood*. No amount of experimentation or technological tinkering alone can overcome this obstacle. Rather, it demands that we devote our efforts to advancing new theories of pattern analysis and to directing experimental efforts toward testing these theories.

In recent years, a theoretical framework for how pattern analysis is done by the visual cortex has begun to emerge. The theory has its roots in ideas proposed more than 40 years ago by Attneave and Barlow, and it has been made more concrete in recent years through a combination of efforts in engineering, mathematics, and computational neuroscience. The essential idea is that the visual cortex contains a probabilistic model of images and that the activities of neurons are representing images in terms of this model. Rather than focusing on what features of “the stimulus” are represented by neurons, the emphasis of this approach is on discovering a good featural description of images of the natural environment, using probabilistic models, and then relating this description to the response properties of visual neurons.

In this chapter, I will focus on recent work that has attempted to understand image representation in area V1 in terms of a probabilistic model of natural scenes. The next section will provide an overview of the probabilistic approach and its relation to theories of redundancy reduction and sparse coding. The third section will then describe how this framework has been used to model the structure of natural images, and the fourth section will discuss the relation between these models and the response properties of V1 neurons. Finally, in the fifth section, I will discuss some of the experimental implications of this framework, alternative theories, and the prospects for extending this approach to higher cortical areas.

Probabilistic models

The job of visual perception is to infer properties of the environment from data coming from the sensory receptors. What makes this such a difficult problem is that we are trying to recover information about the three-dimensional world from

a two-dimensional sensor array. This process is loaded with uncertainty due to the fact that the light intensity arriving at any point on the retina arises from a combination of lighting properties, surface reflectance properties, and surface shape (Adelson and Pentland, 1996). There is no unique solution for determining these properties of the environment from photoreceptor activities; rather, some environments provide a more probable explanation of the data than others based on our knowledge of how the world is structured and how images are formed. Visual perception is thus essentially a problem of *probabilistic inference*.

In order to do probabilistic inference on images, two things are needed:

1. A model for how a given state of the environment (E) gives rise to a particular state of activity on the receptors (the observable data, D). This model essentially describes the process of image formation and can be characterized probabilistically (to account for uncertainties such as noise) using the conditional distribution $P(D|E)$.
2. A model for the *prior* probability of the state of the environment. This expresses our knowledge of how the world is structured—which properties of the environment are more probable than others—and is characterized by the distribution $P(E)$.

From these two quantities, one can make inferences about the environment by computing the posterior distribution, $P(E|D)$, which specifies the relative probabilities of different states of the environment given the data. It is computed by combining $P(E)$ with $P(D|E)$ according to Bayes's rule:

$$P(E|D) \propto P(D|E)P(E). \quad (1)$$

This simple equation provides a mathematical formulation of the essential problem faced by the cortex. By itself, it does not provide all the answers to how the cortex works. But it does provide a guiding principle from which we can begin to start filling in details.

REDUNDANCY REDUCTION The general idea of “perception as probabilistic inference” is by no means new, and in fact it goes back at least to Helmholtz (1867/1962). Attneave (1954) later pointed out that there could be a formal relationship between the statistical properties of images and certain aspects of visual perception. The notion was then put into concrete mathematical and neurobiological terms by Barlow (1961, 1989), who proposed a self-organizing strategy for sensory nervous systems based on the principle of *redundancy reduction*—that is, the idea that neurons encode information in such a way as to minimize statistical dependencies among them. Barlow reasoned that a statistically independent representation of the environment would make it possible to store information about prior probabilities, since the joint probability distribution of a particular state \mathbf{x}

could be easily calculated from the product of probabilities of each component x_i : $P(\mathbf{x}) = \prod_i P(x_i)$. It also has the advantage of making efficient use of neural resources in transmitting information, since it does not duplicate information in different neurons.

The first strides in quantitatively testing the theory of redundancy reduction came from the work of Simon Laughlin and M. V. Srinivasan. They measured both the histograms and spatial correlations of image pixels in the natural visual environment of flies and then used this knowledge to make quantitative predictions about the response properties of neurons in early stages of the visual system (Laughlin, 1981; Srinivasan et al., 1982). They showed that the contrast response function of bipolar cells in the fly's eye performs histogram equalization (so that all output values are equally likely) and that lateral inhibition among these neurons serves to decorrelate their responses for natural scenes, confirming two predictions of the redundancy reduction hypothesis.

Another advance was made 10 years later by Atick and Redlich (1992) and van Hateren (1992, 1993), who formulated a theory of coding in the retina based on whitening the power spectrum of natural images in space and time. Since it had been shown by Field (1987) that natural scenes possess a characteristic $1/f^2$ spatial power spectrum, they reasoned that the optimal decorrelating filter should attempt to whiten the power spectrum up to the point where noise power is low relative to the signal (since a signal with a flat power spectrum has no spatial correlations). The optimal whitening filter thus has a transfer function that rises linearly with the spatial frequency and then falls off where the signal power becomes equal to or less than the noise power. Interestingly, the inverse Fourier transform of such a spatial-frequency response function has a spatial profile similar to the center-surround antagonistic receptive fields of retinal ganglion cells and neurons in the lateral geniculate nucleus (LGN). Some experimental evidence for temporal whitening has also been found in the LGN of cats (Dan et al., 1996).

SPARSE, OVERCOMPLETE REPRESENTATIONS While the principle of redundancy reduction has been fairly successful in accounting for response properties of neurons in the retina and LGN, it would seem that other considerations come into play in the cortex. An important difference between the retina and cortex is that the retina is faced with a severe structural constraint, the optic nerve, which limits the number of axon fibers leaving the eye. Given the net convergence of approximately 100 million photoreceptors onto 1 million ganglion cells, redundancy reduction would appear to constitute a sensible coding strategy for making the most use of the limited resources of the optic nerve. V1, by contrast, *expands* the image representation coming from the

LGN by having many more outputs than inputs (approximately 25:1 in cat area 17—inferred from Beaulieu and Colonnier, 1983, and Peters and Yilmaz, 1993). If the bandwidth per axon is about the same, then the unavoidable conclusion is that redundancy is being *increased* in the cortex, since the total amount of information cannot increase (Field, 1994). The expansion here is especially striking given the evidence for wiring length being minimized in many parts of the nervous system (Cherniak, 1995; Chklovskii et al., 2002). What is being gained by spending extra neural resources in this way?

First, it must be recognized that the real goal of sensory representation is to *model* the redundancy in images, not necessarily to reduce it (Barlow, 2001). What we really want is a *meaningful* representation—something that captures the causes of images, or what’s “out there” in the environment. Second, redundancy reduction provides a valid probabilistic model of images only to the extent that the world can meaningfully be described in terms of statistically independent components. While some aspects of the visual world do seem well described in terms of independent components (e.g., surface reflectance is independent of illumination), most seem awkward to describe in this framework (e.g., body parts can move fairly independently but their movements are also often coordinated to accomplish certain tasks). Thus, in order to understand how the cortex forms useful representations of image structure, we must appeal to a principle other than redundancy reduction.

One way of potentially achieving a meaningful representation of sensory information is by finding a way to group things together so that the world can be described in terms of a small number of events at any given moment. In terms of a neural representation, this would mean that activity is distributed among a small fraction of neurons in the population at any moment, forming a *sparse code*. Such a representation is actually highly redundant, since the activity of any given unit is highly predictable (i.e., it spends most of its time at zero). But so long as it can provide a meaningful description of images, it is more useful than a dense representation in which redundancy has been reduced.

The first quantitative evidence for sparse coding in the visual cortex was provided by Field (1987), who examined the histograms of model V1 neuron activities in response to natural images. He modeled the receptive fields of these neurons using a Gabor function and showed that the settings of spatial-frequency bandwidth and aspect ratio which maximize the concentration of activity into the fewest number of units are roughly the same as those found for most cortical neurons—that is, around 1 to 1.5 octaves and with an approximately 2:1 length:width ratio. In other words, the particular shapes of V1 simple-cell receptive fields appear well suited for achieving a sparse representation of natural images.

In addition to these receptive field parameters, though, the cortex must choose how to *tile* the entire joint space of position, orientation, and spatial frequency in order to provide a complete representation of the image. Simoncelli et al. (1992) have argued that *overcompleteness* is a desirable property for tiling the input space in terms of these parameters, as it allows each output to carry a specific interpretation—that is, the amount of structure occurring at a particular position, orientation, and scale in the image. (An overcomplete representation is one where the number of outputs is greater than the dimensionality of the input.) By contrast, in a *critically sampled* representation (where there are just as many outputs as inputs), it is difficult to ascribe meaning to any one output value since it is corrupted by information from different positions, scales, and orientations. By expanding the representation, then, one achieves a better description of the structure in images.

One can achieve the best of both worlds by combining overcompleteness with sparseness. A technique now widely used in the field of signal analysis is to combine different families of wavelets—*time-frequency atom dictionaries*—in order to achieve the best combination of time and frequency localization for describing a particular signal (Mallat, 1999). Typically, one tries to obtain the sparsest possible representation of a signal by selectively drawing basis functions from different dictionaries according to how well they match the structure in the signal. The result is a highly concise description of the signal that reveals its true time-frequency structure (Chen et al., 2001; Mallat and Zhang, 1993).

Thus, by expanding the image representation and making it sparse, neurons in V1 could achieve a succinct description of images in terms of features specifically tailored to the structures occurring in natural scenes. For example, while an oriented edge element would require several neurons to be represented in the retina or LGN, this structure would be absorbed by the activity of a single unit within a local population in the cortex (Fig. 108.1). While nothing has been

FIGURE 108.1. Sparse coding. By building oriented receptive fields, cortical neurons can represent image structures such as edges using fewer *active* units than in the retina or LGN. *Filled circles*, active units; *unfilled circles*, inactive units.

gained in the ability to describe the edge element per se—that is, there has been no gain in information—the description is now in a more convenient form. In other words, the activity of a single cortical unit conveys more *meaning* about what is going on in the image than does a single retinal or LGN neuron. Note, however, that although the code is sparse, it is still *distributed* in that multiple units still need to take responsibility for coding any given stimulus (Foldiak, 1995).

The conciseness offered by sparse, overcomplete coding is also useful for subsequent stages of processing. For example, once a scene is sparsely described in terms of local edge elements, it would be much easier to model the relationships among these elements to represent contours, since the activities of only a few neurons need to be taken into account. If we were to model these dependencies directly in terms of retinal ganglion cell activities, the number of associations and hence neural connections needed would be far greater. Sparseness is also desirable for pattern matching, since it lowers the probability of false matches among elements of a pattern (Baum et al., 1988; Jaekel, 1989; Willshaw et al., 1969; Zetsche, 1990).

As an aside, it is worth noting an example of where sparse, overcomplete coding is used in abundance: human communication. As pointed out by Zipf (1950), efficient communication involves a trade-off between the size of the vocabulary and its ease of use. One could have a small vocabulary where each word has various meanings, but the correct use of these words would rely heavily on careful choice of word order and establishing the proper context. At the other extreme, one could have an enormous vocabulary where each word is endowed with highly specific meaning, making its use very simple but requiring a large memory capacity to store all the words. Human communication balances this trade-off by having a large but manageable vocabulary. Thoughts are then conveyed by dynamically combining words into sentences. The code is overcomplete since there are many more words than phonemes used to form utterances (or letters to form words), and it is sparse in that any given sentence utilizes only a small fraction of the words in the vocabulary.

A simple probabilistic model of images

This section will describe specifically how the probabilistic approach has been used to model the structure of natural scenes, focusing on a sparse, overcomplete model of images. The next section will then discuss the relation between this model and the response properties of neurons in area V1.

LINEAR SUPERPOSITION MODEL A number of probabilistic models described in the literature have utilized a simple

image model in which each portion of a scene is described in terms of a linear superposition of features (Bell and Sejnowski, 1997; Lewicki and Olshausen, 1999; Olshausen, and Field, 1996a, 1997; van Hateren and van der Schaaf, 1998). It should be noted from the outset, however, that such a linear model of images cannot possibly hope to capture the full richness of the structures contained in natural scenes. The reason is that the true causes of images—light reflecting off the surfaces of objects—combine by the rules of occlusion, which are highly nonlinear (Ruderman, 1997). In addition, the retinal projection of an object will undergo shifts, rotations, and rescaling due to changes in viewpoint, and these types of variation also require more than a linear model to properly describe. However, at the scale of a local image patch (e.g., 12×12 pixels) it is possible that these factors are not very significant. Also, because the mathematics of linear systems are tractable, the linear model provides us with a convenient starting point for building a probabilistic model of images.

In the linear model, an image patch, $I(\mathbf{x})$, is described by adding together a set of basis functions, $\phi_i(\mathbf{x})$, with amplitudes a_i :

$$I(\mathbf{x}) = \sum_i a_i \phi_i(\mathbf{x}) + v(\mathbf{x}) \quad (2)$$

(\mathbf{x} denotes spatial position within the patch). The basis functions may be thought of as a set of spatial features for describing an image, and the coefficients a_i tell us how much of each feature is contained in the image. The variable v represents Gaussian noise, independent and identically distributed (i.i.d.), and is included to model structure in the images that is not well captured by the basis functions. The model is illustrated schematically in Figure 108.2.

Importantly, the basis set is assumed to be *overcomplete*, meaning that there are more basis functions (and hence more a_i s) than effective dimensions (number of pixels) in the

FIGURE 108.2. Image model. *a*, An image patch, $I(\mathbf{x})$, is modeled as a linear superposition of basis functions, $\phi_i(\mathbf{x})$. The image is thus represented, in terms of the model, by the coefficient values a_i . *b*, The prior probability distribution over the coefficients, $P(a_i)$, is peaked at zero, with heavy tails relative to a Gaussian of the same variance (shown as a dotted line) to encourage sparseness.

images. For example, in the instantiation described below, 200 basis functions are used to describe a 12×12 image patch, whereas 144 basis functions would suffice to form a complete representation. Because the representation is overcomplete, there is an infinite number of solutions for the coefficients in equation 2 (even with zero noise), all of which describe the image equally well in terms of mean squared error. In other words, there are multiple ways of explaining any given image in terms of the basis functions.

The degeneracy in the solution caused by overcompleteness is analogous to the ill-posed nature of visual perception discussed in the previous section. As before, two things are needed to infer a solution: a causal model for how the data are generated and a prior distribution over the causes (in this case, the coefficients). The first we have already specified in equation 2. Since the only uncertainty is the noise, which is Gaussian, the probability of an image given the coefficients is just a Gaussian distribution:

$$P(\mathbf{I}|\mathbf{a}, \boldsymbol{\theta}) = \frac{1}{\mathcal{Z}_{\lambda_N}} e^{-\frac{\lambda_N}{2} \sum_{\mathbf{x}} [I(\mathbf{x}) - \sum_i a_i \phi_i(\mathbf{x})]^2}, \quad (3)$$

where $1/\lambda_N$ is the variance of the noise. The boldface notation is used to denote all elements of the corresponding variable (pixels or coefficients), and the symbol $\boldsymbol{\theta}$ denotes all parameters of the model.

The prior probability distribution over the coefficients, a_i , is designed to enforce sparseness in the representation, and it is also (for now) factorial:

$$P(\mathbf{a}|\boldsymbol{\theta}) = \prod_i \frac{1}{\mathcal{Z}_S} e^{-S(a_i)}. \quad (4)$$

S is a nonconvex function that shapes $P(a_i)$ to be peaked at zero with *heavy tails*, as shown in Figure 108.2B. For example, if $S(x) = |x|$, the prior corresponds to a Laplacian distribution, and if $S(x) = \log(1 + x^2)$, the prior corresponds to a Cauchy distribution. Note that although the joint prior over the coefficients is factorial, it need not stay that way, and in fact there are good reasons for making it nonfactorial, as discussed in the next section.

From the above two distributions (Eqs. 3 and 4), the relative probability of different explanations for an image sequence is computed via Bayes' rule, as before (Eq. 1):

$$P(\mathbf{a}|\mathbf{I}, \boldsymbol{\theta}) \propto P(\mathbf{I}|\mathbf{a}, \boldsymbol{\theta}) P(\mathbf{a}|\boldsymbol{\theta}). \quad (5)$$

The posterior distribution, $P(\mathbf{a}|\mathbf{I}, \boldsymbol{\theta})$, rates the probability of each solution for the coefficients, but it still does not tell us how to *choose* a particular solution for a given image. One possibility is to choose the mean, $P(\mathbf{a}|\mathbf{I}, \boldsymbol{\theta}) \mathbf{a}$ $d\mathbf{a}$, but this is difficult to compute because it requires sampling many values from the posterior. The solution we adopt here is to choose the coefficients that maximize the posterior distribution, the *Maximum A Posterior* (MAP) estimate:

$$\hat{\mathbf{a}} = \arg \max_{\mathbf{a}} P(\mathbf{a}|\mathbf{I}, \boldsymbol{\theta}). \quad (6)$$

The MAP estimate $\hat{\mathbf{a}}$ may be computed via gradient descent on $-\log P(\mathbf{a}|\mathbf{I}, \boldsymbol{\theta})$. Thus, $\hat{\mathbf{a}}$ is given by the equilibrium solution to the following differential equation:

$$\tau \dot{a}_i = b_i - \sum_j C_{ij} a_j - S'(a_i) \quad (7)$$

where

$$b_i = \lambda_N \sum_{\mathbf{x}} \phi_i(\mathbf{x}) I(\mathbf{x})$$

$$C_{ij} = \lambda_N \sum_{\mathbf{x}} \phi_i(\mathbf{x}) \phi_j(\mathbf{x}).$$

The important thing to note here is that although the image model is linear, *the transformation from images to coefficients is nonlinear*. The reason is that the derivative of the *sparseness function*, S , is nonlinear. It essentially serves to self-inhibit the coefficients so that only those basis functions which best match the image are used. Thus, inferring the coefficients for an image sequence involves a process of selection, or *sparsification*, rather than simply filtering.

A neural circuit for sparsifying the coefficients according to Eq. 7 is shown in Figure 108.3. Each output unit (coefficient) is driven by the combination of a feedforward term (b_i), a recurrent term ($\sum_j C_{ij} a_j$), and a nonlinear self-inhibition term ($-S'(a_i)$). The feedforward contribution to each unit is computed by taking the inner product between its basis function and the image, akin to a classical receptive field model. The recurrent contribution is inhibitory and is computed by weighting the activities of other units according to their inner product with this unit's receptive field. Each unit is then subject to nonlinear self-inhibition, which discourages it from becoming active, thus encouraging sparse representations.

ADAPTING THE MODEL TO THE STATISTICS OF NATURAL IMAGES
So far, we have formulated a probabilistic model for describing images in terms of a sparse collection of additive fea-

FIGURE 108.3. Neural circuit for computing the coefficients. Each coefficient, a_i , is driven by the combination of a feedforward term (inner product between its basis function and the image), a recurrent term (activities of other coefficients, weighted by the overlap of their basis functions), and a nonlinear self-inhibition term (derivative of the sparse cost function).

tures (basis functions). But what exactly should these features be? One could set them by hand to match the aforementioned Gabor function parameters which yield sparse representations of natural images (Field, 1987), but how do we know that there is not an even better, non-Gabor-like way to shape the basis functions that would lead to an even sparser description of images? We can find out by leaving the basis functions unparameterized and adapting them to best match the structure of natural images.

In general, any of the model parameters θ (which includes the basis functions $\phi_i(\mathbf{x})$, the sparseness function S , and the noise variance $1/\lambda_N$) may be adapted to best match the statistics of natural scenes by maximizing the average log likelihood of the model:

$$\hat{\theta} = \arg \max_{\theta} \langle \log P(\mathbf{I}|\theta) \rangle, \quad (8)$$

where the brackets $\langle \rangle$ mean “averaged over all images” and the likelihood of the model is defined as

$$P(\mathbf{I}|\theta) = \int P(\mathbf{I}|\mathbf{a}, \theta) P(\mathbf{a}|\theta) d\mathbf{a}. \quad (9)$$

A learning rule for the basis functions may therefore be obtained via gradient ascent on the average log likelihood:

$$\begin{aligned} \Delta \phi_i(\mathbf{x}) &\propto \frac{\partial \langle \log P(\mathbf{I}|\theta) \rangle}{\partial \phi_i(\mathbf{x})} \\ &= \lambda_N \langle \langle a_i e(\mathbf{x}) \rangle \rangle_{P(\mathbf{a}|\mathbf{I}, \theta)} \end{aligned} \quad (10)$$

where $e(\mathbf{x})$ is the residual image: $e(\mathbf{x}) = I(\mathbf{x}) - \sum_i a_i \phi_i(\mathbf{x})$.

Looking at Eq. 10, we can see that adapting the basis functions amounts to a simple Hebbian learning rule involving the coefficient activities and the resulting residual image averaged under the posterior distribution for each image. Instead of sampling from the full posterior distribution, though, we shall utilize a simpler approximation in which a single sample is taken at the posterior maximum, and so we have

$$\Delta \phi_i(\mathbf{x}) \propto \hat{a}_i e(\mathbf{x}). \quad (11)$$

In this case, however, we must rescale the basis functions after each update in order to ensure that they do not grow without bound (as described in Olshausen and Field, 1997).

When this procedure is carried out on hundreds of thousands of image patches extracted from natural scenes, the basis functions converge to a set of spatially localized, oriented, bandpass functions, as shown in Figure 108.4. Each basis function was initialized to random numbers, and this solution emerged purely as a result of maximizing the log likelihood of the model. Indeed, it seems reasonable that such functions would form a sparse description of natural images, since only a few of them would be needed to describe a line or contour passing through this patch of space. Why they become bandpass is less obvious, however, and some potential reasons are given in Olshausen and Field (1996b) and Field (1993). The learned basis functions are

well fit by Gabor functions, and the entire set of functions evenly tiles the joint space of position, orientation, and scale, as demonstrated in previous publications (Olshausen and Field, 1996a, 1996b, 1997).

TIME-VARYING IMAGES The model may be extended to the time domain by describing a sequence of images (i.e., a movie) in terms of a linear superposition of spatiotemporal functions, $\phi_i(\mathbf{x}, t)$. Here the basis functions are applied in a shift-invariant fashion over time, meaning that the same function is assumed to be repeated at each point in time. Thus, an image sequence is described by convolving the spatiotemporal basis functions with a set of time-varying coefficients, $a_i(t)$:

$$\begin{aligned} I(\mathbf{x}, t) &= \sum_i \sum_{t'} a_i(t') \phi_i(\mathbf{x}, t - t') + v(\mathbf{x}, t) \\ &= \sum_i a_i(t) * \phi_i(\mathbf{x}, t) + v(\mathbf{x}, t). \end{aligned} \quad (12)$$

The model is illustrated schematically in Figure 108.5.

Again, a sparse factorial prior is imposed on the coefficients over both space (i) and time (t), and the coefficients for an image sequence are computed via gradient descent on the negative log posterior:

$$\tau \hat{a}_i(t) = b_i(t) - \sum_j a_j(t) \star C_{ij}(t) - S'(a_i(t)) \quad (13)$$

$$\begin{aligned} \text{where } b_i(t) &= \lambda_N \sum_l \phi_i(l, t) \star I(l, t) \\ C_{ij}(t) &= \lambda_N \sum_l \phi_i(l, t) \star \phi_j(l, t), \end{aligned}$$

where \star denotes cross-correlation. Note, however, that in order to be considered a causal system, the value of a coefficient at time t' must be determined solely from image frames and other coefficient values prior to t' . For now, though, we shall not bother imposing this restriction, and in the next section we shall entertain some possibilities for making the model causal.

A learning rule for the spatiotemporal basis functions may be derived by maximizing the average log likelihood as before (for details see Olshausen, 2002). When the basis functions are adapted in this manner, using time-varying natural images as training data (van Hateren, 2000), they converge to a set of spatially localized, oriented bandpass functions that now *translate* over time. Shown in Figure 108.6 is a randomly chosen subset of the 200 basis functions learned, each 12×12 pixels and seven frames in time. Again, it seems intuitively reasonable that these functions would form a sparse representation of time-varying natural images, since only a few of them are needed to describe a contour segment moving through this patch of the image.

The tiling properties for velocity, as well as speed versus spatial frequency, are shown in Figure 108.7. The majority of

FIGURE 108.4. Basis functions learned from natural images. Shown is a set of 200 basis functions, each 12×12 pixels in size. Most have become localized well within the image patch, and all have become

oriented, with the exception of one function, which took on the DC component. The functions are also bandpass in spatial frequency, occupying different regions of the spatial-frequency domain.

FIGURE 108.5. Spatiotemporal image model. A time-varying image patch, $I(\mathbf{x}, t)$, is modeled as a linear superposition of spatiotemporal basis functions, $\phi_i(\mathbf{x}, t)$, each of which is localized in time but may be applied at any point within the image sequence.

basis functions translate by less than one pixel per frame. (The frame rate is 25 frames per second, so a speed of one pixel per frame corresponds to 25 pixels per second.) The high-spatial-frequency basis functions are biased toward slow speeds, as expected, because at higher speeds they would give rise to temporal frequencies beyond the Nyquist limit. This limit is shown by the dashed line (e.g., a spatial frequency of 0.25 cy per pixel moving at two pixels per frame, or 50 pixels per second, would give rise to a temporal frequency of 12.5 Hz, which is equal to the Nyquist rate in this case).

Relation to V1 response properties

We now turn to the relation between the image model and the response properties of neurons in area V1. We shall first

FIGURE 108.6. Space-time basis functions learned from time-varying natural images. Shown are 30 basis functions randomly selected from the entire set of 200 functions learned, arranged in columns. Each basis function is 12×12 pixels in space and seven frames in time. Each row shows a different basis function, with time proceeding from left to right.

focus on the response properties of simple cells and then discuss efforts to model the response properties of complex cells, as well as dependencies among them.

SIMPLE CELLS In the neural circuit implementation of the model, the basis functions correspond to the feedforward weighting functions that contribute to the final output value of each unit (Fig. 108.3). If we were to draw an analogy between the coefficients a_i of the model and neurons in V1,

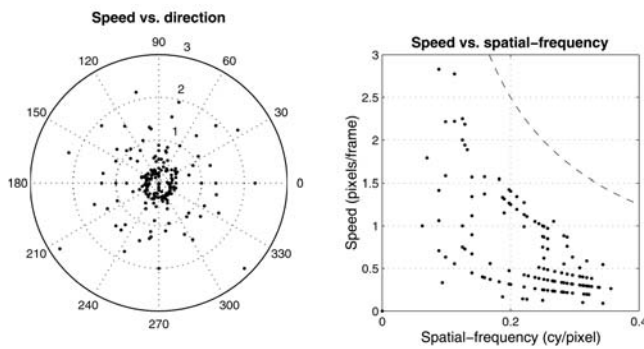

FIGURE 108.7. Basis function tiling properties. Each data point denotes a different basis function. In the polar plot at the left, radius denotes speed (in units of frames per second) and angle denotes the direction in which the basis function translates. In the plot at the right, the dashed line denotes the limit imposed by the Nyquist frequency (12.5 Hz). (The striated clustering is an artifact due to decimation in the spatiotemporal frequency domain.)

then it would seem most appropriate to compare the basis functions $\phi(\mathbf{x}, t)$ to the receptive fields of simple cells. These neurons behave in a somewhat linear manner in that in their response to a stimulus can be fairly well predicted from a weighted sum of inputs over space and time (although see Chapter 52 for a discussion of the response nonlinearities of these neurons). Their spatial receptive fields have been characterized as spatially localized, oriented, and bandpass, similar in form to the basis functions learned by the sparse coding model (spatial-frequency bandwidth of 1.1 octaves, length/width ratio of 1.3; Olshausen and Field, 1996a).

In terms of their temporal properties, simple cells tend to fall into two major categories—those that are separable in space and time and those that are inseparable (DeAngelis et al., 1995; McLean and Palmer, 1989). The latter tend to translate as a function of time, similar to the learned basis functions of the model, and it is this property that is thought to underlie the direction selectivity of V1 neurons (see also Chapters 44 and 48). If one assumes a size of 0.15 degree per pixel for the images used in training, then a speed of 1 pixel per frame (see Fig. 108.7) corresponds to 4 deg/sec, which is within the typical range of speed tuning found in simple cells (DeAngelis et al., 1993).

Given the similarities between the receptive field properties of V1 simple cells and the basis functions of the sparse coding model, it would seem that these neurons are well suited to form a sparse representation of natural images. It is also possible that the space-time separable simple cells could be fit within this framework, since one way to build neurons with space-time inseparable receptive fields is by summing a population of space-time separable units with different time constants. Thus, if the basis functions of the model were constrained such that they did not have access to inputs with arbitrary time delays, it may be possible to obtain both types of receptive field properties.

Ideally, one would like to compare not just the forms of individual basis functions, but also how the population as a whole tiles the joint space of position, orientation, spatial frequency, and velocity. However, to do such a comparison properly would require recording exhaustively from all neurons within a hypercolumn or so of visual cortex. From the partial assays of parafoveal neurons currently available, it would seem that there is an overabundance of neurons tuned to low spatial frequencies compared to the model (De Valois et al., 1982; Parker and Hawken, 1988; van Hateren and van der Schaaf, 1998). This discrepancy could be due to biases in sampling or to the fact that the model is currently ignoring many other stimulus dimensions that the cortex also cares about, such as color, disparity, and so on (Olshausen and Anderson, 1995). In addition, real neurons have a certain level of precision with which they can code information in amplitude and time, whereas in the model there is no limit in precision imposed upon the coefficient amplitudes (i.e., they have essentially infinite precision in amplitude). It seems likely that when such implementation details are taken into account, the bias toward low spatial frequencies could be explained, since the low spatial frequencies in natural scenes occupy a higher dynamic range than high spatial frequencies.

In addition to accounting for known receptive field properties, the model makes a prediction about the types of nonlinearities and interactions among neurons expected in response to natural images. In the neural implementation of the model (Fig. 108.3), each output unit is subject to nonlinear self-inhibition in addition to inhibition from neighbors whose receptive fields overlap with its receptive field. Figure 108.8 illustrates the effect of these output nonlinearities and interactions by comparing the time-varying value of one of the coefficients obtained by maximizing the posterior (sparsification) to that obtained by straightforward convolution (simply taking a feedforward weighted sum of inputs over space and time). The difference is striking in that the sparsified representation is characterized by highly localized punctate events, as opposed to the more graded and prolonged activations obtained with convolution. If we take the coefficients to be analogous to neurons in the cortex, then this would predict that the responses of neurons should be sparser than expected from simply convolving their feedforward weighting function with the image. Note also that the form of nonlinearity here is more complicated than the pointwise contrast response nonlinearity observed in simple cells (Albrecht and Geisler, 1991; Albrecht and Hamilton, 1982), as it involves interactions among units with overlapping receptive fields.

A recent study by Vinje and Gallant (2000, 2002) lends support to the idea of sparsification. They recorded from V1 neurons in an awake, behaving monkey while natural image sequences obtained from free viewing were played both in and around a neuron's receptive field. They showed that when neurons are exposed to progressively more context

FIGURE 108.8. Coefficient signal computed by sparsification (*top*) versus convolving its corresponding basis function with the image sequence (*bottom*) for a 7.4 second image sequence (25 f/s).

around their classical receptive field, the responses become sparser. Importantly, the effect is not just an overall suppression of responses, but rather a combination of suppression and selective enhancement akin to the sparsification seen in Figure 108.8. In the model, this happens because units are effectively competing to describe the image at any given moment. With little or no context, there is more ambiguity about which basis functions are best suited to describe structure within the image, and so the activities would be expected to resemble more closely those predicted from convolution.

Before the sparse coding model can be taken seriously as a model of neural coding, however, one must address the issue of causality mentioned earlier. As it stands, the value of a coefficient at time τ is determined from image frames both prior to and after τ . But of course, real neurons cannot work this way. The model would thus need to be modified so that the value of a coefficient at time τ is determined only from image content prior to τ . This could be done by simply truncating the basis functions so that $\phi(\mathbf{x}, t) = 0$ for $t > 0$. However, it then becomes necessary to modify the dynamics of Eq. 13 so that the coefficients at time τ do not attempt to account for everything that has happened up to time τ . Otherwise, there will be no way for the basis functions to learn the continuity in images that exists from one frame to the next. More generally, there is a need to adopt a serious dynamical (differential equation) model rather than using fixed time delays, as currently formulated. These problems are the focus of current research.

COMPLEX CELLS While the receptive field of a simple cell can be mapped out in terms of its excitatory and inhibitory subfields, the receptive field of a complex cell can only be mapped out in terms of its feature selectivity—that is, orientation, spatial frequency, direction of motion, and so on. The reason is that complex cells by definition exhibit the striking nonlinearity of being locally position- or phase-

invariant. Since these neurons are insensitive to the exact alignment or polarity of an edge within their receptive fields, it is impossible to describe their responses in terms of a linear weighted sum of inputs.

Can these nonlinear response properties of complex cells also be accounted for in terms of a sparse coding model adapted to natural images? Hyvarinen and Hoyer (2000) have approached this question by assuming an architecture in which the basis function coefficients are grouped into local nonoverlapping pools. Another set of units—putative complex cells—then sums the squares of these units, one unit for each nonoverlapping pool. A sparse prior is then imposed on these units, and a set of basis functions is sought which best matches this model to natural images. After training, the “subunits” take on simple-cell-like receptive field properties (spatially localized, oriented, and bandpass), and all the units within a pool share the same orientation preference but have different phases or positions. Thus, the model seems to have learned the same sort of invariance exhibited by complex cells. On the other hand, the architecture of summing the squared outputs of subunits was assumed, and it is unclear what role this had in determining the outcome.

MODELING HORIZONTAL CONNECTIONS AND CONTEXTUAL EFFECTS Even though independence is assumed in the probabilistic models for both simple cells and complex cells above, there are still plenty of statistical dependencies among these units after adapting to natural images. Part of the reason for this is the existence of contours and other more global forms of structure in images which cannot be captured by localized receptive fields. Given that such dependencies exist among V1 neurons, what should be done?

Schwartz and Simoncelli (2001) have argued that the cortex should use its horizontal connections to remove dependencies via divisive normalization. They examined the pairwise dependencies between oriented bandpass filters and showed that although the outputs are decorrelated, they are heavily correlated in their magnitudes. They have proposed a model for reducing these magnitude correlations by dividing each output by the sum of squares of neighboring outputs. The resulting model seems to account well for contextual effects measured in V1 neurons using spatial frequency gratings.

An alternative approach is to use the horizontal connections to directly model the dependencies that exist, rather than removing them. In this scheme, units with colinear basis functions would actually reinforce each other’s activity rather than be suppressive. The idea of reinforcement is consistent with a substantial body of psychophysics (Field et al., 1993; Polat and Sagi, 1993) and physiology (Kapadia et al., 2000). There are also a number of computational models

which have been proposed along these lines for doing contour segmentation (Li, 2001; Parent and Zucker, 1989; Shashua and Ullman, 1988; Yen and Finkel, 1998), but the association connections in these models are usually set by hand and require substantial tweaking to work properly on natural images. Geisler et al. (2001) and Sigman et al. (2001) have measured the co-occurrence statistics of oriented filters on natural images and have shown that they follow a cocircularity structure, meaning that oriented units lying along the same circle are most correlated. It should be possible to incorporate these sorts of dependencies into the sparse, over-complete model by having a nonfactorial prior for the coefficients and adapting the model to images (Olshausen, 1997).

Discussion

Much of visual neuroscience has historically been guided by the question “how do neurons respond to the stimulus?” But what constitutes “the stimulus” in a natural scene is far from obvious. Indeed, years of research in machine vision have shown that the definition of a feature even as elementary as an edge or a contour is essentially an ill-posed problem, as it depends heavily on context and high-level knowledge. Nearly all of the properties of the world we experience are *inferred* from the data coming down the optic nerve, and as we have seen, inference depends on priors, and priors are built upon the statistics of natural scenes. If we accept the fact that these priors are embedded in the neural circuitry of the cortex, then modeling the structure of natural images and studying the response properties of neurons in terms of these models becomes of paramount importance to visual neuroscience.

I have described a simple probabilistic model of images based on sparse coding, and I have shown how the response properties of V1 neurons may be interpreted in terms of this model. Some support for this interpretation is provided by existing data, but the idea is still quite speculative and further tests are needed to rule completely in favor of this hypothesis. The type of experiments needed, though, are those which use natural scenes, or a reasonable facsimile thereof, as stimuli (see Chapter 107).

PROBABILISTIC MODELS AS EXPERIMENTAL TOOLS One of the objections to using natural images as experimental stimuli, often stated by neurophysiologists, is that they constitute an “uncontrolled” stimulus. But probabilistic models provide a principled way to describe the features contained in natural images, which we can then attempt to relate to the responses of neurons. One way this could be done, for example, is through the technique of *reverse correlation*. Rather than correlating neural activity directly with pixel values, as is commonly done, one could instead correlate activity with the sparsified basis function coefficients, a_i , that

are used to describe an image (i.e., the stimulus). Such an approach could potentially yield insights that could not have been obtained through reverse correlation in the pixel domain, because although the image model is linear, the coefficients are a nonlinear function of the image. Ringach et al. (2002) has recently utilized an approach along similar lines, yielding some novel findings about complex cell receptive fields.

It is also possible to run the probabilistic model in a generative mode in order to synthesize images to be used as stimuli. This is done by drawing coefficient values at random, according to the prior, and then generating either static or dynamic images according to Eqs. 2 or 12, respectively. Interestingly, even though the images being generated by this process are structured, the actual generative variables, a_i , are unstructured, so there is no need to correct for correlations in the stimulus (e.g., Theunissen et al., 2001). And in contrast to white noise, such structured images are more likely to be matched to what neurons are “looking for,” thus making it more likely that neurons will respond to a sufficient degree that they may be characterized. Comparing the results of reverse correlation obtained with synthetic images to those obtained with natural images would then enable one to determine which aspects of the latter are due to higher-order structure in natural scenes (beyond that captured by the model).

ALTERNATIVES TO SPARSENESS While sparseness has been the emphasis of this chapter, it should be mentioned that there are other optimality criteria for accounting for the response properties of visual neurons. For example, some have emphasized the role of statistical independence over sparseness and have pointed to the fact that similar results are obtained when independent component analysis (ICA) is applied to natural images (Bell and Sejnowski, 1997; van Hateren and Ruderman, 1998; van Hateren and van der Schaaf, 1998). However, the ICA algorithms used in these cases are also searching for a sparse description of data. For example, Bell and Sejnowski’s (1997) algorithm maximizes the same objective as Eq. 8, and they utilize a sparse (Laplacian) distribution for the prior when training on natural images (see Olshausen and Field, 1997, for a formal derivation of the equivalence). The algorithm used by van Hateren and van der Schaaf (1998) and van Hateren and Ruderman (1998) does not assume an explicit form for the prior but extremizes kurtosis (Hyvarinen and Oja, 1997). When trained on either static or dynamic natural images, the solution found by the algorithm has positive kurtosis, meaning that it is essentially maximizing kurtosis. Since kurtosis is also a measure of sparsity, it would thus be fair to interpret the algorithm as simply maximizing sparseness in this case.

Despite the fact that these previous applications of ICA have confounded the contributions of sparsity and indepen-

dence, it should still be possible to ascertain whether independence alone is sufficient to account for simple-cell receptive field properties. For example, Saito et al. (2000) has shown that when one constrains the basis functions to be orthonormal and minimizes the sum of marginal entropies (to maximize independence), the solution obtained is similar to that obtained by maximizing sparseness. However, the basis set was constrained here to be a member of a particular family of modulated cosine functions. When the bases are not constrained to be orthonormal, maximizing independence can lead to quite different solutions from those obtained by maximizing sparsity (for a spike process) (Saito, 2003).

Another objective that has been proposed for cortical neurons is *stability over time* (Einhauser et al., 2002; Hurri and Hyvarinen, 2003). The idea here is to impose stability on the representation in the hope that neurons will discover invariances in images. Einhauser et al. (2002) have constructed a network architecture similar to Hyvarinen and Hoyer's and have shown that when the derivative of activity is minimized, the receptive fields of subunits in the model resemble those of simple cells. Similarly, Hurri and Hyvarinen (2003) have shown that when the correlation of absolute values or squared outputs is maximized over time, the learned receptive fields also resemble simple-cell receptive fields. These results would seem to support the idea that simple-cell receptive fields also help to achieve invariant representations of time-varying natural images.

Finally, some have attempted to account for cortical receptive field properties purely from second-order statistics arising either from random activity during development (Miller, 1994) or in response to natural images (Li, 1996; Li and Atick, 1994). However, these approaches usually make some explicit assumption about the receptive field properties, such as localization or scale invariance (bandpass structure), in order to achieve properties similar to those of simple cells.

BEYOND V1 Perhaps the greatest promise of the probabilistic approach is its potential to be extended to multistage, hierarchical models of image structure (e.g., Dayan et al., 1995; Lee and Mumford, 2003; Mumford, 1994). Such models could possibly provide insight into the coding strategies used in higher visual areas such as V2 and V4. However, for the linear image model described here, nothing would be gained by simply stacking a number of such models together into a hierarchy, since they would form just another linear model. In order to gain descriptive power, some form of nonlinearity is needed. Hoyer and Hyvarinen (2002) have investigated building a two-stage hierarchical model using a complex cell type nonlinearity. They showed that when a sparse, overcomplete model is trained on the outputs of model complex cells, the learned basis functions become more elongated than those of units in the layer below. Thus, the model would appear to be grouping oriented Gabor-like

elements together into *contour units*. A different approach is taken by Karklin and Lewicki (2003), who use the second-layer units to model the variances of the first-layer units. Their model learns a number of higher-order groupings akin to Gabor functions, although the neurophysiological correlates of these functions are as yet unknown.

Beyond predicting ever more complex receptive fields, there is also the potential for hierarchical models to elucidate the role of two-way interactions that occur between levels of the visual cortical hierarchy via feedback pathways. For example, it has been proposed that feedback pathways may carry predictions from higher levels which are then subtracted from representations at lower levels (Mumford, 1994; Rao and Ballard, 1997). According to these models, the activity in lower levels would be expected to decrease when higher levels can successfully "explain" a stimulus. Recent functional magnetic resonance imaging studies lend support to this general idea, showing that activity in V1 decreases when local shape features are arranged so as to form a global percept of an object (Kersten et al., 1999; Murray et al., 2002).

Another proposed role for feedback pathways, also consistent with these findings, is that they serve to *disambiguate* representations at lower levels (Lee and Mumford, 2003; Lewicki and Sejnowski, 1997). According to this model, neural activity that initially results from the feedforward pass tends to be broadly distributed across a number of units. But as higher-level neurons provide context, activity in the lower level becomes concentrated onto a smaller number of units, similar to sparsification. Presumably, there are yet other possibilities to entertain, and so there is a strong need to develop hierarchical models that could form concrete predictions about what to look for in the cortex.

Summary

Understanding how the cortex performs pattern analysis is a central goal of visual neuroscience. In this chapter, I have presented a probabilistic approach to pattern analysis, and I have shown how it may help to explain a number of known properties of V1 receptive fields in addition to predicting certain nonlinearities (sparsification) in the responses of V1 neurons. The model described in this chapter should be viewed only as a starting point. The challenge ahead is to construct hierarchical models capable of describing higher-order structure in images (e.g., three-dimensional surfaces and occlusion) and to use these models to elucidate the types of representations employed in higher cortical areas, as well as the role of feedback projections.

Acknowledgments

I thank Marty Usrey for help with obtaining numerical estimates of cortical expansion, and I am grateful to an anonymous reviewer for helpful comments. This work was supported by NIMH Grant R29-MH57921.

109 Local Analysis of Visual Motion

EERO P. SIMONCELLI

WE INHABIT AN EVER-changing environment in which sensing, processing, and acting on these changes can be essential for survival. When we move or when objects in the world move, the visual images projected onto our retinas change accordingly. The psychologist J. J. Gibson noted that important environmental information is embedded in this pattern of local retinal image velocities (Gibson, 1950), and thus initiated a scientific quest to understand the mechanisms that might serve to estimate and represent these velocities. Since that time, visual motion perception has been the subject of extensive research in perceptual psychology, visual neurophysiology, and computational theory.

There is an abundance of evidence that biological visual systems—even primitive ones—devote considerable resources to the processing of motion. A substantial proportion of the effort in the field of computer vision has also been devoted to the problem of motion estimation. Although the processing constraints in a biological system are somewhat different from those in an artificial vision system, each must extract motion information from the same type of brightness signal. This chapter adopts the philosophy that in order to understand visual motion processing in the brain, one should understand the nature of the motion information embedded in the visual world and the fundamental issues that arise when one attempts to extract that information (Marr and Poggio, 1977). I'll develop the most basic computational solution to the motion estimation problem, and examine the qualitative relationship between aspects of this solution and the properties of neurons in the motion pathway.

Local motion

Images are formed as projections of the three-dimensional world onto a two-dimensional light-sensing surface. This surface could be, for example, a piece of photographic film, an array of light sensors in a television camera, or the photoreceptors in the back of a human eye. At each point on the surface, the image brightness is a measurement of how much light fell on the surface at that spatial position at a particular time (or over some interval of time). When an object in the world moves relative to this projection surface, the two-dimensional projection of that object moves within the image. The movement of the projected position of each point in the world is referred to as the *motion field*.

The estimation of the motion field is generally assumed to be the first goal of motion processing in machine vision systems. There is also evidence that this sort of computation is performed by biological systems. The motion field must be estimated from the spatiotemporal pattern of image brightness. This is usually done by assuming that the brightness generated by points in the world remain constant over time. In this case, the estimated motion of these constant-brightness points (known as the *optical flow*) is also an estimate of the motion field. But as many authors have shown, the optical flow is *not* always a good estimate of the motion field (e.g., Horn, 1986; Verri and Poggio, 1989). For example, when a shiny object moves, specular highlights often move across the surface of the object. In this situation, the optical flow (corresponding to the highlight motion) does not correspond to the motion of any point on the object. Nevertheless, estimates of optical flow are almost universally used as approximations of the motion field.

In estimating optical flow, we cannot ask about the motion of an isolated point without considering the context surrounding it. That is, we can only recognize the motion of local *patterns* of brightness. But our ability to estimate a unique velocity at a given image location depends critically on the structure of the image in the neighborhood of that location. Consider first the simplest situation, in which an object is moving horizontally, perpendicular to the line of sight. Figure 109.1 depicts three prototypical situations that can arise. First, the local brightness might be constant. In this case, the local measurements places no constraint on the velocity. We will refer to this as the *blank-wall* problem.

Second, the local brightness might vary in only one direction—that is, the spatial pattern could be striped. In this case, only the velocity component that is perpendicular to the stripes is constrained. Any component along the stripes will not create a change in the image and thus cannot be estimated. This is typically known in the literature as the *aperture problem* (Fennema and Thompson, 1979; Marr and Ullman, 1981; Wallach, 1935). The expression refers to the fact that the motion of a moving one-dimensional pattern viewed through a circular aperture is ambiguous. The problem is not due to the aperture but arises from the one-dimensionality of the signal.

Finally, the local brightness may vary two-dimensionally, in which case the optic flow vector is uniquely constrained. But because of the occurrence of underconstrained regions

FIGURE 109.1. Conceptual illustration of motion estimation in three different regions of an image of a horizontally translating cube. In a region of constant brightness (top face of the cube), the local velocity is completely unconstrained since the observed image is not changing over time. We refer to this as the *blank-wall* problem. In a region where the brightness varies only along a unique spatial direction (striped side of the cube), the brightness changes are consistent with a one-dimensional set of velocities: one can determine the motion perpendicular to the stripes but *not* the motion along the stripes. This is known as the *aperture* problem. Finally, in a region where the brightness changes in all spatial directions (hatched side of the cube), a unique velocity is consistent with the observed brightness changes.

(blank-wall and aperture problems), a full solution for the motion problem in which all image points are assigned a velocity vector seems to require the integration of information across spatial neighborhoods of the image (and perhaps over time as well). This concept has been studied and developed for many years in computer vision (e.g., Hildreth, 1984; Horn and Schunck, 1981; Lucas and Kanade, 1981).

In addition to the blank-wall and aperture problems, in which the velocity is underconstrained, there are often locations in an image at which multiple velocity signals interact. In particular, this can occur at occlusion boundaries of objects, where any local spatial neighborhood must necessarily include some portion of both object and background, which are typically moving differently. Another example occurs in the presence of transparently combined surfaces or specular highlights. In each of these cases, the local motion description requires more than one velocity, along with some sort of assignment of which image content belongs to which velocity.

Solutions for the multiple-motion problem have been developed fairly recently. Specifically, a number of authors have proposed that one should simultaneously decompose the image into consistently moving layers of brightness content and estimate the motions within those layers (Ayer and Sawhney, 1995; Darrell and Pentland, 1995; Wang and Adelson, 1994; Weiss and Adelson, 1996). Some authors

have suggested that this sort of solution might be implemented biologically (Darrell and Simoncelli, 1994; Koehlin et al., 1999; Nowlan and Sejnowski, 1995).

We'll return to this point in the "Discussion" section, but for most of the chapter, we'll restrict our attention to the simple case of translational motion over a local patch of the image, ignoring the possibility of multiple motions. As in much of the computational motion literature, we view this as a building block that could be combined with further processing to provide a more complete solution for the analysis of motion. The goal of this chapter is to introduce a framework for thinking about motion and to interpret the components of that framework physiologically.

Computational framework

The problem of motion estimation may be formalized using well-developed tools of estimation theory. Specifically, we adopt a Bayesian framework, one of the simplest and most widely used in the engineering literature. Bayesian approaches have also been used to model various aspects of visual perception (e.g., see Knill and Richards, 1996).

BRIGHTNESS CONSTANCY In any estimation problem, the most essential ingredient is the relationship between the thing one is trying to estimate and the measurements that one makes. In most motion estimation schemes, this relationship comes from the *brightness constancy assumption* (Horn and Schunck, 1981): changes in image brightness are a result of translational motion in the image plane. When expressed mathematically, this gives a relationship between image values and the local velocity:

$$I(x + u\Delta t, y + w\Delta t, t + \Delta t) = I(x, y, t),$$

where u and w are the horizontal and vertical components of the image velocity at position (x, y) and time t . Assuming that the temporal interval Δt is small enough that the left side may be approximated by a Taylor series expansion up to first order, we can replace this with a differential version of the brightness constancy assumption:

$$I_x u + I_y w + I_t = 0, \quad (1)$$

where (I_x, I_y) are the spatial derivatives and I_t the temporal derivative of the image brightness. Note that this equation still corresponds to a particular position and moment in time: we've dropped the arguments (x, y, t) to simplify the notation.

Although the signal I is usually considered to represent the image brightness, the formulation may be generalized. In particular, one can use any function locally derived from the image brightness. For example, one could prefilter the image with a bandpass filter to enhance information at certain frequencies, one could use a point nonlinearity (e.g., logarithm) to reduce the dynamic range of the input, or one could compute a measure of local contrast by dividing by the local

mean. Under such modifications, equation 1 should be interpreted as expressing the constancy of some other (non-brightness) attribute. As such, the usual brightness-based motion estimator may be easily converted into a so-called second-order or “non-Fourier” motion estimator, as has been proposed by a number of authors (e.g., Chubb and Sperling, 1988; Fleet and Langley, 1994; Wilson and Kim, 1994).

Furthermore, the computation of derivatives of discretized images requires one to first perform some local integration by prefiltering with a lowpass filter. The differentiation and filtering operations may be combined, so that derivatives are effectively computed by convolution with the derivative of the prefilter (Simoncelli, 1993). In computer vision, for example, derivatives are often computed using the derivatives of a Gaussian function.

LOCAL COMBINATION OF CONSTRAINTS Equation (1) cannot be solved for the two components of velocity, since it imposes only a single linear constraint. This is simply a differential manifestation of the aperture problem: the derivative measurements characterize the local brightness values in terms of their variation along a single direction (the gradient direction), and thus only the component of velocity in this direction can be estimated. In order to estimate the velocity completely, we must impose further constraints on the problem. A simple solution is to assume that the velocity field is smooth (Horn and Schunck, 1981), or that it is constant over a small spatial neighborhood surrounding the location of interest (Lucas and Kanade, 1981), and to combine the constraints over that region. Alternatively, or in conjunction with the spatial combination, one can combine constraints arising from differently filtered versions of the image (e.g., Nagel, 1983). Many authors have described more sophisticated choices of combination rule (e.g., Black, 1992; Hildreth, 1984), but we will use this simplest form of spatial combination in this chapter.

MEASUREMENT NOISE Next, we assume that the derivative measurements are corrupted by a small amount of noise, as must be true in any real system. For computational convenience, we assume that the noise is additive and that the values are distributed according to a Gaussian probability density. Although this simple noise model is unlikely to be correct in detail (in particular, it is not a very accurate description of the noise in neural responses), it is sufficient to illustrate the fundamental issues of motion estimation.

Mathematically, we write

$$I_x u + I_y w + I_t = n,$$

where n is a random variable representing the noise. This enables us to write the probability of observing the spatiotemporal image structure assuming a given velocity:

$$P(I|u, w) \propto \exp\left[-(I_x u + I_y w + I_t)^2 / (2\sigma_n^2)\right],$$

where σ_n indicates the standard deviation of the noise variable n . Empirically, de Ruyter (2002) measured the relationship between gradient measurements and translational velocity in video footage gathered from a head-mounted camera, and found that it is roughly consistent with this formulation.

Now, as described previously, we combine the constraints over a small spatial region, in which we assume the velocity vector is constant and the noise variables are independent:

$$P(I|u, w) \propto \exp\left(-\sum (I_x u + I_y w + I_t)^2 / (2\sigma_n^2)\right) \quad (2)$$

where the sum combines the measurements at all locations within the neighborhood.

PRIOR PROBABILITY DISTRIBUTION ON VELOCITY Equation (2) describes the *likelihood function*: the probability of observing a spatiotemporal image pattern given a velocity (u, w) . In Bayesian estimation, one reverses this conditionalization using Bayes' rule in order to get the *posterior* distribution:

$$P(u, w|I) = \frac{P(I|u, w) P(u, w)}{\int du \int dw P(I|u, w) P(u, w)}. \quad (3)$$

The probability density $P(u, w)$ is known as the *prior*: it describes the probability of observing each velocity (independent of any particular image measurements).

For the prior probability distribution, we again make a choice of mathematical convenience: we assume that $P(u, w)$ is Gaussian with zero mean:

$$P(u, w) \propto \exp(-\|u^2 + w^2\| / 2\sigma_v^2). \quad (4)$$

As in the choice of the noise model, this may not be an accurate characterization of the distribution of image velocities that an organism would encounter in the world, but it suffices to capture the main aspects of a reasonable solution to the motion estimation problem. The intuition is that in the absence of any specific image information (e.g., in a dark room), one should assume that things are not moving. More generally, the model proposes that slow velocities occur more frequently than fast ones. This hypothetical property of the environment is mirrored by the long-standing hypothesis that the perceived motion of stimuli corresponds to the slowest motion consistent with the observed image information (see references in Ullman, 1979). In particular, Wallach (1935) proposed that humans tend to see line segments as moving in a direction normal to their orientation because the velocity associated with that direction is the slowest of all velocities consistent with the image information.

Combining equations 2 and 4, as specified in equation 3 gives the posterior distribution

$$P(u, w|I) \propto \exp\left[-(u^2 + w^2) / 2\sigma_v^2 - \sum (I_x u + I_y w + I_t)^2 / 2\sigma_n^2\right]. \quad (5)$$

FIGURE 109.2. Illustration of posterior probability densities for the example shown in Figure 109.1.

This specifies a Gaussian distribution over (u, w) whose behavior is illustrated in Figure 109.2. Note that the distribution captures the uncertainties shown in the conceptual illustrations of Figure 109.1. In particular, the posterior density for the blank region is quite broad (it is identical to the prior). In the striped region, the density is elongated and lies along the line that defines the set of velocities consistent with the image constraints. The width along this line is determined by the prior variance, σ_v^2 . The width perpendicular to the line is determined by the noise variance, σ_n^2 , as well as the image contrast. And in the patterned region, the density is much more compact and centered on the correct horizontal velocity.

Physiological interpretation

A Bayesian model is appealing because of its generality and its construction from a relatively small number of realistic assumptions. It can be implemented in a distributed analog network (Stocker, 2001), and has been used in machine vision applications. In previous work, we have shown that the mean (equivalently, the maximum) of the Gaussian posterior distribution described by equation 5 provides a surprisingly good match to human perception of velocity for a variety of translating stimuli (Heeger and Simoncelli, 1993; Simoncelli, 1993; Weiss, 1998; Weiss et al., 2002). In this section, I'll describe the relationship between the elements of this framework and the functional properties of neurons that lie in the *motion pathway* of mammals such as cats or monkeys. This should not be thought of as a quantitative physiological model of motion processing, but rather as a more qualitative assignment of computational function to neural populations along the motion pathway.

We'll work backward through the system, starting from the posterior distribution of equation 5. If we hold the veloc-

ity (u, w) fixed, then this function is "tuned" for the velocity of the input image. That is, it is maximized when the underlying image structure is consistent with the velocity (u, w) , and it decreases as the image motion deviates from that velocity. We may identify this basic property with those neurons in visual area MT that are known as *pattern selective* (Movshon et al., 1986; Chapter 81). These neurons are tuned for retinal image velocity; they respond vigorously to a visual stimulus moving with a particular speed and direction, and are relatively indifferent to the stimulus' spatial pattern (Maunsell and van Essen, 1983; Movshon et al., 1986; Rodman and Albright, 1987).

A number of models posit that a population of such neurons provides a distributed representation of velocity (Grzywacz and Yuille, 1990; Heeger, 1987; Koch et al., 1989; Nowlan and Sejnowski, 1995; Simoncelli, 1993; Simoncelli and Heeger, 1998). Here we assume that the responses within this population correspond directly to samples of the posterior density. That is, the response of each neuron corresponds to equation 5 evaluated at a different "preferred" velocity (u, w) . Note that in this interpretation, no single neuron encodes the velocity of the stimulus, and an actual estimate of the velocity can be obtained only by combining information across the population. For example, one could compute the mean velocity by summing the preferred velocities of all of the neurons in the population, each weighted by the response of that neuron. Also note that in this interpretation, the prior distribution, $P(u, w)$, provides only a gain adjustment (multiplicative scale factor) on each of the neural response. The integral over (u, w) in the denominator of equation 3 corresponds to a sum over the responses of all neurons in the population. We have previously shown that this kind of divisive normalization operation is consistent with the response properties of MT neurons (Simoncelli and Heeger, 1998).

We can make a qualitative comparison of this model to typical neural responses in area MT. The lower left panel of Figure 109.3 shows polar plots of the response of a model MT neuron with preferred velocity $u = 0.3$, $w = 0$ pixels per frame as a function of the normal direction of a drifting sinusoidal grating. As with MT pattern cells (Movshon et al., 1986), the response is tuned for the direction of motion and is largest when this direction matches the preferred direction. The lower right panel shows the response as a function of direction for a "plaid" stimulus, constructed as the sum of two drifting gratings 120 degrees apart. The response is largest when this plaid stimulus is moving rightward, a configuration in which the two constituent gratings are moving at ± 60 degrees from rightward. This response to the direction of pattern motion (rather than to the two component directions) is a characteristic used to identify MT pattern cells (Movshon et al., 1986).

FIGURE 109.3. Direction tuning curves for model components. *Upper left*: model V1 neuron (squared directional derivative) response to a drifting sinusoidal grating; *upper right*: model V1 neuron response to a drifting sinusoidal plaid; *lower left*: model MT neuron (posterior probability) response to a grating; *lower right*: model MT neuron response to plaid.

Figure 109.4 shows the posterior function plotted as a function of stimulus speed (again for a drifting sinusoidal grating). The maximum response occurs at 0.3 pixel per frame, the speed corresponding to the chosen (u, w) . At half height, the curve spans a speed range of about 2 octaves, which is roughly comparable to the responses of some MT cells (Maunsell and van Essen, 1983).

Having identified the posterior distribution with MT pattern responses, we now want to consider the components

FIGURE 109.4. Speed tuning curve for posterior distribution (model MT neuron) to a drifting sinusoidal grating. The absolute scale of the horizontal axis is arbitrary, but the tick marks correspond to increments of speed by multiples of 2.

FIGURE 109.5. Illustration of two identities relating separable and oriented derivative operations. *Top*: A spatial derivative operator at any orientation may be computed as a linear combination of separable (axis-aligned) derivative operators (Eq. 7). *Bottom*: A product of X and Y derivatives may be computed as the difference of two squared, obliquely oriented derivatives (Eq. 6). Operators in both cases are Gaussian derivatives, but the identities hold for derivatives of other functions as well.

(i.e., the *afferents*) from which those responses are generated. The exponent of equation 5 may be expanded (dropping a factor of 2) as follows:

$$f(I, u, w) = - \sum [u^2 I_x^2 + 2uw I_x I_y + w^2 I_y^2 + 2u I_x I_t + 2w I_y I_t + I_t^2] / \sigma_n^2 + [u^2 + w^2] / \sigma_v^2,$$

where the sum is taken over a small spatial neighborhood. Many of the terms contain squared image derivatives, and those that contain products of image derivatives may be written as a difference of two squared derivatives. For example:

$$I_x I_y = [(I_x + I_y)^2 - (I_x - I_y)^2] / 4 = [I_{d1}^2 - I_{d2}^2] / 4, \quad (6)$$

where I_{d1} and I_{d2} are derivatives at angles 45 degrees and -45 degrees, respectively. In general, a derivative at any orientation may be constructed via a suitable combination of axis-aligned (separable) derivative operators (Freeman and Adelson, 1991):

$$I_\theta = \cos(\theta) I_x + \sin(\theta) I_y, \quad (7)$$

where I_θ is a derivative in direction θ . The mathematical relationships of equations 6 and 7 are illustrated in Figure 109.5.

An analogous transformation allows us to write the term containing $I_x I_t$ as a difference of two derivatives. Since one of the axes is now time, the result is a difference of space-time oriented derivatives, I_r and I_l , which are most responsive to vertically oriented structures that are moving rightward/leftward. This construction, known as an *opponent motion* computation, has been previously proposed as an explanation for a number of psychophysical phenomena (Adelson and Bergen, 1985). Similarly, the product $I_y I_t$ results in a difference of squared upward and downward derivatives I_u and I_d . Combining all of this allows us to write the exponent as

$$f(I, u, w) = -\frac{1}{\sigma_n^2} \sum u^2 (I_x^2 + \sigma_n^2 / \sigma_v^2) + uw (I_{d1}^2 - I_{d2}^2) / 2 \\ + w^2 (I_y^2 + \sigma_n^2 / \sigma_v^2) + u (I_r^2 + I_l^2) / 2 \\ + w (I_u^2 - I_d^2) / 2 + I_t^2. \quad (8)$$

The purpose of these transformations is to show that the computation of the posterior is based on a sum of terms that could arise in the responses of primary visual cortical neurons. The receptive fields of so-called *simple* cells in primary visual cortex (area V1) of cats and monkeys are selective for stimulus position and orientation (Hubel and Wiesel, 1962; Chapter 43). Many simple cells are also direction-selective: they give stronger responses for stimuli moving in one direction than in the opposite direction (Chapter 44). Many authors have characterized simple cell responses as the halfwave-rectified (and sometimes squared) responses of linear receptive fields (e.g., Campbell et al., 1968, 1969; Daugman, 1985; Heeger, 1992; Movshon et al., 1978). In these models, the neuronal response is derived from a weighted sum (over local space and recent past time) of the local stimulus contrast. This type of model can explain the primary properties of these cells, including selectivity for stimulus orientation, spatial frequency, temporal frequency, and direction.

The linear derivative filters used in our Bayesian motion estimator (as shown in Fig. 109.5) bear some similarity to the response properties of simple cells: they are tuned for spatial orientation, spatial frequency, temporal frequency, and direction. Example direction tuning curves of squared derivative operators for both gratings and plaids are shown in the top row of Figure 109.3. Note that, as in V1 neurons, the response to the plaid is bimodal: unlike the posterior response shown in the bottom row, the operator responds to each of the components of the plaid rather than to the pattern as a whole.

In general, tuning of first-derivative operators for most variables is significantly broader than that of most simple cells. We have shown in previous work that this inconsistency is easily corrected through the use of higher-order derivative operators (Heeger and Simoncelli, 1993; Simoncelli, 1993; Simoncelli and Heeger, 1998). The Bayesian solution given above may be rederived using such operators, and the form of the result is essentially the same despite the proliferation of terms in the equations.

Also prevalent in the primary visual cortex are *complex* cells, which exhibit similar selectivity for orientation, spatial, frequency temporal frequency, and direction but which are more nonlinear in their response properties. In particular, their responses are relatively insensitive to the precise location of stimuli within their receptive fields. Models of these cells have been based on local oriented *energy*, computed as the sum of squared responses of even- and odd-symmetric

oriented linear filters (e.g., Adelson and Bergen, 1985). In the Bayesian model of this paper, this type of construction could be achieved by combining the constraints obtained from differently filtered versions of the input image. Alternatively, this translation invariance of responses is approximately achieved with a sum of squared linear responses over a local spatial neighborhood, as in equation 8. Summarizing, the posterior distribution of our Bayesian model is constructed from building blocks that resemble direction-selective complex cells. This parallels the physiology, where it has been shown that the neurons that project from area V1 to MT are direction-selective complex cells (Movshon and Newsome, 1996).

Finally, we need to address the construction of the spatiotemporally oriented V1 responses from the primary afferents arriving from the lateral geniculate nucleus. These responses are generally not orientation-tuned and they are not directional (in cats and monkeys). Specifically, the receptive fields are described by a product of a spatial (center-surround) weighting function and a temporal weighting function (Chapter 35). In the context of the Bayesian model, spatial derivative computation (to produce orientation-selective receptive fields) can be obtained by spatial combination of lateral geniculate nucleus receptive fields, as has been suggested physiologically (Hubel and Wiesel, 1962; Reid and Alonso, 1995). A number of authors have suggested that directional responses may be constructed physiologically by superimposing an appropriate set of space-time separable responses (e.g., Adelson and Bergen, 1985; Fahle and Poggio, 1981; Watson and Ahumada, 1983). In the case of the directional derivatives used in this chapter, one need only sum a spatial and temporal derivative operator (with the correct weighting) to obtain a spatiotemporally oriented derivative operator selective for any desired orientation. This construction is made explicit in equation 7 and illustrated in the top panel of Figure 109.5.

Discussion

We have provided a Bayesian analysis for local motion based on a minimal set of assumptions: (1) brightness conservation, (2) a simple model of measurement noise, and (3) a prior preference for slower speeds. Given these assumptions, the components of the optimal solution can be seen to have properties qualitatively matching those of neurons in the mammalian motion pathway.

In previous work, we have shown that this model accounts for a surprising number of psychophysical results demonstrating nonveridical perception of motion stimuli (Weiss et al., 2002). We have also shown that an elaborated variant of this model can be fit more precisely to neural response properties (Simoncelli and Heeger, 1998). In that model, narrower V1 stage tuning curves are achieved through use

of higher-order derivatives, and nonlinear properties of V1 responses are incorporated using divisive normalization.

The particular Bayesian model described in this chapter is the simplest of its kind. A more correct model should include a more realistic model of uncertainty in photoreceptors, as well as in subsequent neural responses. It should also include a prior that more accurately reflects the velocity distribution in the visual environment (although this is quite difficult to model, given that it depends not just on the environment, but also on the motion of the organism). Such modifications are unlikely to lead to qualitatively different behaviors of the solution, but they may produce a more accurate account of the physiology.

Finally, the formulation of the motion estimation problem using brightness constancy is simplistic in assuming that a single translational velocity accounts for the motion in each local region. As described earlier, this assumption is violated in real scenes near occlusion boundaries and in the presence of transparent surfaces. Studies in computer vision have suggested that segmentation or grouping of the scene must be tightly integrated with the motion estimation solution, and a number of authors have proposed joint solutions (e.g., Ayer and Sawhney, 1995; Darrell and Pentland, 1995; Wang and Adelson, 1994; Weiss and Adelson, 1996). These solutions are invariably recurrent, perhaps suggesting that physiological implementations will require recurrent lateral or feedback projections between two neural populations computing velocity and grouping.

110 Visual Boundaries and Surfaces

STEPHEN GROSSBERG

Visual boundaries and surfaces and complementary cortical streams

Visual perception is highly context-sensitive. A visual scene cannot be easily understood by evaluating it just in terms of its local contrasts or individual pixels. It is better understood as a juxtaposition of objects which may mutually occlude one another in a scene or picture. Much evidence suggests that these objects are represented in terms of two types of information: boundaries and surfaces. This chapter reviews aspects of how and why this happens.

Where are visual boundaries and surfaces computed in the brain? Figure 110.1 summarizes three processing streams within the visual cortex that are activated by light impinging on the retina. One stream goes from the retina through the lateral geniculate nucleus (LGN) parvo stage (classified due to its parvocellular cell type) to the cortical processing stages V1 interblob, V2 interstripe, V4, and then to inferotemporal cortex. Another stream goes from retina through LGN parvo, V1 blob, V2 thin stripe, V4, and then again to inferotemporal cortex. A third stream goes from retina through LGN magno (classified due to its magnocellular cell type) to cortical processing layer 4B in area V1, V2 thick stripes, MT, and then parietal cortex. The interblob and blob streams are proposed to compute properties of visual boundaries and surfaces, respectively. Many experiments support this view (e.g., Elder and Zucker, 1998; Field et al., 1993; He and Nakayama, 1995; Lamme et al., 1999; Rogers-Ramachandran and Ramachandran, 1998).

The existence of such streams has led many scientists to conclude that our brains process perceptual qualities such as visual form, color, and motion using different *independent modules*. If the processing streams were independent modules, they could fully compute their particular processes on their own. In contrast, much perceptual data describe strong interactions between perceptual qualities. For example, changes in an object's perceived form or color can cause changes in its perceived motion, and vice versa, while changes in an object's perceived brightness can cause changes in its perceived depth, and vice versa (Egusa, 1983; Faubert and von Grünau, 1995; Kanizsa, 1974; Pessoa et al., 1996; Smallman and McKee, 1995). If geometrical properties like color, form, and depth are not computed indepen-

dently, then what is the geometry by which we really see the world?

Many data suggest that the brain's processing streams compute *complementary* properties (e.g., Grossberg, 2000). Each stream's properties are related to those of a complementary stream much as a key fits its lock or two pieces of a puzzle fit together. We are all familiar with complementarity principles in physics, such as the famous Heisenberg Uncertainty Principle of quantum mechanics, which notes that precise measurement of a particle's position forces uncertainty in measuring its momentum, and vice versa. As in physics, the mechanisms that enable each stream in the brain to compute one set of properties prevent it from computing a complementary set of properties. Each stream exhibits complementary strengths and weaknesses. How, then, do these complementary properties get synthesized into a consistent behavioral experience?

Neural models clarify how *interactions* between these processing streams overcome their complementary deficiencies and generate behavioral properties that realize the unity of conscious experiences. *Pairs* of complementary streams are the functional units that interact together in order to compute unambiguous information about the world. Such interactions may be used to explain many of the ways in which perceptual qualities are known to influence each other. Thus, although analogies like a key fitting its lock are suggestive, they do not fully capture the interactive dynamism of what complementarity means in the brain.

Each stream can possess multiple processing stages. For example, in Figure 110.1, the LGN inputs to cortical areas V1, V2, V4, and then inferotemporal and parietal cortices. Why is this so? One reason is that these stages realize a process of *hierarchical resolution of uncertainty*. *Uncertainty* here means that computing one set of properties at a given stage can suppress information about a different set of properties at that stage. Uncertainty principles are also familiar in physics. In the brain, these uncertainties are overcome by using more than one processing stage to form a stream. Overcoming informational uncertainty utilizes both hierarchical interactions within each stream and parallel interactions between streams that overcome their complementary deficiencies. The computational unit is thus not a single processing stage; it is, rather, an ensemble of processing stages

FIGURE 110.1. Schematic diagram of processing streams in visual cortex in the macaque monkey brain. Icons indicate the response selectivities of cells at each processing stage: rainbow, wavelength selectivity; angle symbol, orientation selectivity; spectacles, binocular selectivity; right-pointing arrow, selectivity to motion in a prescribed direction. (Adapted with permission from DeYoe and Van Essen, 1988.)

that interact within and between complementary processing streams.

Seeing versus recognizing: all boundaries are invisible

The boundary and surface streams obey complementary properties. One therefore needs to analyze both streams to fully understand how either stream normally functions. Figures 110.2*A* and 110.2*B* illustrate three pairs of complementary boundary and surface properties using visual illusions that are induced by variants of a Kanizsa square. In response to viewing Figure 110.2*A*, our brains construct a percept of a square even though the image contains only four black pacman, or pie-shaped, figures on a white background.

Why do our brains construct a square where there is none in the image? There are several reasons for this. One is that there is a *blind spot* in our retinas, a region where no light-sensitive photoreceptors exist. This region is blind because of the way in which the pathways from retinal photoreceptors are collected together to form the optic nerve that carries them from the retina to the LGN in Figure 110.1.

BOUNDARY COMPLETION

oriented inward
insensitive to contrast polarity

SURFACE FILLING-IN

unoriented outward
sensitive to contrast polarity

FIGURE 110.2. Visual boundary and surface interactions. *a*, A Kanizsa square. *b*, A reverse-contrast Kanizsa. *c*, An object boundary can form around the gray disc even though its contrast reverses relative to the background along its perimeter. *d*, An invisible, or amodal, vertical boundary. *e*, An example of neon color spreading. (See color plate 84)

We are not usually aware of this blind spot because our brains complete boundary and surface information across it (Kawabata, 1984). The actively completed parts of these percepts are visual illusions, because they are not derived directly from visual signals on our retinas. In fact, many of the percepts that we believe to be “real” are visual illusions whose boundary and surface representations just happen to look real. What we call a *visual illusion* is typically an unfamiliar combination of boundary and surface information.

Visual illusions provide many instructive examples of how boundaries and surfaces are formed. They also probe subtle relationships between what we can consciously see and recognize. The images in Figures 110.2*A* and 110.2*B* lead to percepts of a Kanizsa square, even though both images contain only four pacman inducers. To form the square, illusory contours form *inwardly* between cooperating pairs of

colinear pacman edges. (If boundaries were formed outwardly from a single inducer, then any speck of dirt in an image could crowd all our percepts with an outwardly growing web of boundaries.) Four such contours form the boundary of the Kanizsa square. This boundary completion process is *oriented* to form contours only between (almost) like-oriented and (almost) colinear inducers in the scene or image. Boundary completion can also complete “real” scenic contours which are not fully detected at the retina due to the blind spot.

The square boundary in Figure 110.2A can be both seen and recognized because of the enhanced illusory brightness within the square relative to the brightness of the background. An explanation of this brightness percept will be summarized below. In contrast, the square boundary in Figure 110.2B can be recognized even though it is not seen; that is, there is no brightness or color difference on either side of the illusory square boundary. Figure 110.2B shows that *some* boundaries can be consciously recognized even though they are perceptually unseen, or invisible. An emerging neural theory of how boundaries and surfaces are formed, called *FACADE* (Form-And-Color-And-DEpth) theory (e.g., Grossberg, 1994, 1997), predicts that *all boundaries are invisible* within the boundary system.

Why, and in what sense, are all boundaries invisible? This property enables boundaries to form around objects that are seen in front of textured backgrounds. For example, consider the boundary around the gray circular disc in Figure 110.2C. The gray disc lies in front of a black and white textured background whose contrasts with respect to the disc reverse along the disc’s perimeter. The brain can build a boundary around the entire disc, despite these contrast reversals. Perhaps the simplest example of a boundary that is completed from opposite contrasts is the reverse-contrast Kanizsa square in Figure 110.2B. Here a square boundary is formed between white and black pacmen on a gray background. The vertical boundaries form between black and white inducers that possess opposite contrast polarity with respect to the gray background: the black inducers have a black/gray, or dark/light, polarity, whereas the white inducers have a white/gray, or light/dark, polarity. Many observers can recognize this boundary without also seeing a contrast difference between the gray color inside and outside the square. Figure 110.2D illustrates yet another invisible boundary that can be consciously recognized.

Boundary formation: filtering and grouping

How does the brain build these boundaries? At an early stage of boundary processing, the brain pools, or adds, signals from cortical cells that are sensitive to opposite contrast polarities. In particular, at each position within the V1

interblobs, individual *simple cells* are most sensitive to a prescribed orientation at each position, but to only one contrast polarity. A simple cell can respond to either an oriented dark/light contrast or an oriented light/dark contrast, but not both. It thus behaves like a polarity-sensitive oriented filter. The outputs of simple cells that respond to the same position and orientation, but to opposite contrast polarities, are pooled at the next processing stage. This pooling process occurs at the *complex cells*.

Complex cells hereby become *insensitive* to the contrast phase, which is one of their defining characteristics (Hubel and Wiesel, 1977). They can detect an object boundary, whatever its relative contrast with respect to the background may be. Thus, a complex cell at any position along the edges of the white or black pacmen in Figure 110.2B, or anywhere along the circular boundary in Figure 110.2C, could be activated. By pooling dark/light and light/dark responses, the boundary system loses its ability to represent visible brightnesses or colors, since its output cannot signal the difference between dark and light. It is in this sense that “all boundaries are invisible.” Outputs from these complex cells activate the *inward* and *oriented* boundary completion process. Boundary completion occurs in, among other places, the V2 interstripe area (Von der Heydt et al., 1984). These three properties of boundary completion (inward, oriented, insensitive to contrast polarity) are summarized in Figure 110.2.

Boundary formation in the brain—also called *perceptual grouping*—is a key mechanism whereby we perceive geometrical objects such as lines, curves, and textured objects. Rather than being defined by such classical units as points and lines, boundaries arise as a coherent pattern of excitatory and inhibitory signals within a feedback network that includes retina, LGN, and V1 interblob and V2 interstripe areas. Grossberg (1984) and Grossberg and Mingolla (1985a, 1985b) introduced the first neural model of how boundary formation occurs in visual cortex. This Boundary Contour System (BCS) model clarifies how perceptual boundaries, or groupings, may be formed by several different types of “contoured” image properties, including edges, texture gradients, shading, and stereo differences. Since that time, steady progress in modeling the neural basis of perceptual grouping has been made (e.g., Gove et al., 1995; Grossberg, 1994; Li, 1998; Mumford, 1992), leading recently to models which clarify how the laminar circuits of visual cortex are designed to achieve perceptual grouping (see below). These models propose how spatially long-range excitatory interactions in cortical layer 2/3 build boundaries across space while interacting with shorter-range inhibitory interactions that suppress incorrect boundary groupings. These interactions select stronger boundary groupings from among many possible interpretations of a scene. A winning grouping may be represented by synchronous activity of the cells that

represent the boundary until it is reset to enable new boundaries to form.

Seeing by the surface stream

Given that boundaries are invisible, how do we see anything? Visible properties of a scene are predicted to be represented within the surface processing system (Grossberg, 1994) within the blob cortical stream between V1, V2, and V4 (Fig. 110.1). A key step in representing a visible surface is the *filling-in* process. What is filling-in, and why and how does it occur?

An early stage of surface processing compensates for variable illumination, or *discounts the illuminant*, in order to prevent illuminant variations from distorting all percepts. Discounting the illuminant attenuates color and brightness signals except near regions of sufficiently rapid surface change, such as edges or texture gradients. These *feature contours* are relatively uncontaminated by illuminant variations. After extracting these feature contours, later stages of surface formation use them to fill-in the attenuated regions with values that are less sensitive to illuminant changes. Filling-in is an example of hierarchical resolution of uncertainty, because the later filling-in stages overcome uncertainties about surface brightness and color that were caused by discounting the illuminant at an earlier processing stage.

How do the illuminant-discounted signals fill-in an entire region? Filling-in behaves like a diffusion of brightness or color across space. For example, consider the percept of *neon color spreading* that is elicited by Figure 110.2E. This figure consists of circular annuli, part of which are black and part gray. In response to this figure, we can see an illusory square filled with a gray color. FACADE theory has proposed an explanation of this percept in terms of interactions between the boundary and surface systems. In particular, the black boundaries cause small breaks, called *end gaps*, in the gray boundaries where they join (Grossberg, 1994). The gray color can spread through these breaks from the annuli into the illusory square. In this percept, filling-in spreads *outward* from the individual gray inducers in all directions. Its spread is thus *unoriented*.

How is this spread of activation contained? Signals from the boundary system to the surface system are predicted to define the regions within which filling-in is restricted via an interblob to blob stream interaction. These boundary signals act as barriers that block the spread of filling-in within the blob stream. Thus, filling-in is a type of anisotropic diffusion in which boundary signals nonlinearly gate, or inhibit, the diffusive flow of surface signal. Without these boundaries, filling-in would spread across space without restriction, and would thereby dissipate its activity, so that no visible surface percept could form. Invisible boundaries thereby indirectly ensure their own visibility through their interactions with the

surface stream, within which all visible percepts are predicted to form. In the neon color spreading example shown in Figure 110.2E, these boundary signals to the surface stream surround the annuli (except for their small breaks) and also form the square illusory contour. That is why the spread of gray is restricted to the square region.

We can now understand finer aspects of the other percepts derived from Figure 110.2. In Figure 110.2A, the square boundary is induced by four black pacmen that are all less luminant than the white background. In the surface stream, the process of discounting the illuminant has the side effect that the pacmen induce local brightness enhancements (the feature contours) adjacent to the pacmen and just within the square boundary. At a subsequent filling-in stage, these enhanced brightness signals spread within the square boundary, thereby causing the entire interior of the square to look uniformly brighter. The filled-in square is visible because the filled-in activity within the square is higher than the filled-in activity outside the square. Filling-in can thereby lead to visible percepts because it is *sensitive* to contrast polarity. These three properties of surface filling-in (outward, unoriented, sensitive to contrast polarity) are summarized in Figure 110.2. They are complementary to the corresponding properties (inward, oriented, insensitive to contrast polarity) of boundary completion. The surface system has been called the *Feature Contour System* (FCS) to denote that it builds up surface properties from *feature contours* that survive the process of discounting the illuminant and that are the basis for the features, such as brightness and color, that we can consciously see in surface percepts (Grossberg, 1994).

In Figure 110.2B, the opposite polarities of the pacmen with respect to the gray background can lead to approximately equal filled-in activities inside and outside the square. In particular, the black pacmen lead to enhanced brightness just within the square boundary, but the white pacmen lead to diminished brightness just within the boundary. When these opposite effects fill in, they can approximately cancel one another. As a result, the gray colors on the two sides of the boundary are approximately equal, so the boundary cannot be “seen.” On the other hand, the boundary can be consciously “recognized” as a salient perceptual event by brain processes that interact with the large boundary signals within the interblob stream. In Figure 110.2D, the vertical illusory contour is invisible because the white background can fill-in uniformly on both sides of the vertical boundary by spreading around the horizontal black lines.

Filling-in also clarifies how our brains can perceive brightnesses and colors across the retinal blind spot. Boundaries that form across the blind spot contain the filling-in of brightness and color there. Boundary completion and surface filling-in also help to explain how we see continuous blue surfaces (Grossberg, 1987a, Section 31), even though

blue cones have a sparse distribution on the retina (Boynton et al., 1985; Chapter 64, this volume). Interacting boundaries and surfaces will also be suggested below to play a fundamental role in three-dimensional (3D) vision and figure-ground perception.

Varied evidence for filling-in: constancy, contrast, and assimilation

Controversy persists about whether or not a physical filling-in interaction exists (Dennett, 1991; Pessoa et al., 1998). Such a question can be answered only by direct experimental test and by showing how neural models can explain more data by including a filling-in process. A number of early modeling articles explained perceptual data by using a neural filling-in process (e.g., Cohen and Grossberg, 1984; Grossberg, 1987a, 1987b; Grossberg and Mingolla, 1985a; Grossberg and Todorovic, 1988). Psychophysical data also supported a filling-in process by characterizing its temporal dynamics (Paradiso and Nakayama, 1991). Arrington (1994) simulated these data using the Grossberg–Todorovic model.

Since that time, neurophysiological evidence for filling-in has also been reported (e.g., Lamme et al., 1999; Lee et al., 1998). Interactions between boundary completion and surface filling-in have also played a key role in more recent explanations of data on 3D figure-ground perception (Grossberg, 1994, 1997; Grossberg and McLoughlin, 1997; Kelly and Grossberg, 2000), texture perception (Grossberg and Pessoa, 1998), brightness perception (Gove et al., 1995; Grossberg and Kelly, 1999; Neumann et al., 2001; Pessoa et al., 1995), visual persistence (Francis et al., 1994), negative aftereffects (Francis and Grossberg, 1996), and the McCollough effect (Grossberg et al., 2002). Most of these data have no other mechanistic explanation to date. Figure-ground perception will be discussed below.

Different combinations of mechanisms may be rate-limiting in explaining percepts which involve filling-in. Three simple mechanisms are sufficient to explain many data about brightness perception (Grossberg and Todorovic, 1988), but not all such data: (1) an on-center off-surround network of cells that obey shunting, or membrane, equations, (2) a boundary formation network, and (3) a surface filling-in network. The cells of the shunting on-center off-surround network preprocess visual inputs by discounting the illuminant and computing Weber-law modulated estimates of image reflectances that contrast-normalize input intensities. These contrast-normalized cell activities then input to the boundary formation and surface filling-in networks. The boundary signals to the surface filling-in network prevent filling-in from crossing boundaries.

Figure 110.3 gives four examples of how this simplest filling-in network works. The lowest row of each panel in the

figure shows a one-dimensional (1D) cross-section of image luminance. The next-lowest row shows how a shunting on-center off-surround network of cells can transform these image intensities. Comparing (A) and (B) shows that such a network can compensate for a gradient of illumination; see the patterns labeled FEATURE in the figure. In so doing, it can also distort the true pattern of image reflectances by generating cusps and dips in the profile of cell activities across space. One of these distortions is the attenuation of image reflectances away from object edges or other rapidly changing luminance gradients across space. This is the key mechanism whereby the illuminant is discounted. Boundary and surface interactions compensate for these distortions by exploiting the information that survives the discounting process. The boundaries create a frame within which the illuminant-discounted signals can fill-in within the surface processing stream; see the patterns labeled BOUNDARY in the figure. Thus, in Figures 110.3A and 110.3B, boundaries form at the luminance discontinuities of the image because the boundary system is sensitive to discontinuities in the activity profile of discounted signals. The pattern of these discounted signals is topographically mapped into filling-in domains (FIDOS) within the surface stream, or FCS. Here the discounted signals can begin to spread across space, contained within boundary signals that are topographically mapped from the BCS into the FIDOS. The result is given in the top row of each panel by the patterns labeled OUTPUT.

Figures 110.3A and 110.3B show how this network can discount the illuminant and recover the original pattern of image reflectances under some circumstances. This is an example of *brightness constancy*. However, due to the discounting process, image reflectances are not always veridically recovered. For example, the STIMULUS in Figure 110.3C contains two steps of equal luminance on a luminance that varies so gradually between them that no boundary is detected. In the OUTPUT profile, *brightness contrast* obtains; that is, the right step is more active than the left step in the OUTPUT activity profile. This is due to the sensitivity of the on-center off-surround network to image contrasts; see the FEATURE pattern. Remarkably, the luminance gradient that caused the brightness contrast is not visible in the final percept. The background has uniform brightness in the OUTPUT because no boundary exists to restrict the filling-in process between the two luminance steps, as also occurs in vivo under such conditions. Thus, this example also demonstrates a “visible effect of an invisible cause.”

Figure 110.3D shows that the same mechanisms can also cause the opposite of brightness contrast: *brightness assimilation* (Helson, 1963) from a display that was studied by Shapley and Reid (1986). Its luminance profile is derived from a standard brightness contrast profile by introducing

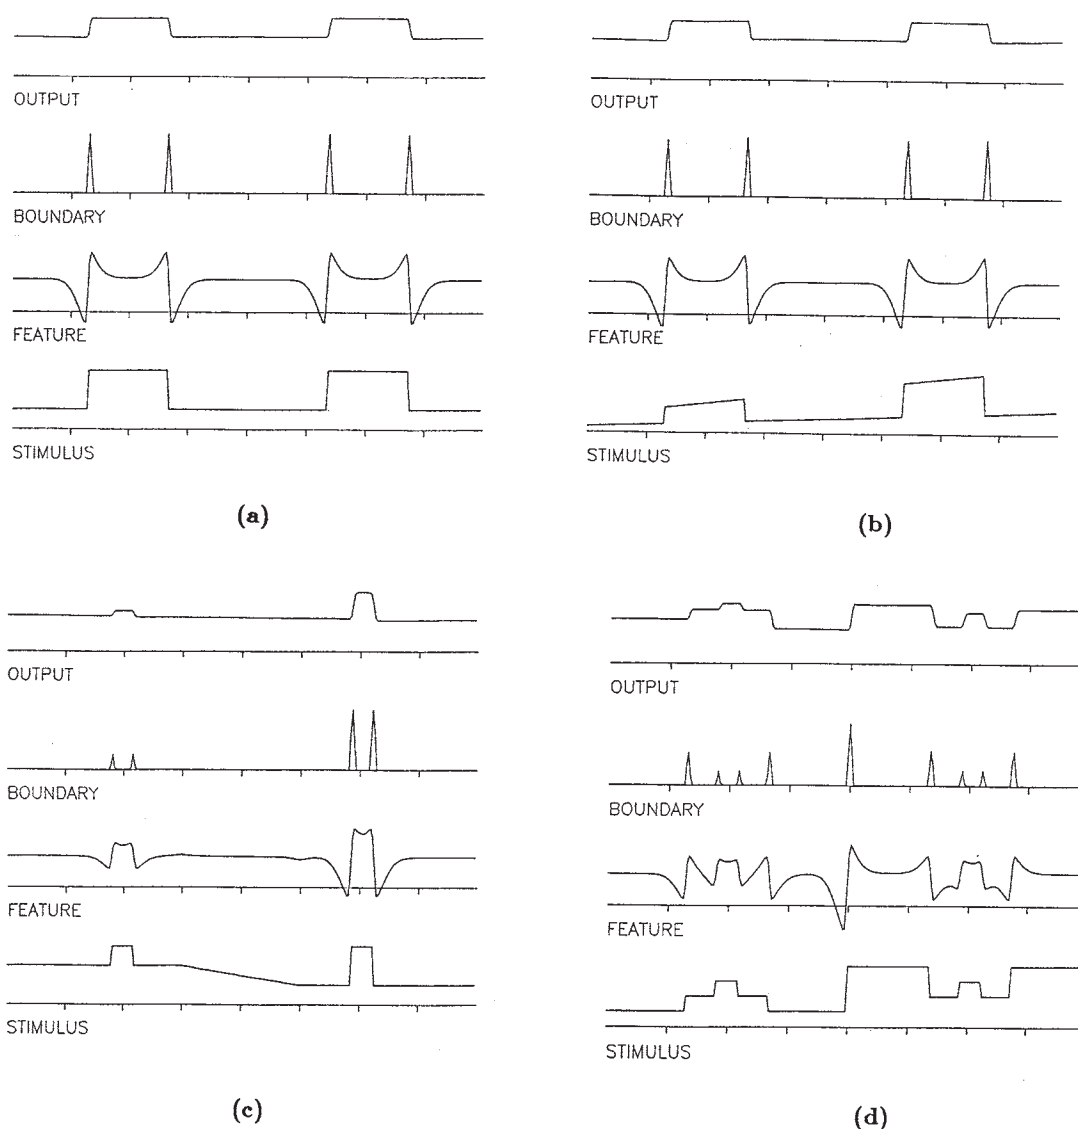

FIGURE 110.3. How filling-in can explain examples of brightness constancy (*a* and *b*), brightness contrast (*c*), and brightness assimilation (*d*). See text for details. (Adapted with permission from Grossberg and Todorovic, 1988.)

two additional test regions. These test luminance steps are the same and are placed on equally but less luminant backgrounds. A simple brightness contrast explanation would suggest that the two steps should have the same brightness. However, humans report that the left step looks brighter than the right one, as also occurs in the OUTPUT activity profile of the model. The perceived brightness of the background has been “assimilated” into the brightness of the steps. Figure 110.3D shows that a spatial pattern of activity cusps and dips is caused by the discounting process. These cusps and dips are broader than the boundaries that they induce. When this FEATURE profile fills-in within its narrower boundaries, assimilation obtains in the OUTPUT as an emergent property of network interactions.

The Grossberg-Todorovic model can explain many other brightness data, including the Craik-O’Brien-Cornsweet

effect, the Koffka-Benussi ring, Kanizsa-Minguzzi anomalous brightness differentiation, the Hermann grid, Land Mondrians, impossible staircases, bull’s-eyes, and nested combinations of luminance profiles. This explanatory success challenges other models of brightness perception. However, these mechanisms cannot, by themselves, explain data on brightness and lightness *scission* or *anchoring* during figure-ground perception. More comprehensive models can explain some scission and anchoring properties (Grossberg, 1999a; Grossberg et al., 1995).

Boundary completion and attention by the laminar circuits of visual cortex

How does visual cortex complete boundaries across gaps due to internal brain imperfections, such as the retinal blind spot,

or due to incomplete contours in external inputs, such as occluded surfaces, spatially discrete texture elements, illusory contour stimuli, or even missing pixels in impressionist paintings? The BCS model predicted how long-range horizontal cooperation interacts with shorter-range competition to do this. The cooperating cells were predicted to satisfy a *bipole* property. Such *bipole cells* achieve inward and oriented boundary completion by firing when they receive inputs from pairs of (almost) like-oriented and (almost) colinear scenic inducers. Von der Heydt et al. (1984) reported bipole cells in cortical area V2. Subsequent psychophysical studies also noted a bipole property during perceptual grouping. Field et al. (1993) called it an *association field*, and Shipley and Kellman (1992) called it a *reliability condition*.

More recently, the BCS was extended to clarify how laminar cortical circuits work (Grossberg, 1999b). This LAMINART model predicts how bottom-up, top-down, and horizontal interactions within the cortical layers achieve (1)

perceptual grouping, (2) attention, and (3) stable development and learning. The model proposes how mechanisms that achieve property (3) imply (1) and (2). That is, constraints on stable development of cortical circuits in the infant determine properties of learning, perception, and attention in the adult.

Figure 110.4 summarizes how known laminar cortical circuits may carry out perceptual grouping and attention. This summary omits binocular interactions for simplicity (but see below). The LGN directly activates V1 layers 4 and 6 (Fig. 110.4a). Layer 6, in turn, sends on-center off-surround inputs to layer 4. Layer 6 can strongly inhibit layer 4 through the off-surround, but the excitatory and inhibitory inputs in the on-center are approximately balanced. Layer 6 can thus modulate the excitability of layer 4 cells but cannot drive them to fire vigorously. This balance helps ensure stable cortical development (Grossberg and Williamson, 2001). The direct LGN-to-4 connections are proposed to drive layer 4 cells. The direct and indirect pathways from LGN-to-4 together form an on-center off-surround network. When layer 4 cells obey membrane, or shunting, equations, this network can contrast-normalize the responses of layer 4 cells (Grossberg, 1973; Heeger, 1992) and thus preserve their sensitivity to input differences over a wide dynamic range.

FIGURE 110.4. Boundary and attentional laminar circuits in interblob cortical areas V1 and V2. Inhibitory interneurons are shown filled-in black. *a*, The LGN provides bottom-up activation to layer 4 via two routes. It makes strong connections directly into layers 4 and 6. Layer 6 then activates layer 4 via a $6 \rightarrow 4$ on-center off-surround network. In all, LGN pathways to layer 4 form an on-center off-surround network, which contrast-normalizes layer 4 cell responses. *b*, *Folded feedback* carries attentional signals from higher cortex into layer 4 of V1 via the $6 \rightarrow 4$ path. Corticocortical feedback axons tend to originate in layer 6 of the higher area and to terminate in the lower cortex's layer 1, where they excite apical dendrites of layer 5 pyramidal cells, whose axons send collaterals into layer 6. Several other routes through which feedback can pass into V1 layer 6 exist. Having arrived in layer 6, the feedback is then "folded" back up into the feedforward stream by passing through the $6 \rightarrow 4$ on-center off-surround path. *c*, Connecting the $6 \rightarrow 4$ on-center off-surround to the layer 2/3 grouping circuit: like-oriented layer 4 simple cells with opposite contrast polarities compete (not shown) before generating half-wave rectified outputs that converge onto layer 2/3 complex cells in the column above them. Groupings that form in layer 2/3 enhance their own positions in layer 4 via the $6 \rightarrow 4$ on-center and suppress other groupings via the $6 \rightarrow 4$ off-surround. There exist direct layer 2/3 \rightarrow 6 connections in macaque V1, as well as indirect routes via layer 5. *d*, Top-down corticogeniculate feedback from V1 layer 6 to LGN also has an on-center off-surround anatomy similar to that of the $6 \rightarrow 4$ path. The on-center feedback selectively enhances LGN cells that are consistent with the activation that they cause, and the off-surround contributes to length-sensitive (endstopped) responses that facilitate grouping perpendicular to line ends. *e*, The model V1/V2 circuit: V2 repeats the laminar pattern of V1 circuitry on a larger spatial scale; notably, the horizontal layer 2/3 connections have a longer range in V2. V1 layer 2/3 projects to V2 layers 6 and 4, just as LGN projects to layers 6 and 4 of V1. Higher cortical areas send feedback into V2 which ultimately reaches layer 6, just as V2 feedback acts on layer 6 of V1. Feedback paths from higher cortical areas straight into V1 (not shown) can complement and enhance feedback from V2 into V1. (Reprinted with permission from Grossberg and Raizada, 2000.)

Figure 110.4*B* illustrates how the modulatory layer 6-to-4 circuit can also be used by top-down signals from V2 layer 6 to attentionally modulate the excitability of V1 layer 4 cells while inhibiting layer 4 cells that are not in the attentional focus.

Boundary completion that obeys a bipole property occurs as illustrated in Figure 110.4*C*. Layer 4 cells activate layer 2/3 cells, which communicate with their layer 2/3 neighbors via long-range horizontal excitatory connections and shorter-range inhibitory interneurons. The strengths of these excitatory and inhibitory interactions are approximately balanced. This balance also contributes to stable cortical development. Activation of a single layer 2/3 cell causes its horizontal excitatory and inhibitory connections to be approximately equally activated. The inhibition cancels the excitation, so a boundary cannot shoot out from individual scenic inducers. When two or more (approximately) like-oriented and (approximately) colinear layer 2/3 cells are activated, the excitation that converges on cells in between can summate, but the inhibitory interneurons form a recurrent inhibitory net that normalizes its total activity. As a result, total excitation exceeds total inhibition, and the cells can fire. A boundary can thereby be completed inwardly, but not outwardly.

If a scene has unambiguous groupings, then this horizontal interaction can rapidly complete boundaries (cf. Thorpe et al., 1996). In response to scenes with multiple possible groupings, competitive interactions in layers 2/3 and 4 can keep the layer 2/3 activities small, while positive feedback signals between layers $2/3 \rightarrow 6 \rightarrow 4 \rightarrow 2/3$ (Fig. 110.4*C*) have a chance to selectively amplify the strongest grouping, which can then generate outputs from layer 2/3, as its strong layer 6-to-4 off-surround signals inhibit weaker groupings. The layer 6-to-4 circuit thus has at least three functions: it contrast-normalizes bottom-up inputs, selects groupings via intracortical feedback from layer 2/3, and primes attention via intercortical feedback from higher cortical levels.

This intimate connection between grouping and attention enables attention to flow along a grouping and thereby selectively enhance an entire object, as Roelfsema et al. (1998) have shown in macaque V1. Because attention acts through an on-center off-surround circuit, it can “protect” feature detectors from inhibition by distractors by using its off-surround, as Reynolds et al. (1999) have shown in V2 and V4. Because both cooperation and competition influence groupings, the effects of colinear inducers can be either facilitatory or suppressive at different contrasts, as Polat et al. (1998) have shown in V1. Grossberg and Raizada (2000) and Raizada and Grossberg (2001) have quantitatively simulated these and related neurophysiological data.

A top-down on-center off-surround from V1 layer 6 to the LGN (Fig. 110.4*D*) can act in much the same way as the top-down signals from V2 layer 6 to V1, as Sillito et al.

(1994) have shown. Figure 110.4*E* synthesizes these circuits into a system architecture, which shows that the horizontal interactions within V2 layer 2/3 can have a broader spatial extent than those in V1 layer 2/3. The V2 interactions carry out perceptual groupings like illusory contours, texture grouping, completion of occluded objects, and bridging the blind spot. The V1 interactions improve the signal-to-noise ratio of feature detectors within the V1 cortical map.

The LAMINART model has been extended to clarify how depthful boundaries are formed (Grossberg and Howe, 2003) and how slanted surfaces are perceived in 3D (Swaminathan and Grossberg, 2001). This generalization is consistent with laminar anatomical and neurophysiological data. For example, suppose that a scenic feature activates monocular simple cells in layer 4 via the left and right eyes. These simple cells are sensitive to the same contrast polarity and orientation. Because they are activated by different eyes, they are positionally displaced with respect to one another on their respective retinas. These monocular simple cells activate disparity-selective binocular simple cells in layer 3B. Binocular simple cells that are sensitive to the same disparity but to opposite contrast polarities then activate complex cells in layer 2/3A. This two-stage process enables the cortex to match features binocularly with the same contrast polarity, yet also to form boundaries around objects in front of textured backgrounds, as in Figures 110.2*B* and 110.2*C*.

3D vision and figure-ground separation

How are depthful boundary and surface representations formed? How are percepts of occluding and occluded objects represented in depth? Multiple problems need to be solved to understand how boundaries and surfaces work together during 3D vision and figure-ground perception. The rest of this section summarizes some of these problems. Then model mechanisms that embody a proposed solution for all these problems will be summarized, as well as a simulation example of how the model works.

THREE-DIMENSIONAL SURFACE CAPTURE AND FILLING-IN

How are the luminance and color signals that are received by the two eyes transformed into 3D surface percepts? FACADE theory posits that multiple depth-selective boundary representations exist and interact with multiple depth-selective surface FIDOS to determine which surfaces in depth can be seen. The same filling-in processes which enable us to see perceptual qualities like brightness and color are predicted to also determine the relative depth of these surfaces. In particular, depth-selective boundaries selectively *capture* brightness and color signals at the subset of FIDOS that support depthful visual percepts. Such a viewpoint predicts that perceived depth and brightness

can interact. In fact, brighter surfaces can look closer (Egusa, 1983).

BINOCULAR FUSION, GROUPING, AND DA VINCI STEREOPSIS
 Granted that surface capture can achieve depth-selective filling-in, how are the depth-selective boundaries formed that control surface capture? Our two eyes view the world from slightly different perspectives. Their different views lead to relative displacements, or disparities, on their retinas of the images that they register. These disparate retinal images are binocularly matched at disparity-sensitive cells, as noted above. The disparity-sensitive cells are used to form depth-selective boundaries, which capture surface filling-in signals at the corresponding depth-selective FIDOs.

When two eyes view the world, part of a scene may be seen by only one eye. No disparity signals are available here to determine the depth of the monocularly viewed features, yet they are seen at the correct depth (Nakayama and Shimojo, 1990). FACADE theory proposes how depth-selective filling-in of a nearby binocularly viewed region spreads into the monocularly viewed region to impart the correct depth. This proposal also explains related phenomena like the *equidistance tendency*, whereby a monocularly viewed object in a binocular scene seems to lie at the same depth as the retinally most contiguous binocularly viewed object (Gogel, 1965). How this works leads to a number of new hypotheses, including how horizontal and monocularly viewed boundaries are added to all boundary representations and how an “asymmetry between near and far” distributes boundaries from nearer to farther surface representations. Without these mechanisms, all occluding objects would look transparent.

MULTIPLE SCALES INTO MULTIPLE BOUNDARY DEPTHS
 When a single eye views the image of an object in depth, the same size of the retinal image may be due to either a large object far away or a small object nearby. How is this ambiguity overcome to activate the correct disparity-sensitive cells? The brain uses multiple receptive field sizes, or scales, that achieve a *size-disparity correlation* between retinal size and binocular disparity. It has often been thought that larger scales code nearer objects and smaller scales more distant objects. For example, a nearer object can lead to a larger disparity that can be binocularly fused by a larger scale. In fact, each scale can fuse multiple disparities, although larger scales can fuse a wider range of disparities (Julesz and Schumer, 1981). This ambiguity helps to explain how higher spatial frequencies in an image can sometimes look closer, rather than more distant, than lower spatial frequencies in an image and how this percept can reverse during prolonged viewing (Brown and Weisstein, 1988). FACADE theory explains these reversals by analyzing how

multiple spatial scales interact to form depth-selective boundary groupings (Grossberg, 1994).

Multiple spatial scales also help to explain how shaded surfaces are seen. In fact, if boundaries were sensitive only to the bounding edge of a shaded surface, then shaded surfaces would look uniformly bright and flat after filling-in occurs, as in the background of Figure 110.3C. However, boundaries respond to shading gradients as well as to edges. Different scales react differently to different regions of the shading gradients, leading to a multiple-depth *boundary web* of small boundary compartments. Such a boundary web traps contrasts locally and leads to a shaded surface percept.

RECOGNIZING OBJECTS VERSUS SEEING THEIR UNOCCLUDED PARTS
 In many scenes, some objects lie partially in front of other objects and thereby occlude them. How do we know which features belong to the different objects, both in 3D scenes and in two-dimensional (2D) pictures? If we could not make this distinction, object recognition would be severely impaired. FACADE theory predicts how the mechanisms which solve this problem when we view 3D scenes also solve the problem when we view 2D pictures.

In the Bregman–Kanizsa image of Figure 110.5, the gray B shapes can be readily recognized even though they are partially occluded by the black snake-like occluder. In Figure 110.5B, the occluder is removed. Although the same amount of gray is shown in both images, the B shapes are harder to recognize in Figure 110.5B. This happens because the boundaries that are shared by the black occluder and the gray B shapes in Figure 110.5A are assigned by the brain to the black occluder. These boundaries form within a boundary representation that codes a nearer distance to the viewer than the boundary representation of the gray shapes. With the shared boundaries removed from the gray B shapes, the B boundaries can be completed behind the positions of the black occluder by using the bipole property. These completed boundaries help to recognize the Bs at the farther

FIGURE 110.5. *a*, Uppercase gray B letters that are partially occluded by a black snake-like occluder. *b*, Same B shapes as in *a* except that the occluder is white and therefore merges with the remainder of the white background. (Adapted with permission from Nakayama et al., 1989.)

depth. In Figure 110.5*B*, the shared boundaries are not removed from the gray shapes, and they prevent the completion of the gray boundaries.

To actually do this, the brain needs to solve several problems. First, it needs to figure out how geometrical and contrast factors work together. In Figure 110.5*A*, for example, the T-junctions where the gray shapes intersect the black occluders seem to be a cue signaling that the black occluder looks closer than the gray shapes. However, if you imagine the black occluder gradually getting lighter until it matches the white background in Figure 110.5*B*, it is clear that when the occluder is light enough, the gray shapes will no longer appear behind the occluder. Thus, geometrical factors like T-junctions are not sufficient to cause figure-ground separation. They interact with contrast relationships within the scene too.

The brain also needs to figure out how to complete the B boundaries “behind” the occluder in response to a 2D picture. In particular, how do different spatial scales get differentially activated by a 2D picture as well as a 3D scene so that the occluding and occluded objects can be seen in depth? Moreover, if the B boundaries can be completed and thereby recognized, then why do we not *see* completely filled-in B shapes too, including in the regions behind the black occluder? This state of affairs clarifies that there is a design tension between properties needed to recognize opaque objects, including where they are occluded, and our ability to see only their unoccluded surfaces. Here again, *the asymmetry between near and far* plays a key role, as noted below.

FROM BOUNDARY-SURFACE COMPLEMENTARITY TO CONSISTENCY Such subtle data make one wonder about how the brain evolved to behave this way. FACADE theory predicts how simple mechanisms that realize a few new perceptual principles can explain figure-ground data when they interact together. One such principle is that boundary and surface computations are complementary. How, then, do we see a single percept wherein boundaries and surfaces are consistently joined? How does *complementarity* become *consistency*? FACADE theory proposes how consistency is achieved by a simple kind of feedback that occurs between the boundary and surface streams. Remarkably, this feedback also explains many properties of figure-ground percepts, including the Bregman–Kanizsa percept. The remainder of the chapter sketches some of these principles and mechanisms, followed by a simulation of the Bregman–Kanizsa percept.

Three-dimensional boundary and surface formation

Figure 110.6 is a macrocircuit of FACADE theory in its present form. Monocular processing of left-eye and right-eye inputs by the retina and LGN discounts the illuminant and

generates parallel signals to the BCS and FCS. These signals go to model cortical simple cells via pathways 1 in Figure 110.6 and to monocular FIDOs via pathways 2. Model simple cells have oriented receptive fields and come in multiple sizes. Simple cell outputs are binocularly combined at disparity-sensitive complex and complex endstopped (or hypercomplex) cells via pathways 3. Complex cells with larger receptive fields can binocularly fuse a broader range of disparities than can cells with smaller receptive fields, thereby achieving a size-disparity correlation. Competition across disparity at each position and among cells of a given size scale sharpens complex cell disparity tuning (Fahle and Westheimer, 1995). Spatial competition (endstopping) and orientational competition convert complex cell responses into spatially and orientationally sharper responses at hypercomplex cells.

How are responses from multiple receptive field *sizes* combined to generate boundary representations of relative *depths* from the observer? Hypercomplex cells activate bipole cells via pathway 4. The bipole cells carry out long-range grouping and boundary completion via horizontal connections that occur in layer 2/3 of area V2 interstripes. Bipole grouping collects outputs from hypercomplex cells of all sizes that are sensitive to a given depth range. The bipole cells then send excitatory feedback signals via pathways 5 back to all hypercomplex cells within the same depth range that represent the same position and orientation, and inhibitory feedback signals to hypercomplex cells at nearby positions and orientations (cf. layer 2/3-6-4 inhibition in Fig. 110.4*E*). The feedback groups cells of multiple *sizes* into a BCS representation, or copy, that is sensitive to a prescribed range of *depths*. Multiple BCS copies are formed, each corresponding to different (but possibly overlapping) depth ranges.

Bipole cells play a key role in figure-ground separation. Each bipole cell has an oriented receptive field with two branches (Fig. 110.7). Long-range excitatory bipole signals combines with shorter-range inhibitory signals to make the system sensitive to T-junctions (Fig. 110.7). In particular, horizontally oriented bipole cells that are located where the top of the T joins its stem receive excitatory inputs to both of their receptive field branches. Vertically oriented bipole cells that process the stem of the T where it joins the top receive excitatory support only in the one branch that is activated by the stem. Because of this excitatory imbalance, inhibition of the stem by the top can cause a gap in the stem boundary (Fig. 110.7), termed an *end-gap*. During filling-in, boundaries contain the filling-in process. Where end-gaps occur, brightness or color can flow out of a figural region. FACADE theory predicts that this escape of color or brightness via filling-in is a key step that initiates figure-ground separation (Grossberg, 1994, 1997; Grossberg and McLoughlin, 1997; Kelly and Grossberg, 2000). Figure 110.8 shows a simulation from Kelly and Grossberg (2000) which illustrates

end-gaps in response to the Bregman–Kanizsa image. End-gaps occur where the horizontal occluder touches the partially occluded B shape at both near (Fig. 110.8*A*) and far (Fig. 110.8*B*) depths.

How do multiple depth-selective BCS copies capture brightness and color signals within depth-selective FCS surface representations? This happens in at least two stages. The first stage of *monocular FIDO*s may exist in V2 thin stripes. Each monocular FIDO is broken into three pairs of opponent FIDOs (black/white, red/green, blue/yellow) that receive achromatic and chromatic signals from a single eye. A pair of monocular FIDOs, one for each eye, corresponds to each depth-selective BCS copy and receives its strongest boundary-gating signals from this BCS copy. Each monocular FIDO may also receive weaker boundary signals from BCS copies that represent depths close to that of its primary BCS copy. In this way, a finite set of FIDOs can represent a continuous change in perceived depth, much as three classes of retinal cones can be used to represent a continuum of perceived colors.

FIGURE 110.8. Binocular boundaries for monocular filling-in in response to a Bregman–Kanizsa image: (a) near depth and (b) far depth. Filled-in monocular FIDOs before boundary pruning occurs: (c) near depth and (d) far depth. (Reprinted with permission from Kelly and Grossberg, 2000.)

Surface capture is triggered when boundary-gating BCS signals interact with illuminant-discounted FCS signals. Pathways 2 in Figure 110.6 input discounted monocular FCS signals to *all* monocular FIDOs. Only some FIDOs will selectively fill-in these signals and thereby lift monocular FIDO signals into depth-selective surface representations for filling-in. The boundary signals along pathways 6 in Figure 110.6 determine which FIDOs will fill-in. These boundary signals selectively capture FCS inputs that are spatially coincident and orientationally aligned with them. Other FCS inputs are suppressed. These properties follow when double-opponent, boundary-gating, and filling-in processes interact. How this happens, and how it can explain data on binocular fusion and rivalry, among other percepts, are discussed in Grossberg (1987b).

Because these filled-in surfaces are activated by depth-selective BCS boundaries, they inherit the depths of their boundaries. Three-dimensional surfaces may thereby represent depth as well as brightness and color. This link between depth, brightness, and color helps to explain *proximity-luminance covariation*, or why brighter surfaces tend to look closer (e.g., Egusa, 1983).

Not every filling-in event can generate a visible surface. Because activity spreads until it hits a boundary, only sur-

faces that are surrounded by a *connected* BCS boundary are effectively filled-in. Otherwise, the spreading activity can dissipate across the FIDO. This property helps to explain data ranging from neon color spreading to how T-junctions influence 3D figure-ground perception (Grossberg, 1994). Figures 110.8C and 110.8D illustrate how filling-in occurs in response to the Bregman–Kanizsa boundaries of Figures 110.8A and 110.8B. The connected boundary surrounding the occluder can contain its filled-in activity, but activity spreads through the end-gaps of the B boundaries, thereby dissipating across space, at both near (Fig. 110.8C) and far (Fig. 110.8D) depths.

An analysis of how the BCS and FCS react to 3D images shows that too many boundary and surface fragments are formed as a result of the size-disparity correlation. This redundancy is clear in Figure 110.8. As noted above, larger scales can fuse a larger range of disparities than can smaller scales. How are the surface depths that we perceive selected from this range of possibilities across all scales? FACADE’s proposed answer to this question follows from its answer to the more fundamental question: how is perceptual *consistency* derived from boundary-surface *complementarity*? FACADE predicts how this may be achieved by feedback between the boundary and surface streams, which is predicted to occur no later than V2. This mutual feedback also helps to explain why blob and interblob cells share so many receptive field properties even though they carry out such different tasks. In particular, boundary cells, which summate inputs from both contrast polarities, can also be modulated by surface cells, which are sensitive to just one contrast polarity.

Boundary-surface consistency derives from a contrast-sensitive process that detects the contours of successfully filled-in regions within the monocular FIDOs. Only successfully filled-in regions *can* activate such a contour-sensitive process, because other regions either do not fill-in at all or their filling-in dissipates across space. These filled-in contours activate FCS-to-BCS feedback signals (pathways 7 in Fig. 110.5) that strengthen boundaries at their own positions and depths while inhibiting redundant boundaries at farther depths. This inhibition from near to far is called *boundary pruning*. It illustrates a perceptual principle called *asymmetry between near and far*. This principle is reflected in many phenomena, including 3D neon color spreading (Nakayama et al., 1990). Grossberg (1994, 1999a) discusses how to explain such data.

How does boundary pruning influence figure-ground separation? Boundary pruning spares the closest surface representation that successfully fills-in a region and inhibits redundant copies of occluding object boundaries that would otherwise form at farther depths. When these redundant occluding boundaries are removed, the boundaries of partially occluded objects can be completed behind them within

FIGURE 110.9. Amodal boundary and surface representations in response to a Bregman–Kanizsa image. Binocular boundaries after boundary pruning occurs: (a) near depth and (b) far depth. Filled-in amodal surface representations at the monocular FIDOs: (c) near depth and (d) far depth. (Reprinted with permission from Kelly and Grossberg, 2000.)

BCS copies that represent farther depths, as we perceive from Figure 110.5A but not 110.5B. Moreover, when the redundant occluding boundaries collapse, the redundant surfaces that they momentarily supported at the monocular FIDOs also collapse. Occluding surfaces thereby form in front of occluded surfaces.

Figures 110.9A and 110.9B illustrate boundary pruning and its asymmetric action from near to far. The near boundaries in Figure 110.8A are retained in Figure 110.9A, but the far boundary of the occluder in Figure 110.8B is inhibited by boundary pruning signals from the contour of the near filled-in surface representation in Figure 110.8C. When these occluder boundaries are eliminated, the B boundary can be colinearly completed, as in Figure 110.9B. Because the boundaries of both the horizontal occluder and the B are now connected, they can contain their filled-in activities within the monocular FIDOs, as shown in Figures 110.9C and 110.9D.

Boundary pruning also helps to explain data about depth/brightness interactions, such as: why do brighter Kanizsa squares look closer (Bradley and Dumais, 1984)? Why is boundary pruning relevant here? A Kanizsa square’s brightness is an emergent property that is determined after *all* brightness and darkness inducers fill-in within the square. This emergent brightness within the FIDOs then influences the square’s perceived depth. Within FACADE, this means

that the FIDO’s brightness influences the BCS copies that control relative depth. This occurs via the BCS-to-FCS feedback signals, including pruning, that ensure boundary-surface consistency (Grossberg, 1997, Section 22).

Visible brightness percepts are not represented within the monocular FIDOs. Model V2 representations of binocular boundaries and monocular filled-in surfaces are predicted to be *amodal*, or perceptually invisible. These representations are predicted to directly activate object recognition mechanisms in inferotemporal cortex and beyond, since they accurately represent occluding and occluded objects. In particular, boundary pruning enables boundaries of occluded objects to be completed within the BCS, which makes them easier to recognize, as is illustrated for the Bregman–Kanizsa display in Figure 110.9. The monocular FIDO surface representations fill-in an occluded object within these completed object boundaries, even behind an opaque occluding object. We can thereby *know* the color of occluded regions without *seeing* them. How, then, do we *see* opaque occluding surfaces? How does the visual cortex generate representations of occluding and occluded objects that can be easily recognized, yet also allow us to consciously see, and reach for, only the unoccluded parts of objects?

FACADE theory proposes that the latter goal is achieved at the binocular FIDOs using a different combination of boundary and surface representations than is found at the monocular FIDOs. The surface representations at the monocular FIDOs are depth-selective, but they do not combine brightness and color signals from both eyes. Binocular combination of brightness and color signals takes place at the binocular FIDOs, which are predicted to exist in cortical area V4. It is here that *modal*, or visible, surface representations occur, and we see only unoccluded parts of occluded objects, except when transparent percepts are generated by special circumstances.

To accomplish binocular surface matching, monocular FCS signals from both eyes (pathways 8 in Fig. 110.6) are binocularly matched at the binocular FIDOs. These matched signals are redundantly represented on multiple FIDOs. The redundant binocular signals are pruned by inhibitory contrast-sensitive signals from the monocular FIDOs (pathways 9 in Fig. 110.6). As in the case of boundary pruning, these *surface pruning* signals arise from surface regions that successfully fill-in within the monocular FIDOs. These signals inhibit the FCS signals at their own positions and farther depths. As a result, occluding objects cannot redundantly fill-in surface representations at multiple depths. Surface pruning is another example of the asymmetry between near and far. Figure 110.10 illustrates how surface pruning works for the Bregman–Kanizsa image. Figure 110.10A shows the signals that initiate filling-in at the near binocular FIDO, and Figure 110.10B shows them at the far

binocular FIDO. Surface pruning eliminates signals from the occluder in Figure 110.10B.

As in the monocular FIDOs, FCS signals to the binocular FIDOs can initiate filling-in only where they are spatially coincident and orientationally aligned with BCS boundaries. BCS-to-FCS pathways 10 in Figure 110.6 carry out depth-selective surface capture of the binocularly matched FCS signals that survive surface pruning. In all, binocular FIDOs fill in FCS signals that (1) survive within-depth binocular FCS matching and across-depth FCS inhibition; (2) are spatially coincident and orientationally aligned with BCS boundaries; and (3) are surrounded by a connected boundary (web).

One further property completes this summary: at the binocular FIDOs, nearer boundaries are added to FIDOs that represent their own and farther depths. This asymmetry

between near and far is called *boundary enrichment*. Enriched boundaries prevent occluding objects from looking transparent by blocking filling-in of occluded objects behind them. The total filled-in surface representation across all binocular FIDOs represents the visible percept. It is called a FACADE representation because it multiplexes the properties of Form-And-Color-And-DEpth that give this theory its name. Figures 110.10C and 110.10D show the enriched near and far binocular FIDO boundaries, respectively, for the Bregman–Kanizsa image. Note the superposition of occluder and occluding boundaries in Figure 110.10D. Figures 110.10E and 110.10F show the filled-in near and far modal surface representations that the surface signals in Figures 110.10A and 110.10B cause within the boundaries of Figures 110.10C and 110.10D. Note that only the unoccluded surface of the B is “visible” in the binocular FIDO representation, even though the entire B surface is completed within the amodal monocular FIDO representation in Figure 110.9D.

Conclusion

This chapter describes some of the complementary properties of boundary and surface computations in the interblob and blob cortical processing streams of visual cortex. These insights lead to a revision of classical views about how visual cortex works. In particular, visual cortex does not consist of independent processing modules. Rather, hierarchical and parallel interactions between the boundary and surface streams synthesize consistent visual percepts from their complementary strengths and weaknesses. Boundaries help to trigger depth-selective surface filling-in, and successfully filled-in surfaces reorganize the global patterning of boundary and surface signals via feedforward and feedback signals. Boundary-gated filling-in plays a key role in surface perception, ranging from lower-level uses, such as recovering surface brightness and color after discounting the illuminant and filling-in the blind spot, to higher-level uses, such as completing depthful modal and amodal surface representations during 3D vision and figure-ground separation. Nor is visual cortex a feedforward filter that passively detects visual features. Rather, it is an integrated system of bottom-up, top-down, and horizontal interactions which actively completes boundary groupings and fills-in surface representations as its emergent functional units. This interactive perspective has enabled recent neural models to simulate quantitatively the dynamics of individual cortical cells in laminar cortical circuits and visual percepts that emerge from their circuit interactions.

How the Visual Cortex Recognizes Objects: The Tale of the Standard Model

MAXIMILIAN RIESENHUBER AND TOMASO POGGIO

OBJECT RECOGNITION is fundamental to the behavior of higher primates. It is also the most remarkable achievement of visual cortex and one that probably influences greatly its overall functional architecture.

Object recognition is a computationally hard problem. The visual system rapidly and effortlessly recognizes a large number of diverse objects in cluttered natural scenes. Computer vision systems are still far from passing the Turing test for vision, that is to “see” as well as human beings do. Very recent work in computer vision, however, has achieved impressive results on specific tasks such as object detection/categorization and face identification, suggesting that the problem is solvable with well-understood modern statistical learning algorithms.

The problem of object recognition is even more difficult from the point of view of neuroscience since it involves several levels of understanding, from the information processing or computational level to the level of circuits and of cellular and biophysical mechanisms. After decades of work in striate and extrastriate areas that have produced a significant and rapidly increasing amount of data, the emerging picture of how cortex performs object recognition may be becoming too complex for physiologists (as David Hilbert famously said about quantum mechanics: “Physics is too difficult for physicists”). Now, paralleling the very recent developments in bioinformatics, computational approaches may be riding to the rescue.

In this chapter, we attempt to take a first step. We review progress in the field. We do so by using a computational model as a tool to summarize, organize, and interpret existing data and discuss open questions. We first sketch the basic facts that have been established during the past three decades and that are now broadly accepted. We then describe a Standard Model that emerges from the data and represents in its basic architecture the average belief—often implicit—of many visual physiologists. In this sense, it is definitely not our model. The broad form of the model is suggested by the basic facts; we have made it quantitative and thereby predictive (through computer simulations). From the precise perspective it provides, we will discuss recent data, new experiments, and important open questions. We will also discuss specific alternative hypotheses

about modules and mechanisms of the model, as well as evidence that may possibly falsify the whole class of interpretations associated with the Standard Model.

Basic facts

Object recognition in cortex is thought to be mediated by the ventral visual pathway (Ungerleider and Haxby, 1994) running from primary visual cortex, V1, over extrastriate visual areas V2 and V4, to inferotemporal cortex IT. Based on physiological experiments in monkeys, IT has been postulated to play a central role in object recognition. IT, in turn, is a major source of input to prefrontal cortex (PFC), “the center of cognitive control” (Miller, 2000) involved in linking perception to memory.

Over the past decade, several physiological studies in non-human primates have established a core of basic facts about cortical mechanisms of recognition that seem to be widely accepted and that confirm and refine older data from neuropsychology. A brief summary of this consensus knowledge begins with the groundbreaking work of Hubel and Wiesel first in the cat (1962, 1965) and then in the macaque (1968). Starting from *simple cells* in primary visual cortex, V1, with small receptive fields that respond preferably to oriented bars, neurons along the ventral stream (Logothetis and Sheinberg, 1996; Perrett and Oram, 1993; Tanaka, 1996) show an increase in receptive field size as well as in the complexity of their preferred stimuli (Kobatake and Tanaka, 1994). At the top of the ventral stream, in anterior inferotemporal cortex (AIT), cells are tuned to complex stimuli such as faces (Desimone, 1991; Desimone et al., 1984; Gross et al., 1972; Perrett et al., 1992). The tuning of the view-tuned and object-tuned cells in AIT depends on visual experience as shown by Logothetis et al. (1995) and supported by Booth and Rolls (1998), DiCarlo and Maunsell (2000), and Kobatake et al. (1998). A hallmark of these IT cells is the robustness of their firing to stimulus transformations such as scale and position changes (Logothetis et al., 1995; Logothetis and Sheinberg, 1996; Perrett and Oram, 1993; Tanaka, 1996). In addition, as other studies have shown (Booth and Rolls, 1998; Hietanen et al., 1992; Logothetis et al., 1995; Perrett and Oram, 1993), most

FIGURE 111.1. The figure shows the first part of the Standard Model. It extends several recent models (see especially Fukushima, 1980; see also Perrett and Oram, 1993; Poggio and Edelman, 1990; Riesenhuber and Poggio, 1999b; Wallis and Rolls, 1997). The view-based module, HMAX, shown here is an hierarchical extension of the classical paradigm (Hubel and Wiesel, 1962) of building complex cells from simple cells. The circuitry consists of a hierarchy of layers leading to greater specificity and greater invariance by using two different types of pooling mechanisms. The first layer in V1 represents linear oriented filters followed by input normalization, similar to simple cells (Carandini et al., 1997); each unit in the next layer (C1) pools the outputs of simple cells with the same orientation but at slightly different positions (scales) by using a maximum operation (see text and Riesenhuber and Poggio, 1999b). Each of these units is still orientation selective but more invariant to position (scale), similar to some complex cells. In the next stage, signals from complex cells with different orientations but similar positions are combined (in a weighted sum) to create neurons tuned to a dictionary of more complex features. The next layer (C2) is

similar to the C1 cells: by pooling together signals from S2 cells of the same type but at slightly different positions (and scales), the C2 units become more invariant to position (and scale) but preserve feature selectivity. They may correspond roughly to V4 cells. In the model, the C2 cells feed into view-tuned cells, with connection weights that are learned from exposure to a view of an object. There may be more levels in the hierarchy than are shown in the figure after the C2 layer. The output of the view-based module is represented by view-tuned model units that exhibit tight tuning to rotation in depth (as well as illumination and other object-dependent transformations such as facial expression) but are tolerant to scaling and translation of their preferred object view. Notice that the cells labeled here as view-tuned units encompass, between PIT and AIT, a spectrum of tuning from full views to components or complex features: depending on the synaptic weights determined during learning, each view-tuned cell becomes effectively connected to all or only a few of the units activated by the object view (Riesenhuber and Poggio, 1999a).

neurons show specificity for a certain object view or lighting condition. In particular, Logothetis et al. (1995) trained monkeys to perform an object recognition task with isolated views of novel three-dimensional objects ("paper clips"; see the objects at the top of Fig. 111.1). When recording from the animals' IT, they found that the great majority of neurons selectively tuned to the training objects were view-tuned (with a half-width of about 20 degrees for rotation in depth) to one of the training objects [about one-tenth of the tuned neurons were view-invariant, in agreement with earlier predictions (Poggio and Edelman, 1990)], but an average translation invariance of 4 degrees (for typical stimulus sizes of 2 degrees) and an average scale invariance of 2 octaves (Riesenhuber and Poggio, 1999b). Thus, whereas view-

invariant recognition requires visual experience of the specific novel object, position and scale invariance seems to be immediately present in the view-tuned neurons (Logothetis et al., 1995) without the need of visual experience for views of the specific object at different positions and scales. A very recent study (DiCarlo and Maunsell, 2003)—using different stimuli and training paradigm—reports translation invariance from one view of less than 3 degrees, pointing to a possible influence of training history and object shape on invariance ranges. Recent functional magnetic resonance imaging (fMRI) data have shown a similar pattern for the lateral occipital cortex (LOC), a brain region in human visual cortex central to object recognition and believed to be the homolog of monkey area IT (Grill-Spector et al., 2001;

Malach et al., 1995; Tanaka, 1997). Optical recordings in monkeys confirmed the view dependency of several face-tuned neurons (Wang et al., 1996).

A comment about the architecture is important: in its basic initial operation—akin to *immediate recognition*—the hierarchy is likely to be mainly feedforward (though local feedback loops almost certainly have key roles, e.g., possibly in performing a maximum-like pooling; see later) (Perrett and Oram, 1993). Event-related potential data (Thorpe et al., 1996) have shown that the process of object recognition appears to take remarkably little time, on the order of the latency of the ventral visual stream (Perrett et al., 1992), adding to earlier psychophysical studies using a rapid serial visual presentation (RSVP) paradigm (Intraub, 1981; Potter, 1975) that have found that subjects were still able to process images when they were presented as rapidly as eight per second.

In summary, the accumulated evidence points to six mostly accepted properties of the ventral stream architecture:

1. A hierarchical buildup of invariances first to position and scale and then to viewpoint and more complex transformations requiring the interpolation between several different object views
2. In parallel, an increasing size of the receptive fields
3. An increasing complexity of the optimal stimuli for the neurons
4. A basic feedforward processing of information (for “immediate” recognition tasks)
5. Plasticity and learning probably at all stages and certainly at the level of IT
6. Learning specific to an individual object is not required for scale and position invariance (over a restricted range)

The Standard Model

Invariance properties of IT neurons with respect to different transformations can be understood from a computational perspective (Riesenhuber and Poggio, 2000b): mathematically, the effects of two-dimensional (2D) affine transformations, such as scaling and translation in the image plane, can be estimated exactly from just one object view. There is no need then to, for example, collect examples of one object at all positions in the image to be able to generalize across positions from a single view. To determine the behavior of a specific object under transformations that depend on its three-dimensional (3D) shape, such as illumination changes or rotation in depth, however, one view generally is not sufficient. Unlike affine 2D transformations, 3D rotations, as well as illumination changes, usually require multiple example views during learning. Mathematically, the space of the orthographic views of one object is spanned by a single view for affine 2D transformations and by two or

more for affine 3D transformations (Poggio, 1990; Ullman and Basri, 1991).

The basic facts summarized earlier, together with the above computational considerations, lead to a Standard Model likely to represent the simplest class of models reflecting the known anatomical and biological constraints.

The model reflects the general organization of visual cortex in a series of layers from V1 to IT to PFC. From the point of view of invariance properties, it consists of a sequence of two main modules based on two key ideas. The first module, shown schematically in Figure 111.1, leads to model units showing the same scale and position invariance properties as the view-tuned IT neurons of Logothetis et al. (1995) using the same stimuli (Fig. 111.3). This is not an independent prediction since the model parameters were chosen to fit Logothetis’ data. It is, however, not obvious that an hierarchical architecture using plausible neural mechanisms could account for the measured invariance *and* selectivity. Computationally, this is accomplished by a scheme that can be best explained by taking striate complex cells as an example: invariance to changes in the position of an optimal stimulus (within a range) is obtained in the model by means of a *maximum operation (max)* performed on the simple cell inputs to the complex cells, where the strongest input determines the cell’s output. Simple cell afferents to a complex cell are assumed to have the same preferred orientation with their receptive fields located at different positions. Taking the maximum over the simple cell afferent inputs provides position invariance while preserving feature specificity. The key idea is that the step of filtering followed by a max operation is equivalent to a powerful signal processing technique: select the peak of the correlation between the signal and a given matched filter, where the correlation is either over position or over scale. The model alternates layers of units combining simple filters into more complex ones—to increase pattern selectivity—with layers based on the max operation—to build invariance to position and scale while preserving pattern selectivity.

In the second part of the architecture, shown in Figure 111.2, learning from multiple examples, that is, different view-tuned neurons, leads to view-invariant units as well as to neural circuits performing specific tasks. The key idea here is that interpolation and generalization can be obtained by simple networks, similar to Gaussian Radial Basis Function networks (GRBF) (Poggio and Girosi, 1990), that learn from a set of examples, that is, input-output pairs. In this case, the inputs are views and the outputs are the parameters of interest such as the label of the object or its pose or expression (for a face). The GRBF network has a hidden unit for each example view, broadly tuned to the features of an example image (see also opde Beeck et al., 2001). The weights from the hidden units to the output are learned from the set of examples, that is, input-output pairs. In principle,

FIGURE 111.2. The figure shows the overall architecture of the Standard Model. The view-tuned module, described in Figure 111.1, is shown here in the inset (up to the C2 layer). The second part of the model starts with the view-tuned cells which represent the output of the view-based module. Invariance to rotation in depth is obtained by combining in a learning module several view-tuned units V_n tuned to different views of the same object (Poggio and Edelman, 1990), creating view-invariant (object-tuned) units O_n . These, as well as the view-tuned units, can then serve as input to task modules that learn to perform different visual tasks such as identification/discrimination or object categorization. They consist

of the same generic learning circuitry (similar to an RBF network; see text) but are trained with appropriate sets of examples to perform specific tasks. In addition to the feedforward processing, there are likely feedback pathways (not shown) for top-down modulation of neuronal responses throughout the processing hierarchy and to support the learning phase. The stages up to the object-centered units probably encompass V1 to anterior IT (AIT). The last stage of task-dependent modules may be localized in AIT or PFC. All the units in the model represent single cells modeled as simplified neurons with modifiable synapses. (Modified from Riesenhuber and Poggio, 2000b.)

two networks sharing the same hidden units but with different weights (from the hidden units to the output unit) could be trained to perform different tasks, such as pose estimation or view-invariant recognition. Depending just on the set of training examples, learning networks of this type can learn to categorize across exemplars of a class (Riesenhuber and Poggio, 1999c), as well as to identify an object across different illuminations and different viewpoints. The demonstration (Poggio and Edelman, 1990) that a view-based GRBF model could achieve view-invariant object recognition in fact-motivated psychophysical experiments (Bülthoff and Edelman, 1992; Gauthier and Tarr, 1997). In turn, the psychophysics provided strong support for the view-based hypothesis against alternative theories (for a review, see Tarr and Bülthoff, 1998) and, together with the model, triggered the physiological work of Logothetis et al. (1995).

Thus the two key ideas in the model are (1) the max operation to provide invariance at several steps of the hierarchy and (2) the RBF-like learning network to learn a specific task based on a set of cells tuned to example views.

Interpreting experimental data

The Standard Model summarizing the basic facts about the ventral pathways predicts additional experimental results

and provides interesting perspectives on still other data. For instance, the model accounts (see Riesenhuber and Poggio, 1999a, 1999c, 2000b) for the response of tuned IT cells to scrambled objects (Vogels, 1999) (see Fig. 5 in Riesenhuber and Poggio, 1999b), clutter (Missal et al., 1997) (Fig. 111.4), and mirror views (Logothetis and Sheinberg, 1996) (see Fig. 4 in Riesenhuber and Poggio, 1999b). It also shows a degree of performance roughly in agreement with physiological and psychophysical data in specific tasks (the same stimuli are used for simulations and experiments) such as the cat versus dog categorization task described by Freedman et al. (2001a) (Fig. 111.6), object identification (in separate experiments faces, cars, paper clips were used; see Figs. 111.5 and 111.7), gender classification, and possibly the face habituation effect of (Leopold et al., 2001).

A key function of models is to clarify key issues. Here we use the Standard Model to discuss several central topics concerning the neural mechanisms of object recognition.

SELECTIVITY Invariance is only one requirement for object recognition, the other one being selectivity. Several studies have established that IT neurons can become tuned to task-relevant objects and their full or partial (Vetter et al., 1995) views (DiCarlo and Maunsell, 2000; Kobatake et al., 1998; Logothetis et al., 1995) or to objects in the monkey's envi-

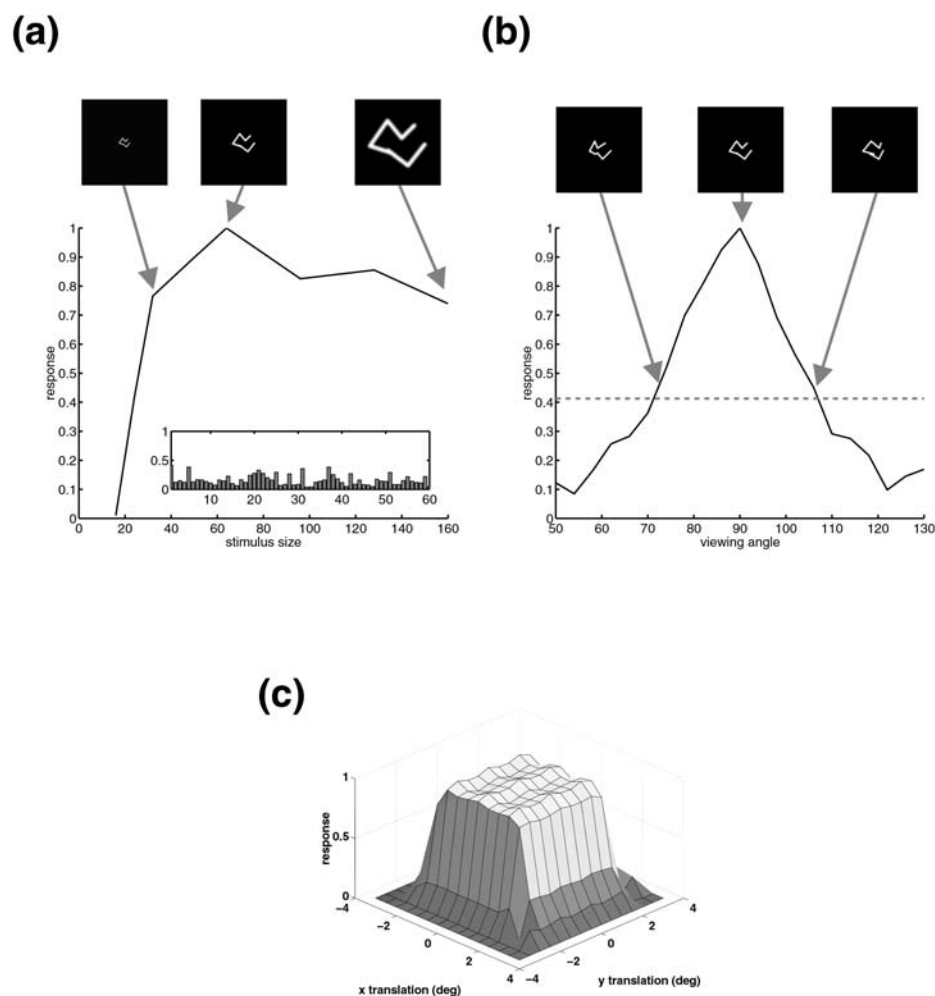

FIGURE 11.3. Responses of a sample model neuron to different transformations of its preferred stimulus. The different panels show the same neuron's response to (a) varying stimulus sizes [the inset shows the response to 60 distractor objects, selected randomly from the paper clips used in the physiology study (Logothetis et al.,

1995)], (b) experiments, rotation in depth, and (c) translation. The training size was 64×64 pixels corresponding to 2 degrees of visual angle. The simulation results shown here are in quantitative agreement with recordings in IT by Logothetis et al. (1995) (see Fig. 8 in that article), using the same stimuli.

ronment (Booth and Rolls, 1998), suggesting that these neurons provide a representation of objects occurring in an animal's environment. The preferred stimuli of neurons in intermediate stages of the ventral stream are less clear, partly owing to the difficulty of knowing which stimuli to use to probe the neural selectivity. Reports of preferred features of neurons in V4, the visual area preceding IT in the ventral pathway, vary, depending on the set of stimuli used to probe responses, including Cartesian gratings (Desimone and Schein, 1987) polar and hyperbolic sinusoidal gratings (Gallant et al., 1996), and contour features (Pasupathy and Connor, 1999). In V2, a recent study (Hegde and Van Essen, 2000) has reported preferences to complex stimuli such as arcs, intersecting lines, and non-Cartesian gratings. Instead of probing neuronal tuning with a fixed set of stimuli, a set of studies (Fujita et al., 1992; Kobatake and Tanaka, 1994; Tanaka, 1993, 1996) used a heuristic "simplification proce-

cedure" in an effort to arrive at the features crucial to activate a neuron. In this approach, a complex natural stimulus (such as a face) to which the neuron under study responds is progressively "simplified" (e.g., by removing color or texture or by reducing complex shapes to simpler geometric primitives) in a way that preserves or increases the neuronal firing. The stimulus that cannot be simplified further without significantly decreasing the firing rate is then labeled the *effective stimulus* for that cell. A study using this paradigm (Kobatake and Tanaka, 1994) has reported an increase in feature complexity from area V2 to anterior IT. However, a recent IT optical imaging study (Tsunoda et al., 2001), supported by single-cell recordings, demonstrates the fundamental difficulty of determining a neuron's preferred feature in higher visual areas. The authors report that simplifying a stimulus often causes additional IT neurons to respond relative to the more complex stimulus. Interestingly, the Standard Model

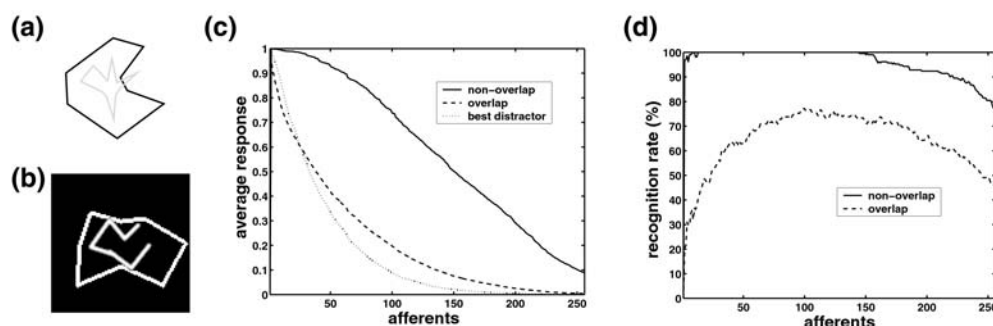

FIGURE 111.4. Recognition in clutter in the Standard Model. *a*, Example stimulus (light gray) and outline background (black) from the experiment by Missal et al. (1997) (redrawn from that source), in which a monkey was trained to recognize polygonal shapes in isolation and on a polygonal background. In the experiment, foreground and background stimuli were of different colors. The study found that while the monkeys' performance was only slightly impaired by the introduction of a background stimulus (from 98% to 89% correct), firing rates of IT neurons were affected much more strongly. *b*, Example stimulus for the corresponding experiment with the model, in which paper clip stimuli were superimposed on polygonal backgrounds (for details, see Riesenhuber and Poggio, 1999a). Unlike in the experiment (Missal et al., 1997), the stimuli and background were of the same color, increasing task difficulty. The foreground clip in *b* was correctly recognized by the corresponding model IT unit (which was the same as in Fig. 111.3).

does in fact predict qualitatively what is observed—neurons tuned to a dictionary of features at different levels of complexity. Moreover, preliminary simulations (Knoblich and Riesenhuber, 2002) suggest that for IT model units the effect of the simplification procedure may well lead to the observations of Tsunoda et al. (2001). In any case, it is important to emphasize that features are defined not only by the specific image but also by the system looking at it. A pattern that seems simple to us may activate more filters in a vision system looking at it than another stimulus that is apparently more complex, depending on the filters used by the system. Thus the Standard Model can provide specific hypotheses to guide experiments regarding how more complex features (and ultimately object-tuned cells) are built from simpler ones.

REPRESENTATION Related to the question of neuronal tuning is the question of the precise nature of object representation in cortex. It has recently been put forward, based on a set of human fMRI studies, that some object classes—faces (Kanwisher et al., 1997), places (Epstein and Kanwisher, 1998), body parts (Downing et al., 2001)—are processed by distinct modules in cortex. Interestingly, another fMRI study (Haxby et al., 2001) has shown that objects of a certain class (e.g., faces) evoke a distributed pattern of activity that is not confined to the aforementioned specialized modules [e.g., the fusiform face area (FFA), a brain area that is strongly activated by face stimuli

(Kanwisher et al., 1997)], and that the part of the activation pattern *outside* the specific module is sufficient for object categorization. Thus, some data appear to argue for a *modular* framework of object representation in cortex, where specific brain areas perform computations unique to the object class at hand, while others support a model in which the same computation is performed for different objects and represented in a distributed way. The latter claim is supported by the Standard Model, which also helps to reconcile the two sets of data. Model IT units have preferred C2 activation vectors that can be full or partial view of an object (Riesenhuber and Poggio, 1999a), depending on their connectivity. The distinction between *complex features* and *object* is largely semantic, since during training a cell can become tuned to a feature that is diagnostic for the object rather than to a full view (Pauls, 1997). What is relevant for object recognition is that the objects to be discriminated produce distinct activation patterns. From the point of view of the model, groups of neurons responding to representatives from the same object class do not have to be segregated but are expected to be interdigitated. Since the activity of one fMRI voxel is the average over typically hundreds of thousands of neurons,¹ strong activation of the FFA for faces would argue for a

(Kanwisher et al., 1997)], and that the part of the activation pattern *outside* the specific module is sufficient for object categorization. Thus, some data appear to argue for a *modular* framework of object representation in cortex, where specific brain areas perform computations unique to the object class at hand, while others support a model in which the same computation is performed for different objects and represented in a distributed way. The latter claim is supported by the Standard Model, which also helps to reconcile the two sets of data. Model IT units have preferred C2 activation vectors that can be full or partial view of an object (Riesenhuber and Poggio, 1999a), depending on their connectivity. The distinction between *complex features* and *object* is largely semantic, since during training a cell can become tuned to a feature that is diagnostic for the object rather than to a full view (Pauls, 1997). What is relevant for object recognition is that the objects to be discriminated produce distinct activation patterns. From the point of view of the model, groups of neurons responding to representatives from the same object class do not have to be segregated but are expected to be interdigitated. Since the activity of one fMRI voxel is the average over typically hundreds of thousands of neurons,¹ strong activation of the FFA for faces would argue for a

¹For cautionary notes about the interpretation of fMRI images see Logothetis et al. (2001).

FIGURE 111.5. Recognition of non-paper clip objects (morphed cars) in HMAX. *a*, The eight prototype cars spanning the car morph space (Riesenhuber and Poggio, 2000a). *b*, Recognition performance of the model on the eight car morph space for a discrimination task in which first a target car was shown from a viewpoint $\phi_0 = 225$ degrees. This car, presented at viewpoint ϕ (varying between 180 and 270 degrees), then had to be discriminated from a distractor car presented at the same viewpoint ϕ . The similarity of the target and distractor cars was controlled by varying the separation of their corresponding parameter vectors in morph space. In particular, the parameter vectors were chosen to lie on lines connecting two prototypes from *a*. The *x*-axis shows viewpoint ϕ of the nonmatch object, *y*-axis target/distractor morph distance d (in steps along the morph line that the sample object lies on, a distance of 10 corresponds to the easiest case of the two cars being

different prototypes), and *z*-axis model discrimination performance for all (ϕ, d) stimulus pairs in the sample set. Stimulus identity was represented by a population code over 16 “car neurons.” The two subplots show the same graph from two different viewpoints to show positive rotations (i.e., toward the front, so that the front of the car is turning toward the viewer, as used in the psychophysical experiments), left plot, and negative rotations (i.e., toward the back, so that the side of the car faces the viewer), right plot. Note that the invariance range for the class of car stimuli is comparable to the results obtained with the paper clip stimuli in psychophysics and modeling (Bülthoff and Edelman, 1992; Logothetis et al., 1994; Poggio and Edelman, 1990) (see Fig. 111.3), demonstrating the generality of the model (over different object classes and representations).

higher density of face neurons in that part of cortex, possibly reflecting the great cognitive importance of face neurons. However, subjects with great expertise for other object classes might show significant activation of parts of cortex for objects from their field of expertise. Indeed, in bird and car experts, brain areas, overlapping with but not limited to the FFA, have been found to be specifically activated by birds and cars, respectively (Gauthier et al., 2000).

Thus the Standard Model suggests the following object representation in cortex [for the appropriate computational simulations, see Riesenhuber and Poggio (1999c, 2000a)], a related proposal can be found in Edelman (1999). A particular object, say a specific face, will elicit different activity in the view-specific V_n and object-specific O_n cells of Figure 111.2 (an example of which is shown in Fig. 111.7). Thus, the memory of the particular face is represented in the identification circuit in an implicit way by a sparse population code through the activation pattern over the coarsely tuned V_n and O_n cells, generally without cells dedicated to repre-

sent individual objects (*grandmother cells*).² Discrimination, or memorization of specific objects, can then proceed by comparing activation patterns over the strongly activated object- or view-tuned units (Riesenhuber and Poggio, 2000a) tuned to a small number of “prototypical” faces (Young and Yamane, 1992). For a certain level of specificity, only the activations of a small number of units have to be stored, forming a sparse code—in contrast to activation patterns on lower levels, where units are less specific and hence activation patterns tend to involve more neurons. In a similar fashion, categorization neurons, located putatively in the PFC, can be trained (Riesenhuber and Poggio, 1999c) to receive input from relevant object-tuned units.

²For special cases in which a small, fixed number of objects had to be discriminated [as, for example, it Logothetis et al. (1995)], the representations found in the model during learning turned out to be more grandmother-like.

FIGURE 111.6. Example of categorization in the Standard Model. *a*, Illustration of the cat/dog stimulus space [used in the physiology experiments of Freedman et al. (2001a)]. The morph space is spanned by the pictures of three cats shown on top (“House Cat,” “Cheetah,” and “Tiger”) and the three dogs below (“House Dog,” “Doberman,” and “German Shepherd”). All prototypes have been normalized with respect to viewing angle, lighting parameters, size, and color. *b*, Response of a cat/dog categorization unit along the nine class boundary-crossing morph lines (*thin lines*). The unit receives input from 144 view-tuned units tuned to cat/dog training stimuli, as used in Freedman et al. (2001a), and was trained to respond differently to cats and dogs (cf. Fig. 111.7). The dashed line

shows the average over all morph lines. The solid horizontal line shows the class boundary in response space, and the dashed vertical line shows the category boundary in morph space the unit was trained on. The images on the bottom are taken from one morph line (from the House Cat to the Doberman) to illustrate the fine shape changes involved in categorization. All stimuli in the left half of the plot are “cats” and all stimuli in the right half are “dogs” (the class boundary is at the morph line center). The model unit correctly categorizes 94% of all stimuli [as good as the monkey trained on the same categorization task (Freedman et al., 2001a)], with errors occurring at the class boundary where categorization is most difficult (Riesenhuber and Poggio, 1999c).

FIGURE 111.7. Tuning of a model face unit. The unit is a view-tuned unit, as shown in Figure 111.2, tuned to the face shown in the lower left. The solid line shows how the unit's response changes as the stimulus is gradually morphed away from the preferred stimulus to another face (faces shown at lower edge of plot). The unit's response changes gradually with changes in the stimulus, permitting subordinate-level discrimination [especially when using a population code consisting of several units tuned to different representatives of the class (Riesenhuber and Poggio, 2000a)]. The

same unit also responds to animal stimuli [cf. Freedman et al. (2001a); responses shown by crosses], but at a lower level than to the faces, permitting a coarse categorization of a stimulus as an animal stimulus based on the face unit's firing (cf. Haxby et al., 2001). As for subordinate-level recognition, combining several such units in a sparse population code (Young and Yamane, 1992), improves recognition performance (Riesenhuber and Poggio, 1999c). [Faces and morphing software courtesy of Thomas Vetter (Blanz and Vetter, 1999).]

CATEGORIZATION AND IDENTIFICATION An object can be recognized at different levels—a face can be recognized as a face, but also more specifically as a “male face,” “Tommy Poggio’s face,” or “Tommy Poggio’s smiling face.” It has been common in cognitive science to assume that recognition of an object at different levels is based on different computational mechanisms (Murphy and Brownell, 1985; Tversky and Hemenway, 1984). In particular, it has been proposed that *subordinate-level* recognition (identification) is based on *configurational* judgments (i.e., based on the spatial arrangement of features), whereas *basic-level* categorization (a face? a dog? a car?) is based on a qualitative representation based on the presence or absence of features. However, as Figure 111.2 makes clear and as we pointed out earlier (Riesenhuber and Poggio, 2000b), all supervised recognition tasks—in which the subject is trained with labeled examples—are identical from a computational point of view: they all involve a classification based on positive and negative exemplars. Indeed, it is not clear why different computations should be required in recognizing a face on the subordinate level and in, for example, determining its gender. Rather, in the simple framework of the Standard Model, the same learning algorithm and architecture can support a variety of object recognition tasks. In particular, identification and categorization circuits (possibly located in PFC) should receive signals from the same or equivalent cells tuned to specific objects or prototypes (in IT). This prediction is supported by recent results from physiology (Opde Beeck et al., 2001), where different monkeys were trained on a discrimination and a categorization task on the same stimuli. Subsequent recordings from neurons in the animals’ IT revealed no systematic differences in the representation of stimuli in the different animals. Further support comes from combined IT and PFC recordings (Freedman et al., in press) of monkeys trained on a cat/dog categorization task (Freedman et al., 2001a), where PFC neurons showed stronger category tuning than IT neurons. Simulation results (Knoblich et al., 2002) suggest that the tuning properties of these IT neurons could in fact arise without any explicit category information during training. Recent human fMRI data which indicate that the FFA is involved not just in subordinate-level face recognition but also in face detection (Grill-Spector et al., 2001) also argue against a specialization of brain areas for recognition tasks such as subordinate-level recognition independent of object class.

The problem with many experiments investigating the relationship between categorization and identification which claim that there is a time advantage of basic-level recognition versus subordinate-level recognition (Jolicoeur et al., 1984; Rosch et al., 1976) is that the tasks used for the different recognition levels are of different difficulty: discriminating a face from a chair (in categorization) is a much easier task than discriminating the faces of the two authors (in

identification), as the latter two are more similar to each other. Assuming that physically similar stimuli produce similar neuronal activation patterns, and that the ability to discriminate between two stimuli requires a certain level of evidence, finer discrimination would require the accumulation of evidence (in the form of firing rate differences) over a longer time period than when the activation patterns are very different.

POOLING AND MAX MECHANISM A key component of hierarchical models of cortical processing, such as Fukushima’s and Hubel and Wiesel’s, is pooling of afferents with similar tuning to increase the neuronal response invariance of certain stimulus transformations. Our version of the Standard Model—the HMAX model of Figure 111.1—assumes that this pooling is done—at some but not all levels in cortical processing—by a *maximum-like operation* rather than by a linear sum.

Invariance for translation and scaling is achieved by pooling the responses from noninvariant neural detectors over multiple spatial positions or scales using a maximum-like operation. Pooling by a maximum operation, as opposed to linear summation, ensures that the invariant response is robust against background clutter and does not lose the selectivity for the original feature. In neural terms, the firing rate of a maximum circuit corresponds to the firing rate of the strongest input pooled over some set of synaptic inputs. The maximum operation can be realized with biologically plausible neural circuits.

It will be critical to evaluate whether there are sets of neurons along the ventral pathway that implement such an operation. The model predicts (Riesenhuber and Poggio, 1999b) that the first stage showing a maximum-operation is a subset of complex cells in V1. Preliminary data (Lampl et al., 2001), obtained by intracellular recordings in simple and complex cells, are encouraging.

Extensions of the Standard Model and open issues

The Standard Model can serve as a conceptual tool to guide experiments and as the integrative “glue” between single-cell physiology and behavior. It also incorporates a large body of experimental data into one coherent framework. However, this framework needs to be extended in a number of directions. For instance, it has to take into account top-down and bottom-up attentional effects (Itti and Koch, 2000), learning at most stages of the hierarchy (Riesenhuber and Poggio, 2000b), and recognition of moving objects (Giese and Poggio, 2003).

ATTENTION Attention permeates most natural object recognition tasks. Thus, all the issues discussed earlier have also to be addressed in the context of task dependency,

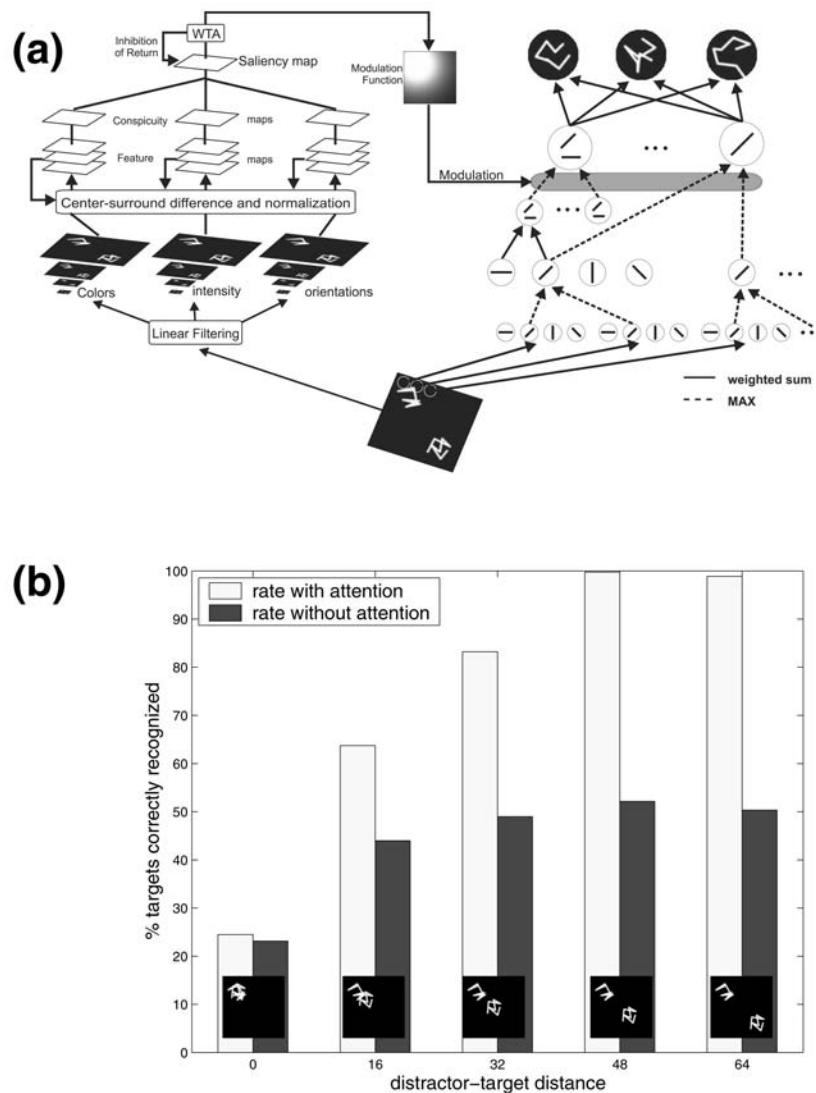

FIGURE 111.8. Coupling of the saliency map (Itti and Koch, 2000) and HMAX (Walther et al., 2002). *a*, Sketch of the integrated system. Targets in the saliency map (*left*) cause a modulation of receptive field size of C2 neurons in HMAX (*right*) by modulating their spatial pooling range (*center*). *b*, Recognition results in HMAX

with and without attentional modulation (cf. Fig. 111.4), depending on the separation of stimuli. Attentional modulation of the spatial extent of receptive fields dramatically improves recognition performance.

context, and attentional control. The experimental paradigms used so far in object recognition simplify these issues to a minimum. The Standard Model does not yet incorporate any attentional bias. This is justified by the fact that recognition is possible for scenes viewed in rapid visual presentation that do not allow sufficient time for shifts of attention (Potter, 1975). Furthermore, electroencephalographic studies (Thorpe et al., 1996) provide evidence that the human visual system is able to perform an object detection task—which includes categorization and search—within 150 msec, which is on the order of the latency of view- and object-tuned cells in IT (Perrett et al., 1992). Recent studies indeed suggest that such object detection tasks can be per-

formed in the near absence of attention (Li et al., 2002) and in parallel (Rousselet et al., 2002). None of this rules out, of course, the use of feedback processing, but it suggests a hierarchical feedforward architecture as the core circuitry underlying immediate recognition, with recursion and higher-level interactions playing a role only over longer time periods.

What should happen, however, in the model when the object to be detected is embedded in a large image? Saliency computation is likely to drive eye movement and to interact with the recognition machinery in this process (Fig. 111.8). Task-dependent priming may affect tuning of cells at different levels of the model.

This calls for investigating the relationship between object recognition and visual attention. The required quantitative theory will assume that object recognition derives its key properties of invariance and specificity from two cortical pathways working in parallel. An attentional system (which may be mapped in part onto the dorsal stream of primate cerebral cortex in addition to certain subcortical structures) selects salient or task-relevant candidate locations in the visual field. Attentional biases include both rapid, bottom-up, saliency-driven components as well as slower, top-down, task-dependent components. Attended locations are processed in a mainly feedforward (ventral) stream from primary visual cortex, to IT cortex, and PFC in order to recognize objects. We expect this cooperation between attentional and recognition systems to be especially relevant in object recognition situations too complex—due to, for instance, visual clutter or ambiguous displays—to be parsed by one feedforward pass through the object recognition pathway in isolation.

LEARNING In the Standard Model simulations described so far, *learning and adaptation* of synapses occur only at the last stages—from the dictionary of features produced by the view-based module in V4 and PIT to the view-tuned, object-tuned, and identification/categorization units. We believe, however, that experience-dependent learning occurs at all stages, possibly starting in V1. There is physiological evidence that the dictionary of complex features in PIT is affected by visual experience (Kobatake et al., 1998). Computationally, hard recognition tasks involving background and clutter require the selection of appropriate complex features, depending on the class of object [early simulations of feature selection used a HyperBF model (Bricolo et al., 1997; Vetter et al., 1995)]. It will be important to investigate with computer experiments how feature sets could be learned using plausible cortical mechanisms and how they may affect object recognition, in particular object detection performance. Simulation results have shown that the model's object detection performance in natural images can be significantly improved by learning target object class-specific intermediate features at the S2 level (Serre et al., 2002). Learning effects may also explain intriguing, recent data on limitations of position invariance (DiCarlo and Maunsell, 2003). It is likely that learning at different stages in cortex takes place over different time scales, the shortest in IT and PFC and the longer in V1.

RECOGNIZING OBJECTS IN MOTION Initial work on extending the Standard Model to the time domain for the recognition of biological movements and actions has begun (Giese and Poggio, 2003). The key idea in this extension of the model is that action recognition is based on learned proto-

typical complex motion patterns. Simulations consistently summarize many existing results and simultaneously provide a plausibility proof that the recognition of complex biological motion patterns might be based on relatively simple, well-established neural mechanisms. In addition, the model shows that biological motion recognition can be based on a relatively limited number of learned prototypical motion patterns. This representational principle is analogous to the encoding of complex stationary three-dimensional shapes in terms of learned *prototypical views*.

In this model, *view-tuned neurons* similar to the units that have been found in area IT of macaques can learn to respond selectively to configurations of the human body that are characteristic of biological movements or actions. The model further assumes that a sequence of such “snapshots” represents a limited number of prototypical example movement patterns. The highest level of the form pathway consists of neurons that respond selectively to whole motion patterns, like walking and running. These neurons integrate the activity of the view-tuned neurons at the previous level that code for the same motion pattern over time. Since recognition of complex movement patterns must be selective for temporal order, the model assumes a simple mechanism that is based on asymmetric lateral connections between the view-tuned, pattern-selective neurons. Lateral connections lead to a network dynamics that stabilizes a traveling activity pulse only if the stimulus frames are presented in the right temporal order. The effectiveness of this mechanism for sequence selectivity has been shown in simulations. Scrambling of the temporal order of the stimulus leads to competition between the stimulus input and the intrinsic dynamics of the network, resulting in a strong reduction of neural activity.

Falsifying the Standard Model

There is no doubt that existing and future data will force modifications of the Standard Model. But what kinds of experiments would falsify it completely and provide no-go results for the whole class of neural architectures associated with it? Data showing that the basic operation is *intrinsically* not feedforward are prime candidates. Dependency of recognition on different computations and computational modules for every object class would be difficult to reconcile with the Standard Model. Finding that supervised forms of categorization and identification do not use the same basic machinery to provide input signals would require a major revision of the Standard Model but not of its view-based HMAX module. The simplest interpretation of the model predicts that both categorization and identification rely on IT, but direct neural correlates of categorization are not in IT. Refutation of this prediction, however, would not falsify the Standard Model (cf. Fig. 111.2).

The road ahead

The architecture of the Standard Model allows us to quantitatively summarize and structure knowledge from experimental data and plan new experiments. It is an implicit map to future experimental work in terms of both its predictions and the questions that are left open. Clearly, the road ahead will require a very close interaction of experiments and computational work.

112 Plasticity of Orientation Processing in Adult Visual Cortex

VALENTIN DRAGOI AND MRIGANKA SUR

NEURONS IN THE PRIMARY visual cortex (V1) have been traditionally considered to be passive filters, extracting elementary features of visual stimuli such as local orientation or direction of motion and responding invariantly to the physical properties of stimuli present in their receptive fields. However, another view has emerged in the past 15 years. According to this view, V1 responses are strongly influenced by the spatial and temporal context in which local features are presented, and their responses are modulated as well by previous visual experience, including perceptual learning and adaptation.

Evidence that even the earliest areas of the adult cerebral cortex have the remarkable capacity to change as a result of experience, a phenomenon termed *plasticity*, has been accumulating steadily. The first reports of plasticity in primary sensory cortex of the adult brain came from studies in the somatosensory cortex, which contains a systematic sensory representation of the body surface. Partially removing inputs to the cortex by peripheral nerve transection or by amputation of a finger reorganized the cortical sensory representation such that the denervated cortex now responded to adjacent fingers or the hand (Merzenich et al., 1983, 1984). In V1, sensory map plasticity was first demonstrated using retinal lesions: cortical regions processing inputs from the lesioned parts of the retina were initially silenced, but then regained activity by shifting receptive fields toward regions of the retina surrounding the lesion (Gilbert and Wiesel, 1992; Kaas et al., 1990). Such lesion-induced plasticity implies either the unmasking of existing connections or the formation of new ones (Darian-Smith and Gilbert, 1994). New connections are typically associated with plasticity during development, when neurons are being wired together, but are unlikely to be a mechanism working on shorter time scales in adulthood during normal sensory processing. The latter kinds of plasticity include dynamic changes in neuronal responses mediating contextual effects and short-term plasticity associated with learning or adaptation.

Dynamics and plasticity of responses in V1

Dynamic effects induced by the spatial context of visual stimuli allow V1 neurons to integrate information from dif-

ferent parts of the visual scene. These effects are manifested when both the classical receptive field (i.e., the receptive field center), and the extraclassical receptive field (i.e., the surround), are stimulated together. The way in which surround stimulation modulates responses elicited by a center stimulus is highly nonlinear and often nonintuitive. Thus, stimuli in the surround can either facilitate or suppress cortical responses, depending on the relative orientation and contrast between the center and the surround. The presence of a surround stimulus with an orientation similar to that of the cell's preferred orientation suppresses the response to a high-contrast optimal stimulus within the receptive field center and facilitates the response to a low-contrast optimal stimulus within the receptive field center (Polat et al., 1998; Somers et al., 1998; Toth et al., 1996). On the other hand, stimulating the surround with a stimulus whose orientation differs significantly from the cell's preferred orientation facilitates responses to optimal stimulation within the center (Levitt and Lund, 1997; Sillito et al., 1995). In this case, the cell responds "supraoptimally," that is, beyond the level expected after stimulation with the optimal orientation.

In addition to integrating inputs from outside their classical receptive fields, V1 responses are sensitive to the history of visual stimulation or short-term experience. For instance, masking a portion of the visual field for several minutes (a situation akin to creating an artificial scotoma) while placing a patterned stimulus around the mask demonstrates the capacity of V1 neurons with receptive fields inside the artificial scotoma to alter their responses. Specifically, after a few minutes of conditioning with the artificial scotoma, the receptive fields of neurons close to the scotoma borders expand beyond their original limits and show an overall increase in responsiveness (Das and Gilbert, 1995; DeAngelis et al., 1995; Pettet and Gilbert, 1992). This type of receptive field plasticity has also been demonstrated at shorter time scales. De Weerd et al. (1995) have shown that after exposure to a static stimulus consisting of a similar artificial scotoma pattern, neurons with receptive fields inside the scotoma borders begin to respond despite the absence of retinal stimulation, a phenomenon associated with the perceptual filling-in effect (Ramachandran and Gregory, 1991).

The dependence of V1 neuron responses on short-term or recent experience is evident in the phenomenon of pattern adaptation: selective exposure for a period of time to patterned stimulation induces transient changes in the selectivity of V1 responses. Pattern adaptation has been characterized with respect to many stimulus dimensions, such as orientation (Blakemore and Campbell, 1969; Carandini et al., 1998; Dragoi et al., 2000; Hammond et al., 1986; Muller et al., 1999; Nelson, 1991), contrast (Carandini and Ferster, 1997; Carandini et al., 1998; Movshon and Lennie, 1979; Ohzawa et al., 1982), spatial frequency (Movshon and Lennie, 1979; Saul and Cynader, 1989), direction of motion (Hammond et al., 1985, 1986; Maffei et al., 1973), and velocity (Hammond et al., 1985).

Cortical neurons also have the adaptive capacity to change their responses with perceptual learning (Gilbert et al., 2001). Perceptual learning in vision is a particular form of plasticity that begins during postnatal life, continues throughout adulthood, and allows us to improve visual performance after active exposure to a structured visual environment. There are many examples of situations in which training has been shown to improve discrimination along a variety of visual stimulus dimensions. For instance, training can improve spatial resolution of the visual system (Fahle and Edelman, 1993; Poggio et al., 1992), the ability to discriminate orientations (Schoups et al., 2001; Vogels and Orban, 1985), the direction of motion (Ball and Sekuler, 1985, 1987), or the depth of visual targets (Fendick and Westheimer, 1983). However, importantly, unlike other forms of learning, in which enhanced performance in one task improves performance in related tasks, perceptual learning is highly specific for the stimulus dimension used in the training task, such as retinal position (e.g., Karni and Sagi, 1991b) or orientation (e.g., McKee and Westheimer, 1978; Ramachandran and Braddick, 1973). This high degree of specificity has important implications for the neuronal mechanisms underlying perceptual learning, for it argues that plasticity must be a phenomenon present in the early visual cortical areas. Indeed, recent work has demonstrated task-specific, learning-induced plasticity of V1 neurons in animals trained to perform either a three-line bisection task (Crist et al., 2001) or an orientation discrimination task (Schoups et al., 2001).

Orientation plasticity in V1

A prominent form of plasticity in the adult visual cortex is the plasticity of orientation tuning. Orientation plasticity can be simply demonstrated by an instant perceptual experiment. If we stare for a brief period of time at oblique lines, the perceived orientation of vertical lines appears tilted away from the obliques; this is the well-known *tilt aftereffect* (Gibson, 1933; Gibson and Radner, 1937; Magnussen and Kurten-

bach, 1980). At longer time scales, the ability of the visual system to discriminate differences in orientation can be improved through perceptual learning. This suggests that visual experience or learning could alter the functional properties of orientation-selective neurons and networks in the early visual cortex of the adult brain.

V1 neurons are selective for the orientation of lines which are presented in their receptive field center (Hubel and Wiesel, 1962). The development of orientation tuning does not require visual experience (Crair et al., 1998; Fregnac and Imbert, 1978; Godecke et al., 1997; Hubel and Wiesel, 1962), although selective experience in early life can modify the orientation preference of neurons (Blakemore, 1977; Blakemore and Cooper, 1970; Hirsch and Spinelli, 1970; Sengpiel et al., 1999; Stryker et al., 1978). The orientation preference of adult V1 neurons has long been considered a stable property that remains fundamentally unchanged after early life. However, recent evidence demonstrates that orientation selectivity of neurons and the way in which orientation is mapped onto the cortex can be altered by visual experience, and these changes have important consequences for visual perception.

There are several ways in which orientation plasticity has been demonstrated in adult V1 neurons. While the details of the inducing procedures define the specifics of cortical plasticity, three major types of orientation plasticity stand out (Fig. 112.1).

ADAPTATION-INDUCED PLASTICITY Continuous visual stimulation for a period of seconds to minutes (a process defined as *adaptation*) at a fixed orientation induces a reversible shift in the preferred orientation of individual neurons away from the adapting stimulus (Fig. 112.1A) (Dragoi et al., 2000; Muller et al., 1999). Interestingly, this form of short-term plasticity induces not only a significant change in optimal orientation but also a reorganization of responses around the new preferred orientation. For instance, a long period of adaptation induces a reduction of responses on the flank of the tuning curve near the adapting stimulus and a facilitation of responses on the opposite flank. This suggests that adaptation-induced orientation plasticity involves an active process of network synaptic changes that lead to a new preferred orientation rather than simply a passive reduction of orientation-selective responses around the adapting orientation.

STIMULATION TIMING-DEPENDENT PLASTICITY Intracortical electrical stimulation paired with visual stimulation for several hours leads to a shift in the preferred orientation of individual neurons (Fig. 112.1B) (Schuett et al., 2001). The shift can occur toward or away from the orientation of the visual stimulus, depending on the temporal order of the visual stimulus and the delivery of the electrical pulses.

LEARNING-INDUCED PLASTICITY

FIGURE 112.1. Different forms of orientation plasticity in V1. *A*, Adaptation-induced orientation plasticity. Short-term exposure for a period of seconds to minutes induces a repulsive shift in the preferred orientation of V1 neurons away from the adapting stimulus (*arrow*). The solid line represents the orientation tuning curve before adaptation, and the dotted line represents the tuning curve after adaptation. *B*, Stimulation timing-dependent orientation plasticity. The figure schematically shows orientation plasticity induced by a combination of cortical microstimulation and visual stimulation. When electrical microstimulation is delivered to a cortical site 65 msec after the visual stimulus (*arrow*), there is a shift in the preferred orientation of V1 neurons toward the visual stimulus orientation (*a*), whereas when electrical microstimulation is delivered after the

visual stimulus, there is a shift in preferred orientation away from the visual orientation (*b*). The solid line represents the tuning curve before microstimulation, and the dotted lines represent the tuning curves after forward (*a*) and backward (*b*) microstimulation. *C*, Learning-induced orientation plasticity. Improvement in orientation discrimination performance during learning is accompanied by an increase in the slope of the tuning curve near the trained orientation (*arrow*). The solid line represents the orientation tuning curve of a V1 neuron before training. The straight solid line represents the slope of the tuning curve at the trained orientation before training; the straight dashed line represents the slope of the tuning curve at the trained orientation after training.

Consistent with previously demonstrated rules of synaptic plasticity based on the precise timing of the presynaptic and postsynaptic activity (spike-timing-dependent plasticity) obtained in slice preparations (Markram et al., 1997; Zhang et al., 1998), electrical stimuli delivered after the visual stimulus-driven activity reaches cortex produces a shift in the preferred orientation of individual neurons toward the visually presented orientation, whereas reversing the temporal order between electrical and visual stimuli produces a shift in preferred orientation away from the visual orientation. Except for the timing between stimuli, this pairing protocol is similar to that introduced by Fregnac et al. (1988), in which the preferred orientation of individual neurons shifted toward the orientation of the visual stimulus. Similarly, the preferred orientation of individual neurons can be induced to shift toward the orientation at a cortical site that is stimulated pharmacologically (Toth et al., 1997) or electrically (Godde et al., 2002), even without a paired visual stimulus. However, the rules of synaptic plasticity underlying such shifts are still likely to involve the relative timing and correlations between input and output spikes of neurons. Yao and Dan (2001) specifically demonstrated that two gratings—one at a tilted orientation and the other at the cell's preferred orientation—flashed in quick succession (8 to 40 msec apart) causes a cell to shift its preferred orientation toward the first grating, whereas flashing the gratings in the opposite order causes the cell to shift its orientation away from the first grating.

LEARNING-INDUCED PLASTICITY Intensive practice in discriminating fine orientation differences increases neuronal orientation discrimination performance at the trained orientation (Shiu and Pashler, 1992; Vogels and Orban, 1985), but not at other orientations or visual field locations (Schoups et al., 2001). The proposed mechanism for this type of plasticity has been linked to the observed increase in the slope of the tuning curve of individual V1 neurons in the vicinity of the trained orientation (Fig. 112.1C) (Schoups et al., 2001).

These forms of orientation plasticity demonstrate the powerful effect of short- and long-term synaptic plasticity rules, such as those previously derived from work in reduced preparations, including cultured neurons and brain slices, on shaping fundamental properties of individual V1 neurons and networks in vivo (Sur et al., 2002). Two questions have recently emerged from our understanding of cortical plasticity: how is orientation plasticity represented across the cortex, and what is its significance for visual perception, including natural vision? Whereas orientation plasticity induced by electrical stimulation does not appear to have a direct impact on vision, adaptation and learning-induced changes in V1 responses offer powerful tools with which to address both questions. In the following sections, we will

focus on plasticity of orientation tuning induced by adaptation as a model system in which to understand the representation, mechanism, and significance of plasticity in V1 networks.

Adaptation-induced orientation plasticity

Our knowledge of adaptation in early visual cortex comes from studies demonstrating that exposure to a potent stimulus for several minutes (pattern adaptation) can cause a reduction in sensitivity to stimulus attributes such as contrast or spatial frequency (Blakemore and Campbell, 1969; Carandini et al., 1998; Movshon and Lennie, 1979; Nelson, 1991; Ohzawa et al., 1982). In light of these experiments, cortical adaptation has been viewed for many years as a local phenomenon mediated by depression of firing at the level of individual neurons, possibly involving tonic hyperpolarization of the membrane potential of V1 cells (Carandini and Ferster, 1997) due to synaptic depression (Abbott et al., 1997; Chance et al., 1998) or to a slow hyperpolarizing membrane potassium current (Sanchez-Vives et al., 2000).

In a recent study, Dragoi et al. (2000) studied adaptation-induced orientation plasticity in V1 and found, in contrast to previous results, that adaptation causes both depression and enhancement of responses to a range of stimulus orientations, along with reorganization of the entire profile of the orientation tuning curve. Figure 112.2A shows how the preferred orientation of a representative V1 cell changes after 2 minutes of exposure to one orientation located on one flank of the cell's tuning curve, followed by a period of recovery, subsequent adaptation to a different orientation located on the opposite flank with respect to the preferred orientation, and a final period of recovery. When the difference between the cell's preferred orientation and that of the adapting stimulus ($\Delta\theta$) is -22.5 degrees, that is, adapting orientation is on the left flank of the tuning curve, there is a shift in preferred orientation to the right, away from the adapting stimulus. In contrast, when the adapting stimulus is presented on the right flank of the tuning curve ($\Delta\theta = 45$ degrees), the preferred orientation shifts to the left and then returns to the original value after 10 minutes of recovery.

These effects of orientation adaptation are short term: the shift in preferred orientation increases with adaptation time until it asymptotes at about 10 minutes of adaptation and then reverses to the original level when the adapting stimulus is removed. Figure 112.2B shows the behavior of one cell that exhibits significant shifts in orientation following adaptation to a stimulus oriented 45 degrees away from the cell's peak orientation (Dragoi et al., 2000). Both the response reduction on the near flank and facilitation on the far flank build up gradually in time: increasing the adaptation time from 10 seconds to 10 minutes shows a progressive

depression of responses on the near flank and a progressive facilitation of responses on the far flank. Interestingly, adaptation and recovery develop at two different time scales, with the rate of recovery being at least an order of magnitude slower than the rate of adaptation (Fig. 112.2C).

Orientation plasticity and the cortical map of orientation preference

Adaptation-induced orientation plasticity is a cortical phenomenon that depends on changes in inputs from other neurons in a local network. Thus, it is conceivable that the

strength of adaptation effects would depend on the specific cortical location of a neuron within the map of orientation preference. V1 neurons are clustered according to their orientation preference in iso-orientation domains (Hubel and Wiesel, 1974), where the optimal orientation of individual neurons varies smoothly across the cortex, and singularities or pinwheel centers (Blasdel, 1992; Bonhoeffer and Grinvald, 1991), which are foci where the optimal orientation of neurons varies rapidly (Fig. 112.3A). The structure of the orientation map in V1 implies that the orientation distribution of local connections would vary with a neuron's position within the map: neurons in pinwheel centers are likely to be connected to neurons of a broader range of orientations than neurons in iso-orientation domains. This suggests that altering the efficacy of intracortical orientation-specific inputs to neurons in different locations of the orientation map in a manner that induces adaptive changes in tuning properties could show dependence on cortical location.

Dragoi et al. (2001) investigated the relationship between adaptation-induced orientation plasticity and a neuron's location in the orientation preference map in V1 of adult cats. Optical imaging of intrinsic signals was used to obtain the orientation map in a patch of V1, and then the vascular pattern of the cortical surface was used in relation to the orientation map to guide electrode penetrations aimed at iso-orientation domains or pinwheel centers (Fig. 112.3A). The specific question was whether the local orientation distribution at the recording site correlated with the degree of plasticity. Anatomical and physiological data in V1 (Das and Gilbert, 1999; Hata et al., 1991; Kisvarday et al., 1997;

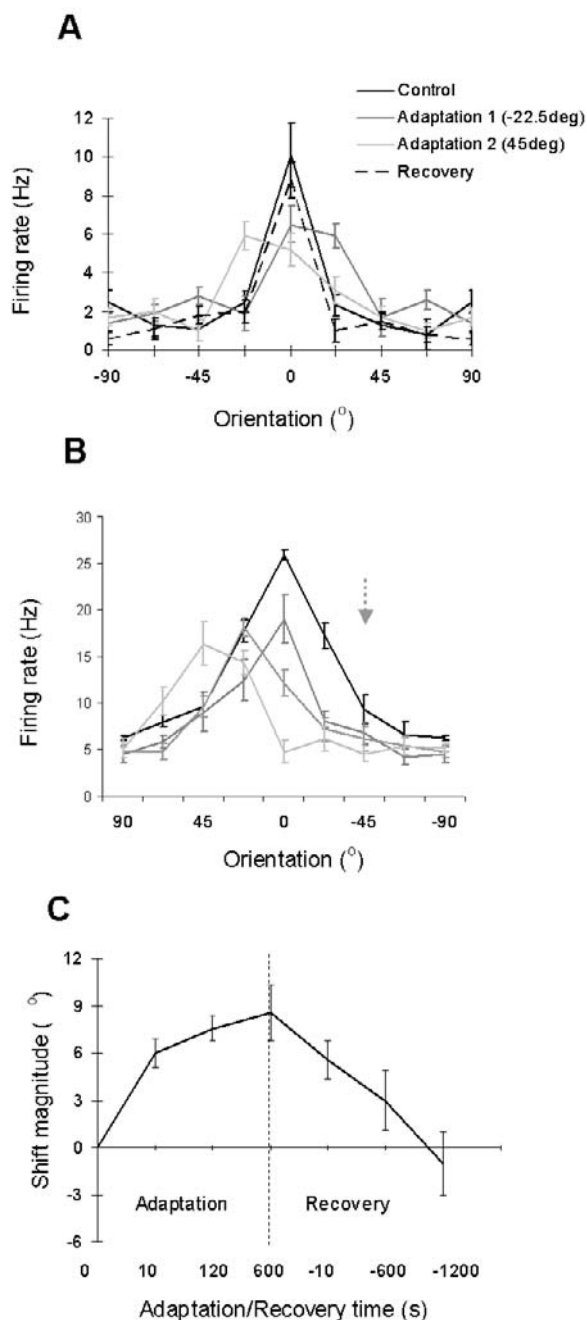

FIGURE 112.2. Adaptation-induced orientation plasticity. *A*, Orientation tuning curves of one representative V1 neuron that was successively adapted to two different orientations. Each graph represents orientation tuning during four conditions: control (black), adaptation to the first orientation (dark gray), adaptation to the second orientation (light gray), and recovery (black, dashed line). In this tuning curve display convention, the control optimal orientation is represented as 0 degrees, and all subsequent tuning curves (during adaptation and recovery) are represented relative to the control condition. *B*, Tuning curves of neurons that show adaptation-induced response suppression on the near flank and response facilitation on the far flank. Each cell was serially exposed to different adaptation periods: 10 seconds, 2 minutes, and 10 minutes. Tuning curves were calculated in each of the four conditions: control (black), 10 seconds adaptation (dark gray), 2 minutes adaptation (medium gray), and 10 minutes adaptation (light gray). The adapting orientation is marked by the gray arrow. *C*, Time course of adaptation and recovery. The graph shows the mean shift magnitude \pm S.E.M. as a function of adaptation and recovery time for a subpopulation of seven neurons. The orientation shift magnitude was calculated after adaptation to a stimulus presented for 10 seconds, 2 minutes, and 10 minutes, followed by recovery to a blank stimulus presented for 10 seconds, 10 minutes, and 20 minutes.

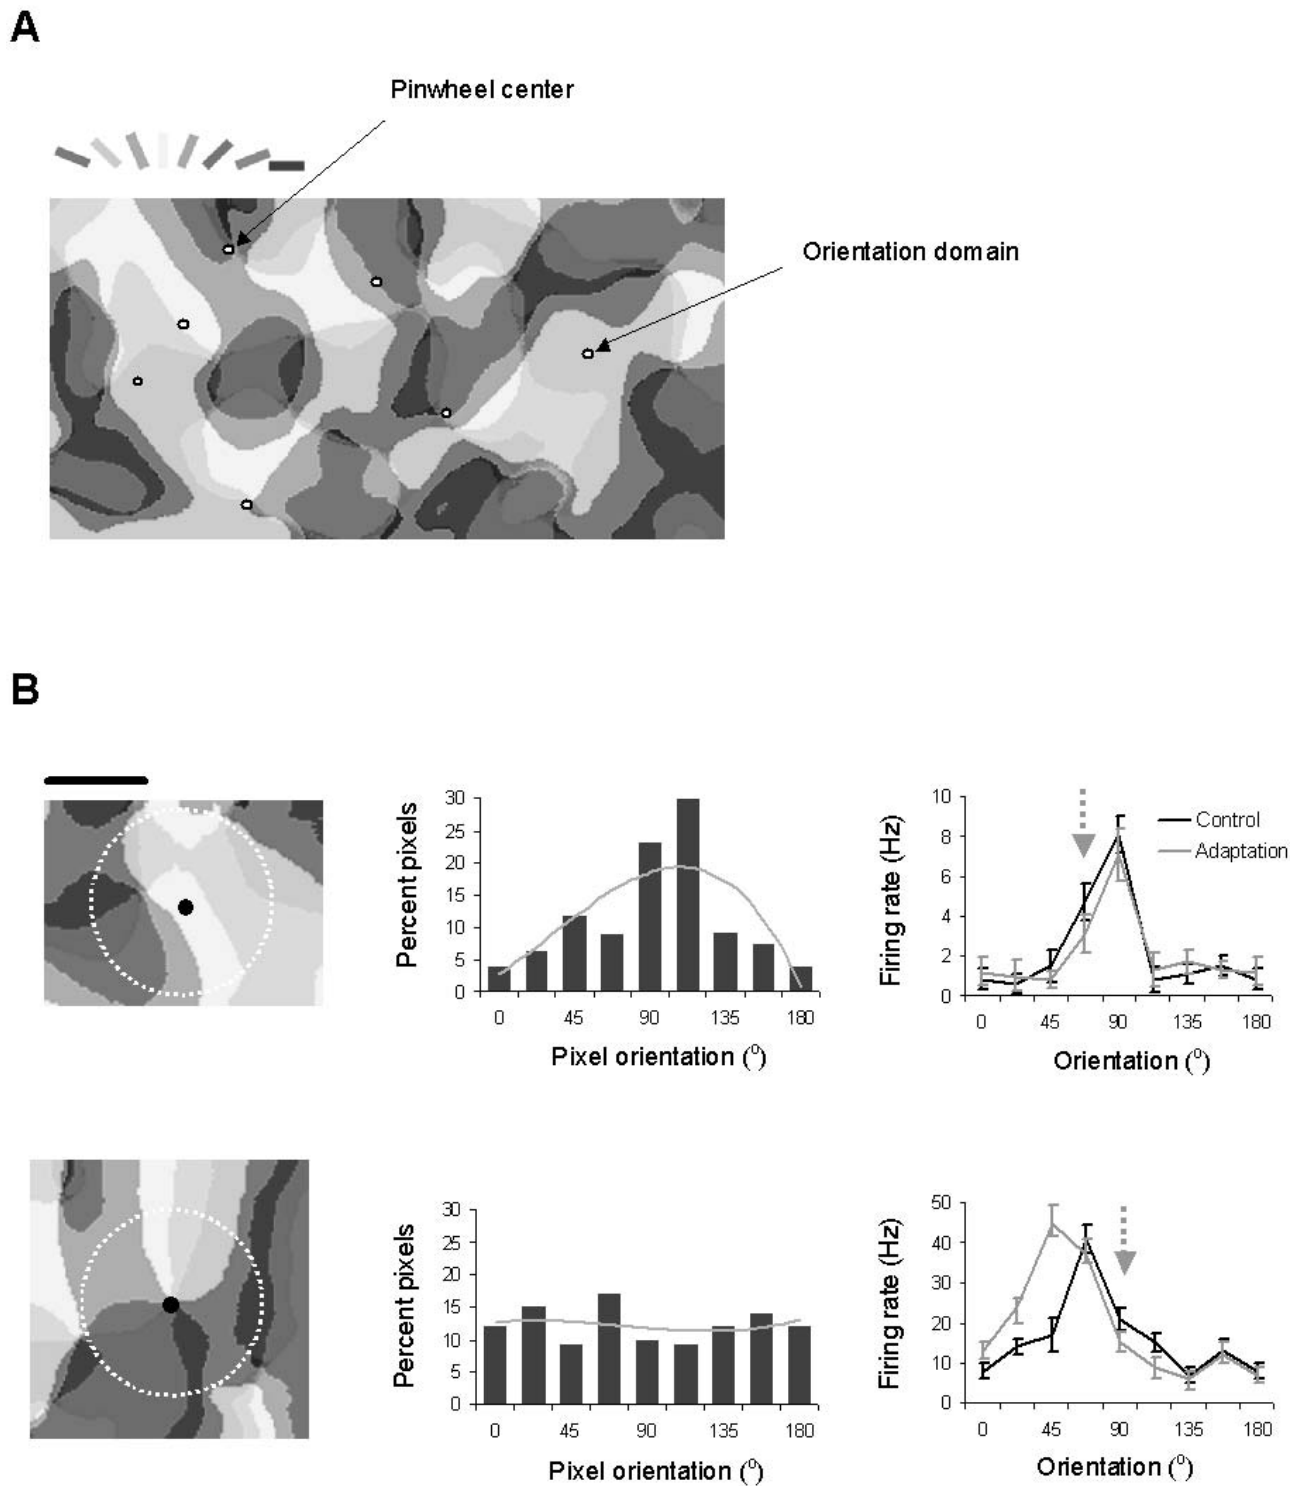

FIGURE 112.3. Adaptation-induced plasticity of orientation tuning and the orientation architecture of V1. *A*, Composite orientation map obtained by intrinsic signal optical imaging. The angle of preferred orientation of each pixel is shown in pseudo-color according to the key at the top. The circles show the location of seven representative neurons to illustrate the range of orientation distributions in recorded neurons. *B*, Relationship between the local orientation distribution at the recording site and the degree of orientation plasticity. *Left*: Two recording sites (filled circles) placed respectively within an iso-orientation domain and a pinwheel

center. The white dotted circle of radius $500\mu\text{m}$ represents the basin of local intracortical inputs. *Middle*: The percentage of pixels at each orientation within $500\mu\text{m}$ of the recording site after pooling the pixels into eight orientation bins between 0 and 180 degrees. The gray curve represents the best third-order polynomial fit to each histogram. *Right*: Orientation tuning curves in the control condition (black) and after adaptation (gray) for the cells recorded at the locations shown in the left panels. The adapting orientation is marked by the gray arrow. Error bars represent S.E.M. (See color plate 85)

Weliky et al., 1995) have demonstrated that local excitatory and inhibitory inputs to cortical cells originate from within an approximate 500 μm radius around the cell body. The critical feature for explaining orientation plasticity was found to be the distribution of local inputs to individual neurons. When the recording site is in the middle of an iso-orientation domain (Fig. 112.2*B*), neurons within a 500 μm radius have a preponderance of orientation preferences similar to that of the recorded neuron, whereas when the recording site is near a pinwheel center, local inputs arise from domains of all orientations. Qualitatively, the orientation distribution of inputs to a neuron is a predictor of the degree of change in its orientation preference. When it has a peaked profile, adaptation induces only minor changes in orientation selectivity (Fig. 112.3*B*), whereas the orientation tuning curve undergoes pronounced changes when the orientation distribution is flat.

What kind of mechanism could generate these effects? The changes in orientation selectivity following adaptation imply a network mechanism that reorganizes responses across a broad range of orientations. For instance, hyperpolarization of neurons at or close to the adapting orientation, due either to membrane mechanisms (such as slow hyperpolarizing Ca^{2+} - and Na^{+} -activated potassium channels; Sanchez-Vives et al., 2000), or to synaptic depression (Abbott et al., 1997), can cause suppression of responses on the near flank of the tuning curve, whereas facilitation of responses on the far flank requires disinhibition (Dragoi and Sur, 2000) and possibly amplification via local excitatory intracortical interactions (Somers et al., 2002). But what is important is that the strength of these effects, which determines the magnitude of the change in preferred orientation, depends on the location of neurons in the orientation map. Neurons in an iso-orientation domain would be only weakly activated by intracortical inputs with orientations that differ from the domain's preferred orientation, whereas neurons located at or near pinwheel centers would receive strong local inputs from neurons of all orientations. Therefore, altering the efficacy of these inputs through adaptation is likely to induce more profound changes in the orientation preference of neurons at or near pinwheel centers. This suggests that adaptation-induced orientation plasticity in V1 is an emergent property of a local cortical network overlaid on a nonuniform orientation map.

Rapid adaptation-induced plasticity

An important question about orientation plasticity is whether the different forms of response change have adaptive significance for vision. Whereas long-term cortical plasticity has been used to explain certain kinds of perceptual learning, the functional implications of the more rapid forms

of plasticity have been less clear. For instance, plasticity induced by short-term adaptation to oriented contours is considered to underlie the tilt aftereffect (see below), but the tilt aftereffect leads to an altered perception of contour orientation.

Two recent studies have demonstrated that the discrimination of orientations is actually improved by adaptation. Clifford et al. (2001) showed that orientation discrimination around vertical orientations improved in human observers after adaptation to either vertical or horizontal gratings but was impaired after adaptation to intermediate orientations. The improvement was greatest when the adapting and test gratings were orthogonal. The study, however, employed long adaptation times of several seconds to 1 minute, a duration unlikely to have a significant role in ongoing natural vision.

Dragoi et al. (2002) asked whether cortical plasticity is involved during the rapid processing of image patterns during natural viewing. During the viewing of a natural scene, we make saccadic eye movements several times a second (Andrews and Coppola, 1999; Yarbush, 1967). Between successive saccades, during visual fixation, the portions of a scene that fall within the receptive fields of V1 neurons are well correlated in local features. Brief adaptation during exposure to such spatially correlated image patches is known to induce short-term changes in the response of V1 neurons by reducing the response at the preferred orientation and hence possibly the correlation among neuronal responses (Attneave, 1954; Barlow, 1990). However, adaptation effects have been mainly described by examining how exposure to a certain image pattern affects the subsequent viewing and discrimination of similar patterns, thus ignoring the properties of natural viewing. Indeed, during natural vision we often make large saccades to explore new regions of visual space, with local attributes (e.g., orientation) that are typically uncorrelated to the previous fixation (Fig. 112.4). Therefore, fixation at one location is likely to be followed by a saccade to an image patch of dissimilar structure. How does brief adaptation affect the discrimination of local image patches of dissimilar structure and their encoding by visual cortical neurons?

Dragoi et al. (2002) showed that orientation discrimination by humans and monkeys is markedly improved when an adapting grating is presented briefly, for a few hundred milliseconds (i.e., for a time equivalent to one visual fixation), followed by a test grating that is orthogonal in orientation to the adapting grating. They also showed that rapid adaptation affects the signaling capabilities of V1 neurons. Specifically, while brief adaptation to an oriented grating broadens orientation selectivity and changes the preferred orientation of individual V1 neurons, it actually enhances the discrimination of orthogonal orientations by sharpening neuronal selectivity.

1°

FIGURE 112.4. Image statistics during natural vision. While viewing a scene, a short saccade is likely to land on an image patch of similar orientation structure, whereas a long saccade is likely to land on an image patch of dissimilar orientation structure.

While most work on adaptation effects on neuronal responses has employed long adaptation and stimulus-response times, stimuli which are presented briefly (Muller et al., 1999; Nelson, 1991) are necessary for examining both the effects of rapid adaptation on cortical responses and the temporal development of neuronal interactions underlying adaptation effects. These temporal interactions are critical for providing clues to the role of temporal interactions in natural vision, as the changing stimulus statistics between eye movements during free viewing introduces complex dynamics in cortical responses.

One efficient way to capture the dynamics of neuronal responses after adaptation would be to estimate the development of orientation tuning by implementing the reverse correlation procedure (de Boer and Kuyper, 1968; Dragoi et al., 1999; Mazer et al., 2002; Ringach et al., 1997). Dragoi et al. thus measured how the orientation tuning of V1 neurons evolves at the millisecond time scale before and after brief adaptation. They stimulated V1 neurons of awake monkeys with movie sequences in which each frame was a high-contrast sine-wave grating of pseudorandom orientation synchronized with the refresh of the monitor and flashed at 60 Hz. The orientation domain was sampled in steps of 11.25 degrees, and each orientation was presented seven times during each movie strip. Spikes were recorded during a control condition (in which movie strips were presented alone) or immediately after adaptation (in which movie strips were preceded by a 400 msec sine-wave drifting grating of fixed orientation). For each recorded action potential, the orientation that had been presented at various

preceding times in the movie sequence was determined. Spikes from completed trials were accumulated in a two-dimensional array based on stimulus orientation and time delay before spiking. A mean spike count was obtained for each stimulus orientation by dividing each spike counter by the number of rewarded trials and by the number of stimulus repetitions within each trial.

Figure 112.5 shows two examples of cells with distinct behaviors during brief adaptation. When the adapting stimulus orientation is near a cell's preferred orientation (small $\Delta\theta$), the development of orientation selectivity is delayed, whereas adaptation orthogonal to a cell's preferred orientation (large $\Delta\theta$) accelerates the development of orientation selectivity. More importantly, however, adaptation near the preferred orientation reduces responses on the near flank of the tuning curve, shifts the preferred orientation away from the adapting stimulus, and increases the width of the tuning curve, whereas adaptation far away from the optimal orientation maintains orientation preference and sharpens orientation tuning.

Significance of adaptation-induced orientation plasticity for vision

These effects of rapid adaptation (with the adapting grating presented for hundreds of milliseconds) on neuronal responses are fundamentally similar to the effects of short-term adaptation (with the adapting grating presented for seconds to minutes). In both cases (cf. Fig. 112.1A or the bottom part of Fig. 112.3B and Fig. 112.5), adaptation with a grating oriented near a cell's preferred orientation alters the tuning curve and broadens selectivity, whereas a grating oriented orthogonal to a cell's preferred orientation preserves the same orientation preference but sharpens selectivity (Dragoi et al., 2000, 2002). How do these neuronal changes explain the perceptual consequences of adaptation?

Population coding models that relate neuronal responses to perception assume that a cell is a "labeled line" for a stimulus, so that each neuron signals the presence of its preferred stimulus within its receptive field. The response of the population is inferred as the vector sum of the individual neuron responses. Two of the response changes induced by short-term adaptation—reduction in response at the adapting orientation and broadening of tuning width—are important for explaining at least the repulsive tilt aftereffect at intermediate orientation differences between adapting and test orientations (Clifford et al., 2001; Sur et al., 2002).

The consequences of rapid adaptation for natural vision can be understood qualitatively from the experimental data now available, and they suggest an interesting functional role for rapid as well as short-term adaptation. On the one hand,

FIGURE 112.5. Temporal dynamics of brief adaptation in V1 neurons revealed by reverse correlation. *Left:* Adaptation near the cell's preferred orientation (small $\Delta\theta$) delays the development of orientation tuning, shifts the preferred orientation away from the adapting stimulus, and broadens orientation selectivity. *Right:* Adaptation at an orthogonal orientation relative to the cell's optimal orientation (large $\Delta\theta$) accelerates the development of orientation tuning, preserves orientation preference, and sharpens orientation selectivity. The graphs within each column show the development of orientation tuning for two neurons at different temporal delays during control (black) and adaptation (gray) conditions. The adapting orientation is marked by the dashed line. Error bars represent S.E.M.

rapid adaptation during fixation induces a suppression of responses on the flank of the tuning curve near the adapting stimulus and a facilitation of responses on the opposite flank, which together constitute a repulsive shift in the preferred orientation of V1 neurons. We suggest that brief adaptation improves the discrimination of orientations close to the neuron's optimal orientation by increasing the slope of the tuning curve in the vicinity of the preadaptation pre-

ferred orientation. This improvement in discrimination performance following iso-orientation adaptation has clear psychophysical support (Clifford et al., 2001; Regan and Beverley, 1985) and could be a mechanism that might be used by the visual system in order to resolve fine orientation details during visual fixation.

On the other hand, since the mean saccade length during free viewing is relatively large, successive fixations are likely to be made on image patches of dissimilar structure. In this case, adaptation to largely dissimilar image patterns improves neuronal performance in V1 by sharpening orientation tuning curves, and there is a corresponding improvement of psychophysical performance on orientation discrimination. Given the ubiquity of successive saccades to patches of dissimilar structure during natural vision, we suggest that the visual system has adapted to the correlational structure of images so as to encode local features more efficiently.

Conclusions

Examining how visual cortical neurons adapt their response properties to short-term exposure to patterned stimulation or to perceptual learning, and how the capacity for adaptive changes is mapped onto the cortex, is fundamental for understanding neuronal mechanisms of conscious visual perception. An astonishing property of adaptation-induced plasticity is the fact that its magnitude changes, depending on cortical location. This suggests that the visual cortex is not homogeneous in its capacity to undergo plastic changes and indicates the existence of a map of orientation plasticity, closely related to the map of orientation preference, in which pinwheel centers constitute foci of maximal plasticity and the rate of orientation change is a measure of the degree of plasticity across V1. Whether there are similar plasticity maps related to other functional maps, such as those for eye preference, spatial frequency, direction, or the effects of attention, remains an open and interesting question.

Plasticity is an integral part of information processing in the cortex. Visual cortex neurons change their responses as they are stimulated, and vision is continually shaped by these response changes. The findings on orientation plasticity induced by adaptation on the time scale of visual fixation demonstrate that these changes can be rapid indeed and can continuously influence vision.

113 Synchrony, Oscillations, and Relational Codes

WOLF SINGER

PSYCHOPHYSICAL AND neurophysiological evidence suggests that the visual system identifies objects by decomposing them into components, by extracting certain sets of features, and by analyzing the relations among the respective components and features. This is an efficient strategy for two reasons. First, it permits unambiguous descriptions of a virtually unlimited number of different objects with a limited set of descriptors for components, features, and relations. Second, it can be scaled and applied also for the description of entire visual scenes, that is, for the infinite variety of configurations in which visual objects can occur. Linguistic descriptions follow the same principle. By recombining in ever-changing configurations a rather limited set of descriptors for objects, components, properties, and relations, a virtually inexhaustible repertoire of descriptions can be composed, both of familiar and novel, concrete and abstract constellations.

This coding strategy is necessarily distributed in nature because it requires recombining and hence separate descriptors for components, features, and relations. Substituting a sentence by a single word that captures the full meaning of the sentence may be advantageous in exceptional cases—for example, if the description refers to a particularly important, frequently recurring event or scene. It would make no sense, however, to invent single-word descriptions for all possible sentences, as this would lead to a combinatorial explosion of the required vocabulary. This suggests an interesting trade-off between the size of the vocabulary, that is, the variety and complexity of the descriptors, on the one hand, and the complexity of the syntactic structures that define the relations between the descriptors, on the other hand. If descriptors address only very elementary components and features, relatively few types of descriptors are required because the diversity of elementary components of objects is limited: a few dozen different atoms suffice to generate a universe of molecules. However, if descriptors are available only for very-low-level components and features, full descriptions of complex objects require highly sophisticated syntactic structures to cope with the large number of nested relations that need to be specified. Conversely, if descriptors exist that not only define elementary components, features, and relations but already certain conjunctions of components and features, more descriptors

are required but the complexity of the syntactic structures necessary for the definition of relations can be reduced. Depending on the nature of the coding task, the cost of descriptors, and the versatility of the relation-defining mechanisms, cognitive systems can be expected to settle for optimally adapted compromises in this trade-off between the sophistication of descriptors and the sophistication of dynamic codes for relations.

Regarding the neuronal implementation of such coding strategies, one expects to find neurons whose responses signal the presence of very elementary components and features, as well as neurons whose responses encode conjunctions of variable complexity. In addition, one expects to find mechanisms that permit a flexible and context-dependent definition of relations among the responses of neurons that code for components, features, and some of their conjunctions.

The numerous investigations of single-cell responses performed over the past decades have provided robust support for the existence of neurons in sensory areas of the cerebral cortex that signal the presence of features and their conjunctions. Some of them encode elementary components and features of perceptual objects, while others are tuned to quite complex conjunctions of components and features. The former prevail at early and the latter at late stages of the processing streams. However, until recently, no systematic investigations were devoted to the analysis of mechanisms permitting flexible and context-dependent definitions of relations among the responses of these neurons. The reasons were mainly conceptual. First, the discovery of neurons responding to complex conjunctions of features indicated that relations are encoded by having feature-selective cells converge on specific conjunction cells, and it was assumed that this mechanism, if iterated sufficiently often, can cope with the definition of all conceivable relations. Second, neurons were considered insensitive to the precise temporal relations among afferent spike trains and to essentially evaluate average rate fluctuations. This predicted that all information about the relatedness of responses should be contained in the amplitude distribution of responses, a conjecture that was corroborated by the observation that in many instances such population rate vectors correlate very well with stimulus configurations or movement trajectories.

All relevant information appeared to be retrievable by recording the event-related responses of single cells, by computing averages of these responses in order to reduce noise, and by comparing the response amplitudes of the various successively recorded neurons. The tremendous explanatory power of single-cell responses made it appear unlikely that any additional information is encoded in the precise temporal relations between the discharges of simultaneously active neurons. These hypotheses provided little incentive to record from more than one unit at a time and to investigate relations among nonaveraged, simultaneously recorded responses. Research focused on the analysis of averaged responses from sequentially recorded neurons.

Systematic search for mechanisms permitting dynamic and flexible definition of relations among distributed responses began after the accidental finding that neurons in the cat visual cortex can engage in oscillatory firing patterns and coordinate the temporal fine structure of their responses by synchronizing their discharges with a precision in the millisecond range (Gray and Singer, 1987, 1989). This finding suggested the hypothesis that the cerebral cortex exploits its ability to coordinate the discharges of distributed neurons in order to define relations that are difficult to encode with conjunction neurons. In the following, some of the theoretical considerations which led to the hypothesis that synchronization could serve as a code for relations are reviewed. Then experiments that were designed to test predictions derived from the synchronization hypothesis are discussed.

Why synchrony?

Figure 113.1 illustrates how relations among features can be encoded by conjunction-specific neurons within hierarchically structured feedforward architectures. Representing relations among components by conjunction units has two undisputed advantages. First, it permits rapid processing because it can be realized in feedforward architectures. Second, it is unambiguous because the response of a particular cell always signals the same relation (labeled line coding). However, if not complemented by additional, more dynamic and context-sensitive mechanisms for the definition of relations, this strategy poses problems. First, excessively large numbers of conjunction units are required to cope with the manifold intramodal and cross-modal relations between the features of real-world objects. Second, it is hard to see how the entirely new relations among the features of novel objects can be represented, as there cannot be an exhaustive repertoire of a priori specified conjunction units for all possible feature constellations. Third, unresolved problems arise with the specification of the nested relations that need to be defined to represent composite objects or scenes containing numerous objects. (For a more detailed review

FIGURE 113.1. Schematic wiring diagram of a hierarchically organized feedforward network that generates conjunction-specific neurons which respond selectively to different perceptual objects. Note that the neurons representing the faces and the vase receive input partially from the same feature-specific neurons.

of the arguments, see Gray, 1999; Singer, 1999; von der Malsburg, 1999.)

These shortcomings can be overcome by assembly coding. Here individual cells signal only components of objects that may consist of rather complex conjunctions of elementary features—while the whole object is represented by the simultaneous responses of the respective component coding cells (Fig. 113.2). Individual neurons can then contribute at different times to the representation of different objects by forming ensembles with varying partners. This reduces dramatically the number of required conjunction units. It also solves the problem of representing novel relations, objects, and scenes because cells representing elementary features can be grouped dynamically in ever-changing constellations and then can represent as an assembly the particular combination of features characteristic of the novel object. However, this coding strategy requires a dynamic

Assembly coding

FIGURE 113.2. Schematic wiring diagram of neuronal architectures serving the representation of perceptual objects by assemblies. Note that the assembly representing the vase shares neurons with the assemblies representing the faces. To ensure stability of the respective assemblies, additional reciprocal connections among neurons constituting an assembly are required (*shaded regions*) that bind responses of neurons belonging to the same assembly.

binding mechanism that can associate cells into assemblies and tag responses of distributed neurons as related once these have formed an assembly. Such dynamic binding mechanisms cannot be implemented in feedforward architectures, as they require additional reciprocal association connections and reentry loops.

An unambiguous signature of relatedness is absolutely crucial in assembly coding because, unlike in labeled line codes, the meaning of responses changes with the context in which they are embedded. It needs to be ensured that the responses of the neurons that constitute an assembly are processed and evaluated together at subsequent processing stages and are not confounded with other, unrelated responses. In principle, this can be achieved by raising jointly and selectively the saliency of the responses belonging to an assembly, and there are three options: first, unrelated responses can be inhibited and excluded from further processing. Second, the discharge frequency of the selected

responses can be enhanced. Third, the selected cells can be made to discharge in precise temporal synchrony. All three mechanisms enhance the relative impact of the selected responses and can therefore be used to tag them as related. Problems arise, however, when several assemblies need to be formed at the same time and need to recruit partly the same neurons—a condition that is likely to occur when a scene contains several objects that have subsets of features in common. This problem has been addressed as the so-called superposition problem and can only be resolved by segregating assemblies in time (Fig. 113.3). One option is to raise jointly the discharge frequency of cells belonging to the first assembly for an interval sufficiently long to permit readout by subsequent stages and subsequently to increase the discharge rate of the cells belonging to the second assembly, and so on. Another option is to label responses of cells belonging to an assembly by synchronizing the respective discharges. As synchronization raises the saliency of individual discharges, it defines relations with much higher temporal resolution than rate modulation and, in principle, permits multiplexing of assemblies, as suggested in Figure 113.3. Single-cell studies have provided robust evidence that attentional mechanisms use inhibition and selective enhancement of the discharge rate for response selection and grouping. However, there is little evidence so far from multielectrode studies that joint increases in discharge rate are used for response selection and grouping in the context of assembly coding. This may be due to the paucity of multielectrode studies searching for such phenomena. However, it is also conceivable that synchronization and temporal multiplexing are better suited for the definition of relations in assembly coding than joint rate increases.

In assembly coding processing, speed is limited essentially by the rate at which relational codes can be generated and read out. If relations are defined by joint rate increases, readout requires temporal summation of successively arriving excitatory postsynaptic potentials (EPSPs) and hence integration over a sequence of EPSPs. If integration intervals are shorter than the average interspike intervals, EPSPs do not summate effectively and rate increases cannot be detected. Synchronization, by contrast, exploits exclusively spatial and no additional temporal summation to raise the saliency of responses. Therefore, relations can be defined—at least in principle—with a temporal resolution corresponding to the duration of individual EPSPs. Thus, assemblies can be reconfigured and multiplexed at much faster rate when synchronization is used as a tag of relatedness instead of joint rate enhancement. Another, potentially important advantage of using synchrony as a tag of relatedness is that relations can be specified independently of firing rate. Discharge rates depend on numerous variables, such as the physical energy of stimuli or the match between stimulus and receptive field properties. Response amplitudes

The superposition problem

The only solution: segregation in time

are thus rather ambiguous indicators of relatedness. As synchrony can be modulated by temporal regrouping of discharges and thus can be varied independently of firing rates, synchronicity and rate can be used as orthogonal codes. Signals indicating the presence and the properties of visual features can thus be kept separate from signals indicating how these features are related.

Another advantage of using synchronization as a tag of relatedness is that synchronized input is transmitted with minimal latency jitter (Abeles, 1982; Diesmann et al., 1999). Thus, signatures of relatedness can be relayed with great reliability across processing stages, which contributes to reducing the risk of false conjunctions. Finally, synchronization enhances processing speed by accelerating synaptic

FIGURE 113.3. Options for the solution of the superposition problem. Superposition problems arise if perceptual objects are present whose corresponding assemblies partly share the same neurons (*upper box*). In this case, different assemblies need to be segregated in time to avoid false conjunctions. One option is to raise successively the saliency of responses belonging to the respective assemblies by enhancing the discharge rate of the corresponding responses (*lower box*, option 1). An alternative solution is to enhance the saliency of responses belonging to a particular assembly by making the discharges of the respective neurons coincident in time (option 2). This permits rapid multiplexing of the different assemblies because coincidence can be evaluated within short time intervals, as it does not require temporal summation. Here it is assumed that the different assemblies alternate at intervals of approximately 25 msec. Note that this temporal structure can be, but does not have to be, obvious in the discharge sequences of individual neurons (channels 1 to 12) but that the spike density function of the population response shows an oscillatory modulation in the 40 Hz range. Note also that the constellation of neurons contributing spikes to the oscillatory population response changes from cycle to cycle.

transmission per se because synchronized EPSPs trigger action potentials with minimal delay.

Constraints of synchrony

In conclusion, these features make response synchronization an attractive strategy to encode relations. However, in order to be effective, several additional constraints need to be met. First, neuronal networks must be able to modify and to coordinate the temporal patterning of spike trains in a context-dependent manner. Second, it must be possible to structure episodes of coordinated firing and to change the constellations of synchronously discharging neurons within a few tens of milliseconds in order to be compatible with processing speed. Third, the temporal signatures of coordinated discharge sequences must be preserved with millisecond precision across processing stages. Fourth, neuronal networks must be able to distinguish synchronous from temporally dispersed activity with a precision in the millisecond range; that is, synchronous input must have a stronger impact on neurons than asynchronous input. Fifth, since Hebbian learning is based on the evaluation of relations, activity-dependent modifications of synaptic gain must be gated by the synchronicity of pre- and postsynaptic discharge patterns and not only by the mere covariation of rate changes if relations are encoded by synchrony.

However, even if all these constraints are met, this is still not proof that the cerebral cortex uses response synchronization to tag responses as related. It also needs to be shown that the occurrence and structure of synchronous discharge patterns are related in a meaningful way to perceptual or motor processes requiring dynamic grouping of responses. If synchronization matters, it should be possible to predict

behavior from measures of synchrony. Ideally, one would like to obtain not only correlative but also causal evidence for such relations by manipulating synchrony and studying the behavioral consequences.

Are the constraints met?

Evidence suggests that neuronal networks are capable of transmitting temporal patterns with the required precision and of distinguishing between coincident (synchronous) and noncoincident (temporally dispersed) input signals with the necessary temporal resolution. Specialized circuits of the auditory system can exploit latency differences in the sub-millisecond range for sound localization. Signal transduction in the retina is slower than in the ear, but the visual system is also capable of resolving temporal patterns with a precision in the millisecond range. Psychophysical experiments suggest that stimulus onset asynchronies of less than 10 msec can support perceptual grouping. The visual system binds simultaneously appearing pattern elements and segregates them from elements presented with temporal offset (Alais et al., 1998; Lee and Blake, 1999; Leonards et al., 1996; Usher and Donnelly, 1998).

This indicates that temporally modulated responses can be transmitted over several processing stages with a precision in the millisecond range. Supportive evidence comes from electrophysiological investigations. Cross-correlations between simultaneously recorded responses of retinal ganglion cells, relay neurons in the lateral geniculate nucleus, and cortical cells show that the oscillatory patterning of retinal responses is reliably transmitted to the cortex (Castelo-Branco et al., 1998). Given the high frequency of the retinal oscillations (up to 100 Hz), this implies that synchronized volleys of discharges are transmitted over several synaptic stages with a precision in the millisecond range. The well-synchronized cortical responses to flicker stimuli point in the same direction (Rager and Singer, 1998). As indicated by the precise temporal modulation of responses in area MT of the monkey visual cortex, temporal fidelity of synaptic transmission is not confined to primary sensory pathways but also holds for cortico-cortical connections (Buracas et al., 1998). Simulation studies indicate that such precision is readily obtained with neurons that operate with conventional time constants. The only prerequisite is that transmission occurs in parallel channels that interact through diverging and converging axon collaterals (Diesmann et al., 1999). Once neurons at the same processing level have synchronized their discharges, the highly coherent pulse packets are conveyed with minimal dispersion across several synaptic stages, as postulated for synfire chains (Abeles, 1991).

Evidence is also available that synchronization can be established and dissolved very rapidly (within maximally a

few tens of milliseconds). Simulations with spiking neurons revealed that networks of appropriately coupled units can indeed undergo very rapid transitions from uncorrelated to synchronized states and vice versa (Gerstner, 1996). In physiological recordings, it is not uncommon that neurons engage in synchronous activity, often with additional oscillatory patterning, at the same time that they increase their discharge rate in response to the light stimulus (Gray et al., 1992).

The postulate that synchronized activity must have a stronger impact in target structures than temporally dispersed firing is also supported by data. Simultaneous recordings from coupled neuron triplets along thalamocortical and intracortical pathways in the visual system have revealed that EPSPs synchronized within intervals below 2 or 3 msec are much more effective than EPSPs dispersed over longer intervals (Alonso and Martinez, 1998; Alonso et al., 1996; Usrey and Reid, 1999). Multielectrode recordings from several sites of the cat visual cortex and retinotopically corresponding loci in the superior colliculus indicated that the impact of a particular group of cortical cells on target cells in the colliculus increases substantially whenever the cortical cells synchronize their discharges with other cortical cell groups projecting to the same site in the tectum (Brecht et al., 1998). Enhanced saliency of synchronized responses can also be inferred from experiments in amblyopic cats which showed a close correlation between reduced synchrony in primary visual cortex and a loss of responses in higher visual areas (Roelfsema et al., 1994; Schröder et al., 2002). Similar conclusions are suggested by simulation studies (Bair and Koch, 1996; Niebur and Koch, 1994) and in vitro experiments (Stevens and Zador, 1998).

Several mechanisms, some of which have been identified only recently, can account for the enhanced efficacy of synchronously arriving EPSPs. First, because of their exponential decay, simultaneous EPSPs summate more effectively than temporally dispersed EPSPs, and there is some evidence for supralinear summation due to voltage-gated dendritic conductances (Schiller et al., 2000). Second, firing threshold is sensitive to the rising slope of the depolarization and lowers for fast-rising depolarizations such as those characteristic of synchronously arriving EPSPs (C. M. Gray, personal communication). Third, the effect of EPSPs is dramatically enhanced when they coincide with a back-propagating dendritic spike and hence with the input that generated this spike (Larkum et al., 1999). All three mechanisms are sensitive to temporal dispersions of EPSPs in the range of a few milliseconds.

Further evidence that precise temporal relations among neuronal discharges matter in cortical processing comes from investigations of synaptic plasticity. Varying the temporal relations between presynaptic EPSPs and postsynaptic spike responses in simultaneously recorded coupled cortical

cells revealed that long-term potentiation (LTP) results when the EPSP precedes the postsynaptic spike within intervals of 10 msec or less while the polarity of the modification reverses to long-term depression (LTD) as soon as the EPSP follows the spike (Markram et al., 1997). Thus, shifts of a few milliseconds in the timing relations between pre- and postsynaptic discharges suffice to invert the polarity of use-dependent synaptic modifications. The mechanism permitting such precise evaluation of the temporal contiguity of pre- and postsynaptic responses is the active dendritic response associated with the back-propagating spike. The following results obtained from visual cortex slices point in the same direction. They suggest that the temporal windows for Hebbian coincidence matching are sharpened further if neurons engage in oscillatory responses.

Pyramidal cells of rat visual cortex slices were made to discharge tonically at 20 or 40 Hz by injecting sinusoidally modulated current through a patch pipette. Simultaneously, EPSPs were evoked at 20 Hz by electrical stimulation of excitatory afferents. Changing the phase relations between pre- and postsynaptic activity revealed that the stimulated input tended to undergo LTP when the EPSPs were coincident with the spikes, while afferents consistently underwent LTD when the EPSPs fell in the troughs of the membrane potential oscillations. Thus, phase shifts of about 12 msec between individual EPSPs and spikes reversed the polarity of the synaptic modifications (Wespatat et al., 2001, 2003). This indicates that Hebbian modifications are sensitive to the precise phase relations of high-frequency discharges. If the modifications were gated solely by rate covariations, one would not expect such polarity reversals because pre- and postsynaptic discharge rates were the same in the two conditions. This implies further that precise synchrony serves as a signature of relatedness not only in the context of Hebbian learning but also in signal processing. The reason is that the temporal windows within which coincident synaptic events or spikes are treated as related must have the same duration in signal processing and learning, as any discrepancy would cause learning of false conjunctions.

In conclusion, there is converging evidence from different experimental approaches that cortical networks can handle temporal patterns with high precision and that precise timing relations among the discharges of distributed neurons are computationally relevant. Thus, the major constraints for the use of synchrony as a relation defining code are met. But does the brain exploit this option?

General properties of response synchronization

Synchronization of activity is defined operationally as a transient increase in coincident firing of two or more units that exceeds the level of coincidences predicted from estimations of actual discharge rates. Therefore, synchroniza-

tion must be assessed by correlation analysis and cannot be deduced from comparisons of rate fluctuations alone. Because the synchronization phenomena which are of interest here result from internal interactions, the time of occurrence of synchronized discharges is locked only loosely or not at all to external events. This intertrial variability precludes detection of synchronized response segments in histograms averaged over successive trials. Thus, episodes of enhanced response synchronization are detectable only if responses of different neurons are recorded simultaneously and subjected to a trial-by-trial correlation analysis.

The results of such analyses indicate that synchronization by internal neuronal interactions is a frequent phenomenon that occurs in many cerebral structures (for recent reviews, see Engel et al., 2001; Singer, 1999). It has also been noted that response synchronization is often associated with an oscillatory patterning which is best revealed by recording jointly the activity of several adjacent cells. The reasons for the better detectability of oscillations in population responses are two. First, individual cells tend to skip oscillation cycles in an irregular manner; second, oscillatory epochs are usually short and oscillation frequencies variable. Therefore, the periodicity of oscillatory population responses is often not apparent in the firing patterns of individual cells, even if their discharges are precisely phase locked to the oscillatory activity of the population. For this reason, synchronized oscillatory activity is detected best with methods that assess population responses such as recordings of multi-unit activity, local field potentials (LFPs), or the electroencephalogram (EEG). These global signals can then be correlated with the activity of individual cells to determine whether the discharges of the recorded cells are correlated with the synchronized activity of surrounding cell populations. Such measurements of spike-field coherence have proven highly efficient to detect changes in the synchronization of neurons and in the frequency of oscillatory patterning (see below).

Several properties make response synchronization, as it has been observed in the visual cortex, a good candidate mechanism for the definition of relations. First, synchronization is sufficiently precise, in particular when it occurs on the basis of beta and gamma oscillations, to raise the saliency of the synchronized responses and to be computationally effective. Second, joint firing is not simply the result of coherent, stimulus-locked variations in discharges rate, nor is it a trivial reflection of anatomical connectivity such as shared input. Rather, synchronization is generated by dynamic interactions within the cortical network, and its spatiotemporal patterning depends on a large number of variables; among these are the stimulus configuration (Engel et al., 1991b; Gray et al., 1989), the architecture of the intracortical synchronizing connections (Engel et al., 1991a; Löwel and Singer, 1992), the activation state of the cortical

network (Herculano-Houzel et al., 1999; Munk et al., 1996), and attention-dependent effects (Fries, et al., 2001b; Roelfsema et al., 1997; Steinmetz et al., 2000). These multiple influences endow synchronization with the required context sensitivity. Third, synchronization can be established across different cortical areas (Engel et al., 1991c; Roelfsema et al., 1997) and even hemispheres (Engel et al., 1991a) which is required for a relational code. Fourth, synchrony has been shown to vary independently of rate changes (Herculano-Houzel et al., 1999; Riehle et al., 1997), which is advantageous for the encoding of relations (see above). Fifth, synchronization is not an all-or-none phenomenon. When populations of cells engage in synchronous oscillatory activity, individual cells can skip cycles (Buzsaki, 1996; Buzsaki and Chrobak, 1995), and cells participating in population oscillations of different frequency can engage in partial correlations (Jensen and Lisman, 1998). This can be exploited to express graded and nested relations (Luck and Vogel, 1997). Sixth, when cells engage in synchronous oscillatory activity, the probability increases that the same cells synchronize in subsequent trials (Herculano-Houzel et al., 1997, 2003). In principle, this makes it possible to store information about relations by changing synchronization probability.

In the following some of these features of response synchronization will be discussed in more detail. Emphasis is placed on synchronization phenomena in the visual system and on relations between synchrony and cognitive processes.

Perceptual grouping

Scene segmentation and perceptual grouping are typical examples of low-level visual functions requiring flexible definition of relations. If internal synchronization of discharges serves to tag responses as related and to ensure their joint processing, synchronization probability among neurons in early visual areas should reflect some of the basic Gestalt criteria according to which the visual system groups related features during scene segmentation. Multielectrode studies designed to test this prediction revealed that neurons distributed across different columns within the same or different visual areas and even across hemispheres tend to synchronize their responses with close to zero phase lag when activated with a single contour but fire independently when stimulated simultaneously with two different contours (Engel et al., 1991a; Engel et al., 1991b; Engel et al., 1991c; Freiwald et al., 1995; Gray et al., 1989; Kreiter and Singer, 1996). Further analysis of the dependence of synchrony on receptive field and stimulus configurations confirmed that the probability and strength of response synchronization reflected elementary Gestalt criteria for perceptual grouping such as continuity, proximity, similarity in the orientation

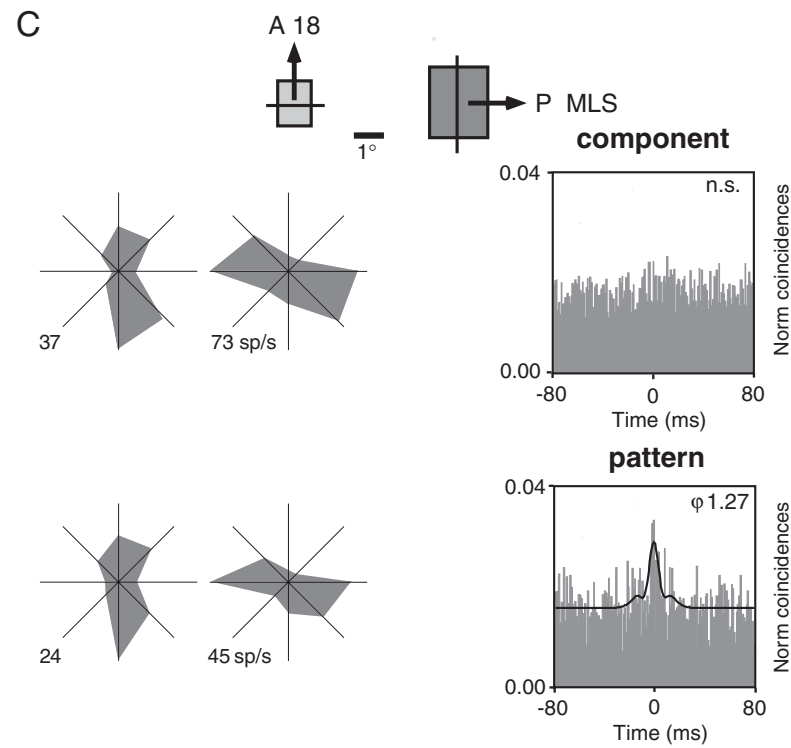

domain, colinearity, and common fate (for review, see Gray, 1999; Singer, 1993; Singer et al., 1997). These early experiments were performed in anesthetized animals, but more recent multielectrode recordings from awake cats and monkeys indicate that these synchronization phenomena are not artifacts of anesthesia but are even more pronounced when the animals are awake and attentive (Friedman-Hill et al., 2000; Fries et al., 1994; Fries et al., 1997; Gray and Viana Di Prisco, 1997; Kreiter and Singer, 1992, 1996; Maldonado et al., 2000). It is noteworthy that none of these systematic changes in synchronization probability have been associated with systematic stimulus-dependent changes of the neurons' discharge rate.

A particularly close correlation between neuronal synchrony and perceptual grouping has recently been observed in experiments with plaid stimuli. These stimuli are well suited for the study of dynamic binding mechanisms because minor changes of the stimulus cause a binary switch in perceptual grouping. Two superimposed gratings moving in different directions (plaid stimuli) may be perceived either as two surfaces, one being transparent and sliding on top of the other (component motion), or as a single surface, consisting of crossed bars, that moves in a direction intermediate between three of the component vectors (pattern motion) (Adelson and Movshon, 1982; Stoner et al., 1990). Which percept dominates depends on the luminance of grating intersections, because this variable defines the degree of transparency, or on the duty cycle of the gratings, because this variable determines changes in foreground-background assignments (Albright and Stoner, 1995). Component (pattern) motion is perceived when luminance conditions are compatible (incompatible) with transparency (Fig. 113.4*A*). Here is a case where the percept changes when the assignment of relations among stimulus components changes. If responses evoked by the two different gratings are treated as unrelated and only responses evoked by the contours of the same grating are bound together, one perceives two surfaces; conversely, if responses to all contours are treated as related, one perceives a single surface. If assignment of these different relations is achieved by selective synchronization, two predictions must hold (Fig. 113.4*B*): First, neurons whose responses represent the moving contours of the same grating should always synchronize. This is the case for cells that prefer the direction of motion of one of the two gratings and have colinearly aligned receptive fields. Second, groups of neurons that are tuned to respond to different gratings should synchronize their responses if they mediate the percept of pattern motion because in this case they must signal that all contours belong to the same surface and are related. By contrast, the same groups of cells should not synchronize if they mediate the percept of component motion because in this case their responses must be treated as unrelated. Such

B Predictions on Synchronization

	component: pattern:	sync sync
	component: pattern:	no sync sync
	component: pattern:	no sync sync

differential synchronization behavior should be particularly pronounced for cell pairs that have clear preferences for the two different gratings, that is, for cells with spatially offset receptive fields that are sharply tuned for the different directions of motion of the two gratings.

Cross-correlation analysis of responses from cell pairs distributed either within or across areas 18 and the post-eromedial lateral suprasylvian complex (PMLS) of lightly anaesthetized cats confirmed these predictions. Cells synchronized their activity if they responded to contours that were perceived as belonging to the same surface (Castelo-Branco et al., 2000) (Fig. 113.4C). Analysis of the neurons' discharge rate confirmed that most of the cells in these visual areas respond preferentially to the component gratings of the plaids (component specific cells; Gizzi et al., 1990) and not to the pattern as a whole. However, in contrast to synchrony, variations in response amplitude failed to reflect the transition from component to pattern motion induced by transparency manipulation. Dynamic changes in synchronization could thus serve to encode in a context-dependent way the relations among the simultaneous responses to spatially superimposed contours and thereby bias their association with distinct surfaces.

In all experiments referred to in this review, trials with different stimulus configurations were interleaved randomly to counterbalance possible effects of slow drifts in central state that may have caused covariations of discharge rate at a slow time scale. Moreover, phasic response components were excluded from correlation analysis to avoid artifactual correlations due to instationarities in discharge rate (Brody, 1999a, 1999b). Accordingly, the shift predictors (correlograms between responses to the same stimulus configuration selected from different trials) were always flat, indicating that the changes in the correlations were caused by context-dependent changes of internal interactions and not by changes in stimulus-locked or state-dependent covariations of discharge rate.

Perceptual selection

If synchronization serves to raise the saliency of responses, one should expect that it is used as a mechanism for response selection that is complementary to response selection by rate

increases. The studies described in this paragraph deal with such aspects of response selection. A close relation between synchronization and response selection has been found in cats that suffered from strabismic amblyopia, a developmental impairment of vision associated with suppression of signals conveyed by the amblyopic eye, reduced visual acuity, and crowding. *Crowding* refers to the inability of amblyopic subjects to identify target stimuli if these are surrounded by nearby contours and is thought to result from false binding of responses evoked by the target and the embedding background. Quite unexpectedly, the response properties of individual neurons in the primary visual cortex appeared normal, and the neurons continued to respond vigorously to stimuli which the animals had been unable to resolve through the amblyopic eye during prior behavioral testing. The only significant correlate of amblyopia detected in this study was a reduction of response synchronization among neurons driven by the amblyopic eye. This reduction in synchrony became particularly pronounced when responses were evoked with gratings that had been identified in previous behavioral experiments as too fine to be resolvable by the animal through the amblyopic eye (Roelfsema et al., 1994). This impaired ability to synchronize responses is likely to account for at least some of the perceptual deficits: by reducing the saliency of responses, it could explain why signals from the amblyopic eye cannot compete successfully with the well-synchronized responses from the normal eye and are excluded from supporting perception when both eyes are open. Recent recordings from area 21, a higher visual area, have indeed shown that the poorly synchronized responses evoked from the amblyopic eye drive neurons in area 21 less efficiently than the well-synchronized responses from the normal eye (Schröder et al., 2002). Poor synchronization is also likely to be responsible for the reduction in visual acuity and for crowding. If grouping of responses related to the same contour and segregation of responses evoked by unrelated contours require intact synchronization mechanisms, then impaired synchronization is likely to impede the disambiguation of responses evoked by closely spaced stimuli.

A correlation between response synchronization and stimulus selection has also been documented in experiments on binocular rivalry that were again performed in strabismic

FIGURE 113.4. *A*, Two superimposed gratings that differ in orientation and drift in different directions are perceived either as two independently moving gratings (component motion) or as a single pattern drifting in the intermediate direction (pattern motion), depending on whether the luminance conditions at the intersections are compatible with transparency. *B*, Predictions on the synchronization behavior of neurons as a function of their receptive field configuration (*left*) and stimulation conditions (*right*). *C*, Changes in the synchronization behavior of two neurons recorded

simultaneously from areas 18 and the PMLS that were activated with a plaid stimulus under component (*upper graph*) and pattern motion conditions (*lower graph*). The two neurons preferred gratings with an orthogonal orientation (see the receptive field configuration at the top and the tuning curves obtained with the component and pattern, respectively) and synchronized their responses only when activated with the pattern stimulus (compare the cross-correlograms on the right). (Adapted from Castelo-Branco et al., 2000.)

animals (Fries et al., 1997, 2002). Perception in strabismic subjects always alternates between the two eyes. This can be exploited to investigate how neuronal responses to constant stimuli change if they pass from being selected and perceived to being suppressed and excluded from perception and vice versa (Fig. 113.5). The outcome of these experiments was surprising because the responses of neurons in areas 17 and 18 were not enhanced in amplitude when they supported perception and were not attenuated when they were excluded from supporting perception. A close and highly significant correlation existed, however, between changes in the strength of response synchronization and the outcome of rivalry. Cells mediating responses of the eye that won in interocular competition increased the synchronicity of their responses upon presentation of the rivalrous stimulus to the other, losing eye, while the reverse was true for cells driven by the eye that became suppressed. The synchronized responses exhibited an oscillatory modulation in the gamma frequency range, and rivalry-related changes in synchrony were particularly pronounced in measurements of spike-field coherence (see above). Thus, in primary visual cortex there are instances where internal selection of responses for further processing is associated with enhanced synchronization rather than increased firing. This agrees with rivalry experiments in awake, behaving monkeys which showed no systematic relation between the strength of visual responses and perception in early visual areas but a clear correlation between perceptual suppression and loss of neuronal responses in higher visual areas (Leopold and Logothetis, 1996; Logothetis and Schall, 1989; Sheinberg and Logothetis, 1997). This is what one expects if the saliency of the responses from the two eyes is adjusted at early processing stages by modulating synchronization rather than discharge rates.

Dependency on central states and attention

A characteristic feature of response synchronization is its marked state dependency. It is particularly prominent when the cortex is in an activated state, that is, when the EEG is desynchronized and exhibits high power in the beta and gamma frequency range (Fig. 113.6) (Herculano-Houzel et al., 1999; Munk et al., 1996). In particular, synchronization over long distances that requires oscillatory patterning of responses breaks down completely when the EEG gets “synchronized” and exhibits high power in the low-frequency range (<10 Hz). This close correlation between the occurrence of response synchronization, on the one hand, and EEG states characteristic of the aroused and performing brain, on the other hand, may be taken as support for a functional role of precise synchrony in cortical processing.

The magnitude and precision of synchronization in the beta and gamma frequency range also vary in the fully

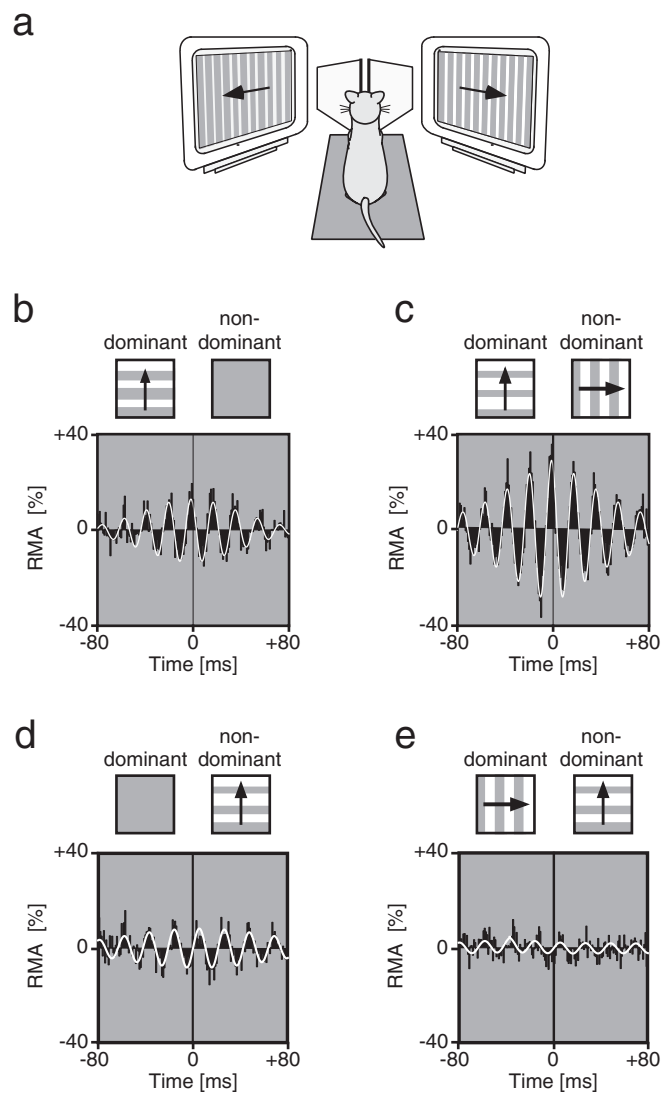

FIGURE 113.5. Neuronal synchronization under conditions of binocular rivalry. *A*, Using two mirrors, different patterns were presented to the two eyes of strabismic cats. Panels *B* to *E* show normalized cross-correlograms for two pairs of recording sites activated by the eye that won (*B*, *C*) and lost (*D*, *E*) in interocular competition, respectively. Insets above the correlograms indicate stimulation conditions. Under monocular stimulation (*B*), cells driven by the winning eye show a significant correlation, which is enhanced after introduction of the rivalrous stimulus to the other eye (*C*). The reverse is the case for cells driven by the losing eye (compare conditions *D* and *E*). The white continuous line superimposed on the correlograms represents a damped cosine function fitted to the data. RMA, relative modulation amplitude of the center peak in the correlogram, computed as the ratio of peak amplitude over offset of correlogram modulation. This measure reflects the strength of synchrony. (Modified from Fries et al., 1997.)

FIGURE 113.6. State dependence of response synchronization. *Upper row:* Power distribution in the EEG recorded during three episodes from an anesthetized cat. *Lower row:* Averaged cross-correlograms of multiunit responses evoked by a drifting grating and recorded from two different sites in A17 during corresponding episodes. Note that the synchronization of the responses and the oscillatory modulation in the gamma frequency range increase with

increasing gamma activity in the EEG. Inserts in the power spectra give the relative power in the delta and gamma frequency range. Inserts in the cross-correlograms give the oscillation frequency (Hz) and the relative modulation amplitude of the center peak (MA) and of the first side peak (MAS). (From Herculano-Houzel et al., 1999.)

aroused brain and are then correlated with fluctuations of attention. Such modulation of synchrony has been observed in cats trained to perform a visually triggered motor response. The visual, association, somatosensory, and motor areas involved in the execution of the task synchronized their oscillatory activity in the beta frequency range as soon as the animals focused their attention on the relevant stimulus; the strength of synchronization among areas reflected precisely the coupling of these areas by corticocortical connections. Immediately after the appearance of the visual stimulus, synchronization increased further, and these coordinated activation patterns were maintained until the task was completed. However, once the reward was available and the animals engaged in consummatory behavior, these coherent patterns collapsed and gave way to low-frequency oscillatory activity that did not exhibit any consistent relations with regard to phase and areal topology (Roelfsema et al., 1997). These results suggest that an attention-related process had imposed a coherent temporal patterning on the activity of cortical areas required for the execution of the task. Such anticipatory enhancement of coherence could facilitate rapid synchronization of responses both within and across areas once the stimulus appears, thereby accelerating selection and grouping of responses.

Anticipatory synchronization patterns would be particularly effective if they exhibited some topological specificity and reflected the architecture of tangential intracortical connections. In that case, they could serve as a readout mechanism that translates the grouping criteria defined by intercolumnar connections into dynamic patterns of coher-

ent activity against which incoming signals can be matched. Recent evidence supports such a scenario. Measurements of fluctuations in response latency revealed that self-generated gamma activity exhibits a specific patterning that reflects the grouping criteria of vicinity and colinearity. Response latencies of neurons in striate cortex fluctuate considerably for identical, repeatedly presented stimuli, but these fluctuations are not random. Rather, they are correlated across cortical columns sharing similar feature preferences (Fries et al., 2001a). Correlating response latencies of cells recorded from one site with the fluctuations of LFPs recorded from a site in the opposite hemisphere that had the same orientation preference revealed that response latencies could be predicted from the phase of the ongoing LFP oscillations if these were in the gamma frequency range. This suggests that the synchronization of the very first spikes of a response is due to ongoing oscillatory fluctuations of the cells' membrane potential and that these fluctuations can be coherent over large distances, in this case across hemispheres. These oscillations of membrane potential delay or advance responses to light stimuli, depending on the timing of the stimulus relative to the phase of the ongoing oscillation. The reason is that in oscillating cells the discharges evoked by a barrage of EPSPs are only loosely time-locked to the EPSPs and occur predominantly around the peak of the respective next depolarizing cycle because of an NMDA receptor-mediated delay mechanism (Volgushev et al., 1997). As a result, cells located in coherently oscillating columns become synchronized right from the beginning due to latency adjustment.

Analysis of the receptive field properties of cell pairs revealed that latency fluctuations are often coherent for cells that have overlapping receptive fields. For cells with nonoverlapping fields, these fluctuations are coherent only if the cells have a similar orientation preference. These results suggest that columns encoding spatially contiguous stimuli or contours with similar orientation tend to oscillate spontaneously in phase. This, in turn, enhances through latency adjustment the temporal coherence of responses to nearby contours or to contours with similar orientation preference. As contours appearing in such constellations tend to be grouped perceptually, this mechanism of response coordination could be exploited for perceptual grouping. Anatomical evidence indicates that the corticocortical association connections link preferentially columns coding for related features that tend to be grouped perceptually (Gilbert and Wiesel, 1989; Malach et al., 1993; Schmidt et al., 1997; Ts'o and Gilbert, 1988), and physiological data suggest that these corticocortical connections contribute to the synchronization of spatially segregated groups of neurons (Engel et al., 1991a; König et al., 1993; Löwel and Singer, 1992). Thus, spontaneous activity could serve to continuously translate the functional architecture of the association connections into coordinated fluctuations of neuronal excitability. The coherent oscillations of the LFP could then be regarded as the dynamic correlate of the grouping rules defined by the association connections. Inevitably, the pattern of these fluctuations is also modified by top-down influences from higher cortical areas and by immediately preceding changes of sensory input. Both effects would be equivalent to the functions commonly attributed to attentional mechanisms, the selection and binding of expected events as a consequence of either bottom-up priming or intentional top-down selection. The observed fluctuations could thus be equivalent to the system's updated expectancy that is determined by the fixed, locally installed grouping rules, by top-down influences, and by preceding sensory input. Seen in this context, ongoing activity assumes the function of a predictor against which incoming activity is matched (Grossberg, 1999). One of the effects of matching these predictions with incoming signals is a rapid temporal regrouping of output activity (see Fig. 113.7).

Direct evidence for an attention-dependent anticipatory modulation of synchronous gamma oscillations has recently been obtained in area V4 of the monkey visual cortex (Fries et al., 2001b). While the monkey expected a visual stimulus that needed to be discriminated, coherence between "spontaneous" unit discharges and LFP oscillations increased in the gamma frequency range. This increase was specific for the site where the relevant stimulus was expected to appear and was not associated with a modulation of discharge rate. When the stimulus appeared, responses exhibited better coherence when the stimulus was attended

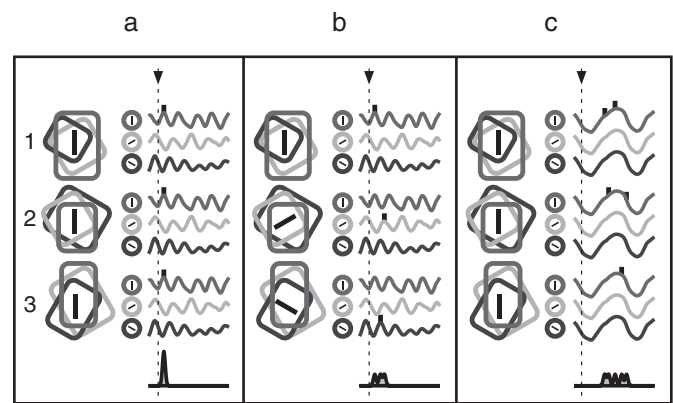

FIGURE 113.7. A model of rapid feature selective neuronal synchronization through correlated latency shifting. *A*, Three groups of neurons are shown schematically as circles (*middle column*). The three groups have relative frequencies at different locations in the visual field (*left column*), and each group contains neurons with three different orientation selectivities (*small black bars inside circles*). The graphs in the right column depict LFPs dominated by gamma frequency oscillations that reflect the neurons' membrane potential fluctuations. The model assumes that fluctuations are coherent for neurons of the same orientation preference but incoherent for neurons preferring dissimilar orientation. When a stimulus array of three vertical bars (*black bars over the relative frequencies*) is presented, only the neurons selective for vertical orientations respond. The arrow and the dotted vertical line over LFPs indicate the time when stimulus-driven synaptic input reaches the recorded neurons. As their response onsets are shifted coherently by the coherent membrane potential fluctuations, their first spikes are correlated and add up to a strong population response, shown as a spike density function in the lowest trace. Note that for the sake of clarity, we have focused on the effect of similarity of orientation selectivity and ignored relative frequency overlap as a factor influencing the strength of latency correlations. *B*, The same conventions as in *A*, but stimulation with bars of different orientations. Neurons of different orientation selectivities are activated by the three bars. As in this case, the neuronal membrane potentials fluctuate incoherently, the response onsets are not aligned, and the population response is spread out in time. *C*, The same conventions as in *A*, but the LFP is dominated by low-frequency oscillations. These low-frequency oscillations are globally synchronous (coherence is not dependent on orientation selectivity), but due to their low frequency, they have no latency-shifting effect. Upon stimulation with three aligned bars, the neurons fire more spikes than with gamma-dominated LFP (*A*), but the latency is long, the spikes are not synchronized, and the responses to nonaligned bars would exhibit the same temporal dispersion as the responses to aligned bars. (Courtesy of Pascal Fries.)

to than when attention was directed to another, distracting stimulus. Similar attention-dependent enhancement of synchrony has been observed among neurons in the somatosensory cortex of monkeys engaged in a tactile discrimination task (Steinmetz et al., 2000).

These results suggest that cognitive processes consist not simply of the extraction and recombination of features but also of an active matching operation in which afferent sensory activity is compared with self-generated dynamic

states. This anticipatory nature of cortical computations is probably one reason why processing of sensory signals is so fast (for a detailed review of relations between top-down processing and synchronous oscillations, see Engel et al., 2001).

Plasticity of synchronizing connections

If synchronization serves to establish relations between neuronal responses, synchronizing connections must be susceptible to use-dependent modifications. This is required to implement new grouping criteria by learning and to stabilize assemblies representing previously experienced conjunctions. Synchronization probability must increase durably for groups of cells that have been forced previously to engage repeatedly in highly synchronous firing, and the mechanism mediating these use-dependent changes in synchronization probability must be capable of distinguishing between synchronous and nonsynchronous firing with a temporal resolution that is in the same range as the temporal precision of observed synchrony. Both postulates have recently received experimental support. Herculano-Houzel et al. (1997, 2003) have shown that synchronization probability increases between groups of neurons if these engage repeatedly in synchronous oscillatory firing in the gamma frequency range. This enhanced tendency of neurons to synchronize their responses to coherent stimuli can be reduced again by having the same cells engage repeatedly in oscillatory firing patterns that are decorrelated. These increases and decreases of synchronization probability appeared to depend on the precise phase relations of the oscillatory discharges during conditioning because, on a coarser time scale (>50 msec), the neurons' activity overlapped completely in both conditioning paradigms.

To obtain these lasting modifications in synchronization probability in anesthetized cats, it was necessary to pair the light stimuli that induced synchronous (asynchronous) oscillatory firing of cortical cell pairs with electrical stimulation of the mesencephalic reticular formation (MRF). Activation of the MRF has several probably causally related effects. It desynchronizes the EEG, as is the case with arousal. This, in turn, enhances oscillatory modulation of visual responses in the gamma frequency range and increases the magnitude and precision of synchronization (see above). These effects are probably mediated by muscarinic receptors in the cortex that are activated by enhanced release of acetylcholine from projections originating in the basal forebrain. This is suggested by two observations: first, MRF stimulation enhances acetylcholine release in striate cortex, and in nonrodents the only source of cholinergic afferents to striate cortex is the basal forebrain (Mesulam et al., 1983). Second, iontophoretic application of scopolamine in the striate cortex abolishes both gamma oscillations and response synchrony

(Rodriguez et al., 2001, 2003). The facilitation of lasting modifications of synchronization probability by MRF stimulation could thus have two quite different causes. It could be due to enhanced synchrony and the resulting increase in cooperativity among synchronously active synaptic inputs, but it could also be due to the plasticity-enhancing effect of acetylcholine. Both scenarios are supported by experimental evidence. Experiments on use-dependent synaptic plasticity in slices of the hippocampus and the visual cortex have revealed that induction of modifications such as LTP and LTD is facilitated both by increasing cooperativity among synaptic inputs (Gustafsson and Wigstrom, 1986) and by application of carbachol, the latter effect being mediated by muscarinic receptors (Bröcher et al., 1992). Both increased cooperativity and muscarinic activation enhance depolarization, the latter via blockade of K^+ currents. This, in turn, augments entry of calcium via NMDA receptors and voltage-gated calcium channels, thus increasing the probability of the occurrence of LTP and LTD (Hansel et al., 1997). However, there are numerous other routes by which acetylcholine can facilitate plasticity because muscarinic receptors modulate a variety of intracellular signaling cascades that control NMDA receptor efficacy, Ca^{2+} release from internal stores, and gene expression.

The observation that synchronous and asynchronous firing had opposite effects on synchronization probability, although discharge rates were comparable in the two conditions, suggests that the mechanism mediating the long-term modifications is sensitive to the precise phase relations among the oscillatory discharges rather than to the covariation of discharge rates. The recent slice data on spike timing-dependent plasticity and the phase sensitivity of LTP and LTD are compatible with this interpretation (see above).

Synchronized gamma oscillations and visual perception in human subjects

In a series of pioneering EEG studies, evidence has been obtained that the engagement in cognitive tasks requiring figure-ground distinctions and feature binding (Tallon-Baudry et al., 1996, 1997) or perceptual switching during perception of bistable figures (Keil et al., 1999) or the retention of visual patterns in short-term memory (Tallon-Baudry et al., 1998, 1999) are associated with transient increases of gamma oscillations in cortical areas involved in the respective tasks. These findings have recently been extended by the demonstration that during a face recognition task, populations of neurons not only synchronize locally on the basis of gamma oscillations but also phase-lock across large distances with zero phase lag. A particularly interesting finding was that these large-scale synchronization patterns dissolved and settled into new configurations at exactly the time when

subjects recognized the pattern and prepared the execution of the motor response (Rodríguez et al., 1999).

A close correlation has also been found between the establishment of coherent gamma oscillations across cortical areas and the acquisition of a visuotactile association in classical conditioning. Once subjects have learned about the association between a visual and a tactile stimulus, the visual stimulus evokes gamma activity over the visual cortex that is coherent with gamma activity over the somatosensory cortex contralateral to the stimulated finger; this coherence breaks down again upon extinction (Miltner et al., 1999). Finally, evidence has been obtained in an MEG study on binocular rivalry that activity evoked from the eye that dominates perception during rivalry is better synchronized than activity evoked by the suppressed eye (Tononi and Edelman, 1998; Tononi et al., 1998). This agrees with the rivalry experiments in cats (Fries et al., 1997).

Consistent with a functional role of synchronized gamma oscillations is the observation that these oscillations are closely related to arousal and attention. In human subjects, gamma oscillations are enhanced in responses to attended as compared to nonattended stimuli (Gruber et al., 1999; Müller et al., 2001; Tiitinen et al., 1993). They disappear in deep anesthesia (Madler and Pöppel, 1987) but are present during paradoxical sleep, where dreaming, that is, reactivation of memories, is thought to occur (Llinas and Ribary, 1993; Steriade, 1999).

Conclusions

Taken together, the data and arguments presented in this chapter support the notion that neuronal networks are capable of evaluating with a precision in the millisecond range the temporal relations among the discharges of neuronal populations, and that precise timing relations are computationally relevant in the context of both signal processing and synaptic plasticity. Evidence suggests further that cortical networks exploit this ability not only to transmit with high temporal fidelity the temporal features of stimuli across processing stages but also to impose temporal signatures on neuronal activity that can be used in a variety of ways. Frequently observed signatures are an oscillatory patterning and precise synchronization of discharges. Evidence available so far suggests that the oscillatory patterning serves to synchronize responses at variable time scales and that synchronization enhances with high temporal resolution the saliency of the synchronized discharges. This, in turn, appears to be used for a variety of functions that require selection of responses for further joint processing. Changes in synchrony correlate with both preattentive switches in stimulus selection—as indicated by the rivalry experiments—and with attention-dependent stimulus selection. Furthermore, synchronization appears to be used to label responses as related

FIGURE 113.8. Representation of solutions for the readout of assemblies. The distributed responses of assemblies A to C could be read out (bound together) by conjunction-specific neurons that receive convergent input from the members of each of the three assemblies (*upper box*). This solution is not attractive because it leads to a combinatorial explosion of the number of required readout units. Moreover, it generates a bottleneck problem (*middle box*) because the activity of individual readout neurons needs to be redistributed onto large assemblies of neurons to orchestrate executive functions. The alternative option is the readout of assemblies by assemblies (*lower box*). This requires parallel reentry connections between the respective cortical areas in which “sending” and “receiving” assemblies are configured.

in the context of both signal processing and use-dependent synaptic modifications. This latter function has the characteristics of a binding mechanism that permits rapid context-dependent definition of relations in ever-changing constellations. It is therefore ideally suited to serve as a selection mechanism in assembly coding that associates distributed responses with one another and ensures their joint

processing. Assembly coding, in turn, appears necessary to cope with the representation of the astronomical number of possible relations that can exist among the features of real-world objects and among the objects constituting visual scenes. Thus, both theoretical considerations and experimental evidence converge in the conclusion that the cerebral cortex probably uses two complementary strategies to encode relations: first, an explicit representation of relations by the responses of conjunction specific neurons and, second, an implicit representation of relations by dynamically associated assemblies. The first strategy seems to be applied for the representation of a limited set of conjunctions and is probably reserved for items that occur very frequently and/or are of particular behavioral importance. The second strategy seems to be reserved for the representation of novel conjunctions and all those relations that do not warrant explicit representation, either because these would require too many neurons or because the contents to be represented are too infrequent to justify the implementation of specialized and henceforth committed neurons.

A frequently posed question is how the distributed activity of assemblies is read out in order to support decisions and instantiate actions. The intuitively most plausible solution would be to postulate readout neurons, as indicated in Figure 113.8, that receive convergent input from the respective assemblies and have their thresholds adjusted so that they discharge only if all members of the assembly discharge in synchrony. This, however, would jeopardize all the advantages of assembly coding and would reintroduce exactly those problems whose solution requires assembly coding: the combinatorial explosion of object specific units, the difficulty of representing novel contents, the lack of systematicity, and the bottleneck problem. Therefore, alternative readout strategies are required. The most straightforward scenario appears to consist of mapping assemblies onto assemblies without interposed convergence nodes (Fig. 113.8). If one assumes that executive commands are also implemented by assemblies of distributed neurons, sensory assemblies could be mapped directly onto motor assemblies. The only constraint is that distributed learning processes at the level of the reciprocal connections between sensory and motor assemblies ensure that the formation of a particular assembly at the input stage favors stabilization of the corresponding assembly at the output stage. In this case, processing could remain distributed all the way through the system. If so, this has consequences with respect to the formulation of working hypotheses and the design of experiments. If codes are distributed and if relations between responses are defined in the temporal domain, then the search for sensory or motor representations will require simultaneous recording from large numbers of neurons and evaluation of higher-order correlations among their responses.

114 The Neuronal Basis of Visual Consciousness

CHRISTOF KOCH AND FRANCIS CRICK

WE OUTLINE IN THIS chapter some of our present ideas about consciousness in general and visual consciousness in particular. (For an up-to-date summary, see Crick and Koch, 2003.) For now, we believe that the most productive research strategy is to focus on the neuronal correlates of consciousness (NCC). The next step is to establish the exact nature of the causal relationship between neuronal events and subjective feelings and, finally, to understand the thorny philosophical problem of qualia or subjective feelings and how they can arise out of certain physical systems. We assume that higher mammals, such as rodents or primates, share certain forms of sensory consciousness with humans, even though these animals lack language skills.

To characterize the NCC, we have to contrast neural activity that directly gives rise to conscious sensations, thoughts, or action with neural activity that is associated with unconscious, stereotyped, and on-line visuomotor behavior. Where is the difference between these forms? How do these differences in activity relate to the ventral and dorsal streams (Ungerleider and Mishkin, 1982)? We emphasize the importance of explicit representations, the idea of essential nodes in a network, and whether such nodes correspond to the columnar properties of a patch of cortex. We also discuss whether the correlated firing of a set of neurons is needed for consciousness and the role of cortical area V1 and prefrontal areas in consciousness. We end by briefly describing some of the relevant experiments. For earlier versions of these ideas, see Crick and Koch (1998) and Koch and Crick (2000).

Prolegomenon to any study of consciousness

The most puzzling aspect of vision and visual perception is that it gives rise to conscious seeing: to the vivid sense of a hot pink shirt, the sight of the face of a loved one, or the profound sense of depth when gingerly stepping up to the edge of a bluff. After a hiatus of half a century or more (e.g., Westheimer, 1999), the physical origins of consciousness are once again being vigorously debated in numerous books and monographs published in the past decade. What is it that we can ascertain about the neurobiological basis of consciousness, in particular visual

consciousness, and what can we reasonably assume at this point in time? Neuroscientists have made a number of working assumptions that, in the fullness of time, need to be justified more fully.

Firstly, and most importantly, is the assumption there is something to be explained—that the subjective content associated with a conscious sensation exists and has its physical basis in the brain. Philosophers refer to this as *qualia*, *what-it-is-like*, the *aboutness of consciousness*, and other terms. At this point in time, no even remotely satisfactory accounts of why brains can produce subjective feelings have been presented. Our strategy is to focus for now on other aspects of qualia where progress can be made.

There is general agreement that much of consciousness is private. I cannot convey to you exactly how red looks to me, even if experiments show that you and I respond to colors in a very similar way. We have claimed (Crick and Koch, 1995a) that this is because, at each stage of processing in the cortex, the information symbolized is recoded, so that the more internal neural activity is expressed only very indirectly in any motor output, such as speech. On the other hand, a person can say whether two shades of red appear identical or not. It is not surprising that much of the content of consciousness is largely private. What is mysterious is the exact nature of these internal experiences.

Secondly, consciousness is one of the principal properties of the human brain, a highly evolved system. Therefore, it must have some useful function to perform. It is extremely unlikely that the well-structured nature of conscious representations are epiphenomena without any causal function, as is sometimes asserted by philosophers. We (Crick and Koch, 1995b) assume that the function of visual consciousness is to produce the best current interpretation of the visual scene—in the light of past experiences—and to make it available, for a sufficient time, to the parts of the brain which contemplate, plan, and execute voluntary motor outputs (including language). This needs to be contrasted with on-line or zombie behaviors that bypass consciousness but can generate stereotyped motor outputs (see below).

Thirdly, at least some animal species possess some aspects of consciousness. In particular, this is assumed to be true for nonhuman primates such as the macaque monkey. Visual

consciousness is likely to be similar in humans and monkeys for several reasons. (1) For most sensory tasks (e.g., for visual motion discrimination, as discussed in Chapters 81 to 83), trained monkeys behave as humans do under similar conditions. (2) The gross neuroanatomy of humans and nonhuman primates is the same once the difference in size has been accounted for. This is not to deny differences in the microcircuitry or the existence of cell types unique to humans and great apes (Nimchinsky et al., 1999). (3) As emphasized throughout this book, functional brain imaging in humans is confirming the existence of a functional organization similar to that characterized by single-cell electrophysiology in the monkey.

As a corollary, it follows that neither language nor a highly developed sense of the self or of others is necessary for consciousness to occur. Indeed, even severely autistic individuals can carry out very complex sensory discrimination tasks and show no evidence of deficits in sensory discrimination or detection tasks, conscious or not (Baron-Cohen, 2001). Of course, language does enrich consciousness considerably, but there is little hard evidence that it is necessary for conscious sensations to occur.

Conscious and nonconscious visual behaviors

We can state bluntly the question that neuroscience must ultimately answer: it is probable that at any moment some active neuronal processes in our heads correlate with consciousness, while others do not; what is the difference between them? We refer to the minimal neuronal mechanisms necessary and sufficient for any one specific conscious percept as the *neuronal correlates of consciousness* (NCC). We believe that at this point in time, it is empirically most profitable to seek to identify the NCC and to defer many of the other problems (such as qualia).

It is critical to distinguish levels of consciousness (as in drowsy versus awake) from the NCC associated with a specific phenomenal content. This distinction reflects everyday experience of the distinction between being conscious versus unconscious, on the one hand, and being conscious of a high C versus not being consciousness of this tone. *Enabling factors* are required for any conscious sensation to occur without reflecting any specific one.

Cognitive and clinical research demonstrates that much complex information processing can occur without involving consciousness. In normal subjects, such *unconscious* processing includes priming, many aspects of oculomotor behaviors, the implicit recognition of complex sequences, posture adjustment, and many highly trained behaviors, such as driving, climbing, dancing, playing tennis and so on (Koch and Crick, 2001; Velmans, 1991).

Milner and Goodale (1995) make a masterful case for the existence of *on-line* systems that bypass consciousness (see

also Rossetti, 1998). Their function is to mediate relatively stereotyped visuomotor behaviors, such as eye and arm movements, posture adjustments, and so on, in a very rapid manner. On-line agents—or *zombies*, as we call them—operating in the here and now and lacking direct access to working memory, are complemented by one or more networks for object classification, recognition, and identification. It is coalitions of neurons in these latter networks that give rise to conscious perception.

The exact relationship between zombie and conscious systems is unclear. In one reading, these might coexist as anatomically distinct streams in the brain. Milner and Goodale (1995) suggest that the on-line system mainly uses the dorsal visual stream (see Chapter 34), implying that all activity in this pathway is unconscious. They consider the ventral stream (see Chapters 77 and 79), on the other hand, to be largely conscious. Another interpretation holds that zombie and conscious systems share the same anatomical substrate but correspond to different modes. For instance, it is quite possible that feedforward activity that rapidly moves through the relevant networks to trigger motor action correspond to on-line behaviors, while sustained firing activity that is modulated by corticocortical feedback, in particular from prefrontal cortex, is a critical component of the NCC.

The broad properties of the two hypothetical entities—the on-line and the seeing systems—are shown in Table 114.1 following Milner and Goodale (1995; for critical evaluation and alternative views, see Boussaoud et al., 1996; Franz et al., 2000). The on-line system may have multiple subcomponents (e.g., for eye movements, arm movements, body posture adjustment). Under normal conditions, on-line behaviors coexist with conscious percepts, or actions. Indeed, there is evidence that in some circumstances the seeing system can interfere with the on-line system (Rossetti, 1998).

TABLE 114.1 <i>Comparison of the hypothetical on-line system and the seeing system</i>		
	On-Line System	Seeing System
Visual inputs handled	Must be simple	Can be complex
Motor outputs	Stereotyped responses	Many possible responses
Minimum time needed for response	Short	Longer
Effect of a few seconds' delay	May not work	Can still work
Coordinates used	Egocentric	Object-centered
Certain perceptual illusions	Not effective	Seen
Conscious	No	Yes

Source: Based on Milner and Goodale (1995).

One striking piece of evidence for on-line behaviors comes from studies on patient D. F. Her brain has diffuse damage produced by carbon monoxide poisoning. She is able to see color and texture very well but is very deficient in seeing orientation and form. In spite of this, she is very good at catching a ball. She can “post” her hand or a card into an elongated slot without difficulty, though she is unable to report the slot’s orientation. If the stimulus is removed and D.F. is asked to delay her response by a few seconds, she is unable to orient her hand properly. That is, her on-line visuomotor behaviors do not have access to working memory since they operate in the here and now. This observation might be used to distinguish all manner of zombie actions from conscious ones.

We suspect that while these suggestions about two systems are on the right lines, they are probably oversimplified. The little that is known of visual neuroanatomy would suggest that there are likely to be multiple cortical streams, with numerous anatomical connections between them (Distler et al., 1993). For example, recent data implicate the superior temporal cortex in humans as critical for spatial awareness, attention, and exploration (Karnath, 2001). It is difficult to assign this brain area unambiguously to either the ventral or the dorsal pathway, raising the possibility that it acts as an interface between the two. Furthermore, the neuroanatomy does not suggest that the sole pathway goes up to the highest levels of the visual system, and from there to the highest levels of the prefrontal system and then down to the motor output. There are numerous pathways from intermediate levels of the visual system to intermediate frontal regions.

Other examples of residual visual behaviors in the absence of conscious visual sensation in brain-damaged patients include *blindsight* (see Chapter 40) and the *visual neglect syndrome* (Driver and Mattingley, 1998). In extinction, the presence of a visual stimulus in the intact hemifield successfully competes with the stimulus in the lesioned hemifield: the latter one is simply not perceived. Typically, these symptoms are associated with lesions in the contralateral posterior parietal lobes (for an alternative view, see Karnath, 2001). This has been taken as *prima facie* evidence for the importance of these areas for visual consciousness.

Bilateral damage of both parietal lobes can give rise to *Balint syndrome*. Such patients see only one thing at a time, neglecting everything but the one object that currently captures their attention (Rafal, 1997). Yet the critical point is that they can still see something. This leads us to conclude that the areas involved in spatial neglect are not strictly necessary for conscious object vision per se. It is likely, though, that parietal areas provide attentional modulation of processing in the ventral pathway by biasing the competition among neuronal assemblies there.

Finally, two groups of people who appear to function, on occasion, in the absence of conscious sensations are a subset of patients with complex partial epileptic seizures (Penfield

and Jasper, 1954) and sleepwalkers (Revonuso et al., 2000). Both can execute routine behaviors, including mumbling, walking, moving furniture, driving, and other automatic behaviors without being able to interact in a meaningful manner (e.g., have a conversation) with their environment or recall anything that occurred during the seizure or the somnambulistic episode. It is possible that the NCC is shut down but that enough specific nervous activity remains to support zombie behaviors (Koch and Crick, 2001).

All of this evidence suggests that many behaviors occur in the absence of conscious sensation. This offers the possibility of a *contrastive program* in which the neural mechanisms underlying automatic or zombie behaviors are compared to those underlying any one conscious sensation, the NCC proper. However, the existence of unconscious behaviors also implies that one has to exercise great caution when working with animals, babies, or severely aphasic patients to infer conscious when some seeming “complex” task is carried out. It therefore becomes important to develop criteria to distinguish optomotor behaviors controlled by zombie agents from those that require consciousness. Interposing a delay of a few seconds between the visual stimulus and the required response seems currently the most promising litmus test.

The existence of a host of zombie behaviors also raises the question of why we need consciousness at all. Why aren’t we large bundles of on-line behaviors? We proposed (Crick and Koch, 1998) that while this might be appropriate for animals with a limited behavioral repertoire, such as a fruit fly, it would not do for mammals, with their enormous range of behaviors. Instead, evolution produced a general-purpose system which can deal with all sorts of contingencies and permits the animal to plan in parallel with a host of very rapid but special-purpose and stereotyped zombie behaviors. The price is speed: consciousness, reflection, and planning requires a fraction of a second or more.

The nature of the visual representation

We argued (Crick and Koch, 1995b) that to be aware of an object or event, the brain has to construct a multilevel, explicit, symbolic interpretation of part of the visual scene. By *multilevel* we mean, in psychological terms, different levels such as those that correspond, for example, to lines or eyes or faces. In neurological terms, we mean, loosely, the different levels in the visual hierarchy (Felleman and Van Essen, 1991).

The important idea is that the representation must be explicit. The word representation is used here in the sense that it should be easy to infer the presence or absence of the feature that is made explicit in the cellular response (one could formalize this using a perceptron).

Note that while the *information* needed to represent a face is contained in the firing of the ganglion cells in the retina, the retina lacks an *explicit* representation for faces.

The evidence from brain damage, especially in humans, suggests that certain parts of the cortex are essential for a person to be conscious of certain aspects of the visual sensation or percept, such as color, motion, and faces. Zeki and Bartels (1999) have, very reasonably, described such a piece of the cortex as an essential node for that aspect of the percept, though *key node* might be a better term. What should be considered *one aspect* must be decided by experiment. Thus, *motion* is not necessarily a single aspect. Indeed, there is evidence from brain damage (Vaina and Cowey, 1996) that F.D., a patient with rather limited brain damage, is impaired in the detection of second-order or texture-based motion but does perceive first-order or intensity-based motion.

The term *essential node* should not be taken to imply that a person who possessed only the relevant essential node would be conscious of that aspect of the percept. It is highly probable that to produce that aspect of consciousness, the node would have to interact with other parts of the brain. A node is a node, not a network. The point is that damage to that essential node would specifically remove that particular aspect of the sensation or percept while leaving other aspects relatively intact.

The concept of an essential node is important. It implies that if there is no essential node for some possible aspect of consciousness, the subject cannot be conscious of it. Zihl's patient (Zihl et al., 1983) can see a car, but if the car is moving, she does not see its movement because the essential nodes for movement have been damaged. So it is important not to assume that, for example, the brain can *necessarily* consciously detect some particular change in its firing activity. It will not be able to do so unless there is some essential node to *consciously* register that type of change.

It is plausible that an explicit representation (at an essential node) might be a smallish group of neurons employing coarse coding to represent some aspect of the visual scene. In the case of a particular face, all of these neurons can fire to somewhat face-like objects (see Chapter 78). We suggest that one set of such neurons will be all of one type, will probably be fairly close together, and will all project to roughly the same place. If all such groups of neurons (there may be several of them, stacked one above the other) were destroyed, then the person would not see a face, though he or she might be able to see the parts of a face, such as the eyes, the nose, and the mouth. There are other places in the brain that explicitly represent other aspects of a face, such as the emotion the face is expressing or its angle of gaze.

An attractive proposition is that the stimulus feature common to most neurons within a cortical column is what is made explicit there. Thus, orientation is one feature explicitly represented in V1, as are the direction and speed of motion in area V5. We call this the *columnar hypothesis*. Note that an explicit representation is a necessary but not sufficient condition for the NCC. As outlined in the section

"Bistable Percepts," it matters a great deal where these neurons project.

A representation of an object or event will usually consist of representations of many of the relevant aspects of it, and these are likely to be distributed, to some degree, over different parts of the visual system. How these properties are bound together is one aspect of the binding problem (see Chapter 113). It is possible that in many cases the firing of pyramidal neurons in all layers within a column that code for the object need to be synchronized for this to occur.

Much neural activity, a great deal of which is probably unconscious, is usually needed for the brain to construct a representation. It may prove useful to consider this unconscious activity as the computations needed to find the best interpretation, while the interpretation itself may be considered to be the results of the computations, only some of which the subject is then conscious of. To judge from perception, the results probably have something of a winner-take-all character.

In the past, we wondered whether only some types of specific neurons might express the NCC. Silence these, and a very specific loss of some specific content of consciousness might occur (such as the inability to perceive a certain type of motion). A weaker version of this hypothesis holds that the NCC depends on some crucial biophysical or anatomical property of some network in the brain. Again, blocking this feature could lead to a very specific loss of some aspect of subjective feelings.

An alternative possibility is that the NCC is necessarily global, usually identified with some emergent property of very large, diffuse assemblies of neurons. In one extreme form this would mean that, at one time or another, any neuron in cortex and associated structures could express the NCC, and it would be foolish to locate consciousness at the level of single neurons.

These possibilities are nonexclusive; it is possible that both local and global properties of the brain are necessary for consciousness to occur. While our thinking over the past decade has stressed particular neuronal mechanisms, that of Edelman and Tononi has focused on certain global aspects of networks (their *dynamic core* hypothesis; Edelman and Tononi, 2000). Both ideas might be valid.

Conscious visual representations are likely to be distributed over more than one area of the cerebral cortex and possibly over certain subcortical structures as well. We have argued that in primates—contrary to received opinion—they are not located in primary visual cortex (see below).

Whatever the NCC is, it must be present in the two hemispheres. Careful study of split brain patients demonstrates that one hemisphere usually supports language, while the linguistic competence of the other is severely reduced. Yet, even this nondominant hemisphere can clearly reason,

respond purposefully, and plan complex behaviors. From this, one can conclude that split-brain patients have, within the confines of a single skull, two brains with two conscious minds (Bogen, 1997; Sperry, 1974).

What is essential for visual consciousness?

The term *visual consciousness* almost certainly covers a variety of processes. When one is actually looking at a visual scene, the experience is very vivid. This should be contrasted with the much less vivid and less detailed visual images produced by trying to remember the same scene (a vivid recollection is usually called a *hallucination*). We are concerned here mainly with normal visual experiences. It is possible that our dimmer visual recollections, imagery, are mainly due to the back pathways in the visual hierarchy biasing the “noise” in earlier stages of the system.

Some form of very-short-term memory seems almost essential for consciousness, but this memory may be very transient, lasting for only a fraction of a second. The existence of *iconic memory*, as it is called, is well established experimentally (Coltheart, 1983; Gegenfurtner and Sperling, 1993).

Psychophysical evidence for short-term memory (Potter, 1976) suggests that if we do not pay attention to some part or aspect of the visual scene, our memory of it is very transient and can be overwritten (masked) by the following visual stimulus. This probably explains many of our fleeting memories when we drive a car over a familiar route. If we do pay attention (e.g., to a child crossing the road), our recollection of this can be longer-lasting.

Our impression that at any moment we see all of a visual scene very clearly and in great detail is illusory, partly due to ever-present eye movements and partly due to our ability to use the scene itself as a readily available form of memory, since in most circumstances the scene usually changes rather little over a short span of time (O'Regan, 1992; see Chapter 102). What we can grasp very rapidly and preattentively is the gist of a scene (Mack and Rock, 1998; Wolfe, 1998). It is this that provides us with the illusion of being able to apprehend the entire scene at once. It is likely that there are neurons at the higher visual levels whose firing directly encodes the *gist* of that scene. These neurons would then be key culprits for mediating the sensation of seeing everything at once.

Although working memory expands the time frame of consciousness, it is not obvious that it is essential for consciousness. It seems to us that working memory is a mechanism for maintaining one or a small sequence of items in consciousness. In a similar way, the episodic memory enabled by the hippocampal system (Zola-Morgan and Squire, 1993) is not essential for consciousness, though a person without it is severely handicapped.

Is attention necessary for consciousness? It seems that it is enriched by visual attention, though top-down attention is not essential for visual consciousness to occur (Braun and Julesz, 1998; Rock et al., 1992). Attention is broadly of two types: bottom-up, saliency-driven, and task-independent; and top-down, produced by the planning parts of the brain. Visual attention can be directed either to a location in the visual field, to a feature, or to one or more objects. The neural mechanisms that achieve this are still being debated. But they are likely to involve biasing the competition among groups of cells coding for neighbouring objects in favor of the attended one (Desimone and Duncan, 1995). See our earlier discussion of neglect and Balint syndromes.

How does the timing of events affect the percept?

The timing of the emergence of consciousness has been called *microgenesis* (Bachmann, 2000). We can easily see something of a visual input, such as a flash of lightening, even though it lasts for a very short time, provided that it is strong enough. Bloch's law states that for a stimulus duration less than about a tenth of a second (for a diffuse flash), the brightness of the stimulus appears the same, provided that the product of its intensity and its duration are constant. In some sense, the system is integrating the input over some short time interval.

How bright does a flash of light appear if its intensity is kept the same but its duration varies from trial to trial? This can be estimated by comparing its apparent brightness with the brightness of a similar but constant light. A typical result has been described by Efron (1967). As the duration increases, the light appears more intense until, for a duration of about 40 msec, it reaches a maximum, after which the subjective brightness declines to a steady value (Fig. 114.14). As Efron has pointed out, this description can be misleading. It expresses the results of *multiple* trials, each one for one particular duration of flash. It does not show what a person experiences at a *single* trial. That is, for a flash of length of, say, 125 msec, the subject does not see the brightness of the flash increasing rapidly and then decreasing somewhat. On the contrary, the subject reports that she saw a steady brightness. This distinction, which has been widely overlooked, is important.

The results suggest that the NCC comes into being abruptly rather than gradually. Once the relevant neural activity reaches some threshold, a constant percept of brightness results, at least for a short time.

Instead of a single flash of light, what do we see if a complex scene, such as people dining in a restaurant, is flashed for different short durations? The general result is that for very short exposures, one perceives the general nature of the scene—the gist, as mentioned earlier. As the flash is made longer, we can report more details. Once again,

FIGURE 114.1. How does a conscious percept and the neural activity that encodes it evolve in time? *A*, Schematic drawing of the relationship between subjectively perceived brightness and stimulus duration. A flash of intermediate duration is perceived as brighter than a flash of much longer duration. Yet the percept associated with a single trial does not wax and wane, as suggested by this function; instead, it remains constant. *B*, Hypothetical time course of the critical activity at the essential node coding for the brightness percept. Once this exceeds some amplitude, this NCC activity is sustained enough to project widely throughout cortex, and the subject becomes consciousness of the stimulus and its brightness. Awareness is expressed until the NCC drops below some level (the two threshold values do not have to be identical: the phenomena of hysteresis).

in any one trial we do not see the scene change. We just see more for longer flashes.

This might suggest that some of the higher levels of the visual hierarchy reach the necessary threshold for consciousness before the lower levels do. Possibly the lower levels need some feedback from the higher levels to boost their activity above threshold.

In *masking*, two (or more) inputs are involved (Bachmann, 2000; Enns and DiLollo, 2000). When the two inputs blend, this is sometimes referred to as *integrative masking*, though the term *blending* might be preferable. Pattern masking occurs when two rather different spatially superimposed contours interfere. When two patterns are not superimposed but spatially adjacent, the interference is called *metaccontrast*. Masking can also occur when the masking pattern does not abut the target pattern but is nearby. This is now called *object-substitution masking* (Enns and DiLollo, 1997).

Suppose that a red circular disc and an otherwise identical green disc are flashed simultaneously onto the same place in the retina. Not surprisingly, the subject sees a yellow disc. If the red disc alone is flashed first, for only 10 msec, immediately followed by the green disc for 10 msec, the subject does not see a red disc turning green but just a yellow disc. The yellow has a greenish tinge compared to the yellow produced when the two colors are flashed simultaneously. If the green disc comes before the red disc, the yellow is a little redder (Yund, et al., 1983). The subject perceives a mixture of the inputs, with a bias toward the later one—this turns out to be a general rule. This suggests some form of integration, with the later signal having a somewhat greater weight. If one disc appears 100 msec before the other, little blending occurs. This suggests that, in this instance, the integration time is less than 100 msec.

When masking produces interference, this is because, in some sense, the mask is competing with the target. The subject can easily report the target if there is no mask, but if the mask is spatially superimposed on the target and occurs at about the same time, his responses are mostly at chance—he reports that he did not see the target. He does better if there is a delay of 100 msec or so between the onset of the target and the onset of the mask. The mask interferes with processing of the target in the integration period leading up to consciousness. It is plausible that once some kind of neural activity due to the target has reached a certain threshold, the following mask cannot interfere with it so easily. This suggests that the conscious activity may show hysteresis—as Libet (1973) has claimed—since the activity is probably held above a threshold to some extent by some mechanism, such as loops with positive feedback (Fig. 114.1*B*). This activity corresponds to the NCC for the attribute encoded by the essential node, say the target's brightness, location, or color. The attribute remains consciously accessible until the activity dips below a lower threshold (Fig. 114.1*B*), at which point it becomes perceptually invisible.

In *metaccontrast*, the subject can see the target if the onsets of the target and mask are simultaneous, but fails to see it if the onset of the mask is delayed by a short period, typically 50 to 100 msec or so. This is presumably because the target and the mask are initially activating different places in the brain, and it takes time for their activities to interfere with each other.

The most interesting case is *object-substitution masking*, that is, when the target and the mask are spatially separate. No masking occurs if the target and the mask come into view simultaneously and disappear simultaneously. Masking does occur if, instead, the mask continues beyond the disappearance of the target. No masking occurs if the target is especially salient or if attention is focused on the target location beforehand.

The phenomenon of *masked priming* implies that (unconscious) processing of the masked target proceeds to fairly high levels. That is, some level of priming occurs whether or not the prime was masked, suggesting that the physiological correlate of priming (short-term synaptic changes?) can occur in high-level cortical areas without giving rise to consciousness.

Enns and DiLollo (2000) suggest that one is not conscious of the details of the target until the activity it has produced first reaches a higher level (when there is integration) and then flows back to a lower level (possibly iteratively). They propose that it is at one of the lower levels that the activity of the sustained mask interferes with conscious seeing, presumably of the details of the pattern.

Until recently, visual psychologists did not relate their results to the complex organization of the primate visual system. The study of masking in the alert monkey by neurophysiologists has only just begun (Macknik and Livingstone, 1998; Thompson and Schall, 2000). A careful study of the neurophysiological effects of masking should throw light on the processes leading to consciousness, on the integration times for the signal to reach above the thresholds for consciousness, and on the ways interference works. In general, the times involved seem to range from 50 to 100 msec up to 200 msec or more. This upper limit approaches the typical time between eye movements.

The picture that emerges from these speculations is a rather curious one. It bears some resemblance to Dennett's multiple drafts model (Dennett, 1991), though Dennett's ideas, though suggestive, are not precise enough to be considered scientific. The content of consciousness, instead of being a continuous, ever-changing flux, may be more like a rapid series of "static snapshots." Movement, like other attributes, is signaled in a static way by special neurons. That is, movement is not symbolized by a change in time of the symbols for position, but by special neural symbols that represent movement of one sort or another. If the essential nodes for these symbols are lost, as in Zihl's patient, then though she can see the moving car, she cannot see it moving.

There is little evidence for a regular clock in the brain with a mechanism that integrates over intervals of constant duration and then starts afresh over the next interval. The duration of a snapshot is likely to depend on various factors, such as contrast, saliency, competition, and so on. Purves and his colleagues (1996) have described several psychological effects, such as a wagon-wheel effect under constant illumination, which hint that there are some clock-like effects in vision. This would be worth further study.

The brain has a problem with time, since time is needed to express a symbol (by neurons firing, a process spread out over time), so it is not surprising if it symbolized changes in time, such as movements, in a special way and differences in time in another way.

We are dealing with an intrinsically parallel system to which we have limited access introspectively. This is probably why we find it so hard to understand how it works. This does not mean that we cannot usefully analyze it into smaller parts that interact dynamically, just as the holistic properties of a complex organic molecule, such as a protein, can be understood by the interactions of its many amino acids and the atoms of which they are made. In the brain, an essential node may be a useful unit of analysis. It may turn out that the best way to describe the NCC for any one percept is in terms of the activities at the relevant essential nodes and their dynamic interactions. This suggestion resembles the dynamic core of Edelman and Tononi (2000).

Bistable percepts

Perhaps the most relevant experimental approach to tracking down the footsteps of the NCC for now is to study the behavior of single neurons while the subject is looking at something that produces a bistable percept. The visual input, apart from minor eye movements, is constant, but the subject's percept can take one of two alternative forms. This happens, for example, when one looks at a drawing of the Necker cube. Which neurons follow the constant retinal input and which ones the variable percept?

A more practical alternative is to study binocular rivalry (Myerson et al., 1981). If the visual input into each eye is different but perceptually overlapping, one usually sees the visual input as received by one eye alone, then by the other one, then by the first one, and so on. This approach has been explored by Logothetis and his colleagues, who trained macaque monkeys to report which of two rivalrous inputs they saw. The fairly similar distribution of switching times strongly suggests that monkeys and humans perceive these bistable visual inputs in the same way. In the first set of experiments, Logothetis and Schall (1989) investigated neurons in area MT (also referred to as V5). The stimuli were vertically drifting horizontal gratings. Of the relevant neurons, only about 35% were modulated according to the monkey's reported percept. Surprisingly, half of these responded in the opposite direction to the one expected. Leopold and Logothetis (1996) used stationary gratings. The orientation was chosen in each case to be optimal for the neuron studied and orthogonal to it in the other eye. The authors recorded how the neuron fired during several alterations of the reported percept. While only a small fraction of foveal V1/V2 neurons followed the percept, about 40% of neurons in V4 did. Interestingly, about half of V4 cells were anticorrelated with the stimulus.

The results of the Sheinberg and Logothetis (1997) experiments are striking. Instead of using binocular rivalry, they exploited a related paradigm: *flash suppression*. An image is presented to one eye for a second or longer. A different image

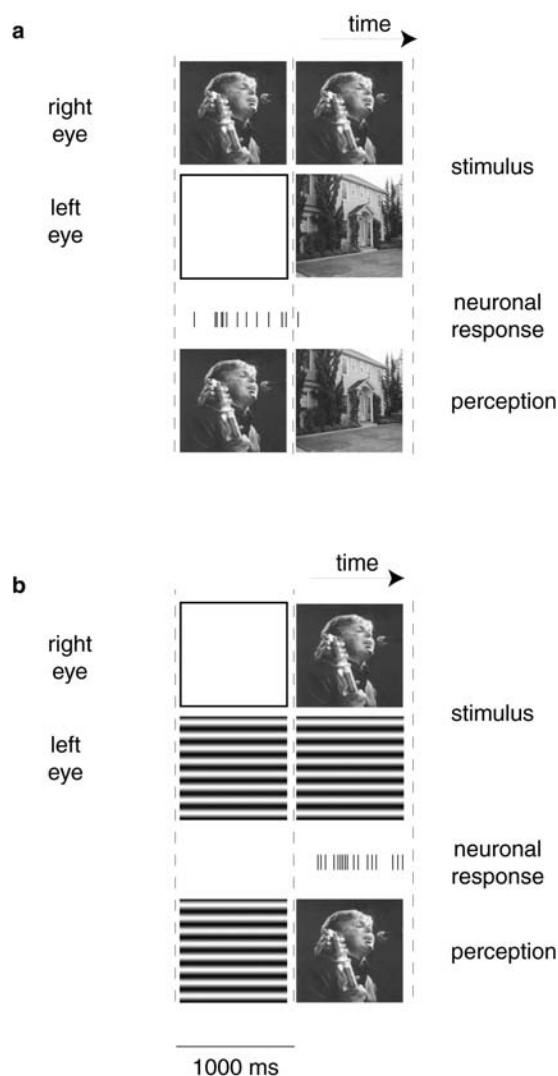

FIGURE 114.2. Example of a response of a single neuron in the left parahippocampal gyrus of a human patient during flash suppression. *A*, A photo of one of the Beatles, Paul McCartney, is projected into the right eye of the patient. After 1 second, a picture of a house is flashed into the left eye. This novel image completely suppresses the percept of McCartney and only the house is consciously seen. *B*, The converse situation: a horizontal grating is shown to the left eye. After 1 second, the image of McCartney is flashed into the right eye, completely suppressing the grating percept, although this image is still present on the left retina. The particular neuron recorded here follows the conscious percept of the patient rather than the retinal stimulus. It fires only to its preferred stimulus—McCartney—whenever the subject perceives this stimulus. (From Kreiman et al., 2002.)

is then flashed into the other eye. The former image is perceptually completely suppressed by the novel pattern, even though the first image is still present on the retina (Fig. 114.2). The mechanisms underlying flash suppression are unrelated to either forward masking, adaptation, or any other mechanism that reduces the visibility of the ipsilateral flash (Wolfe, 1984). Flash suppression is easy to obtain, is

very robust, and can be exactly timed, unlike the transitions occurring during binocular rivalry.

Sheinberg and Logothetis (1997) recorded from individual neurons in the monkey's superior temporal sulcus (STS) and inferior temporal cortex (IT). Overall, approximately 90% of the relevant neurons in STS and IT reliably predict the perceptual state of the animal. That is, these neurons follow the percept rather than the retinal stimulus. Moreover, many of these neurons respond in an almost all-or-none fashion, firing strongly for one percept, yet only at background levels for the alternative one.

Although the vast majority of electrophysiological single-cell experiments are carried out in animals, under exceptional circumstances such recordings are possible in humans. These occur in a subset of pharmacologically intractable epilepsy patients undergoing evaluation for surgical treatment. Kreiman et al. (2000) found many neurons to be tuned for specific categories of visually presented stimuli (e.g., famous people such as politicians or entertainers, faces of unknown actors expressing various emotions, animals or cars). Many of these cells fire selectively when their preferred stimulus is perceived but not when it is perceptually suppressed during flash suppression (Kreiman et al., 2002). About two-thirds of a total of 48 selective medial temporal lobe (MTL) neurons followed the percept (Figs. 114.2 and 114.3). No neuron responded in a significant manner to its preferred visual stimulus if this stimulus was physically present on the retina but perceptually suppressed. That is, there is no evidence for a neuronal representation of perceptually suppressed, that is unconscious, stimuli in the higher echelons of the visual hierarchy. Thus, both IT neurons in the macaque and MTL neurons in humans follow the subject's conscious percept.

Of course, without further experiments it is not possible to distinguish between correlation and causation. It does not automatically imply that just because a particular neuron follows the percept, its firing is part of the NCC. Do the MTL neurons carry a mere copy of the neuronal signal already expressed in IT for transfer into working memory or are neurons in the hippocampus, amygdala, and entorhinal cortex in normal also necessary for conscious perception? Where are these neurons projecting to? At the moment, it is technically difficult to interfere selectively, transiently, deliberately, and reversibly with these cellular populations in primates, but it is essential to have this knowledge or it will be almost impossible to understand the neural nature of consciousness.

What is the role of V1 in visual consciousness?

We have argued (Crick and Koch, 1995b) that primates are not directly conscious of the features represented by the neural activity in primary visual cortex. Activity in V1 may be necessary for vivid and veridical visual consciousness (as is activity in the retina), but we suggest that the firing of none

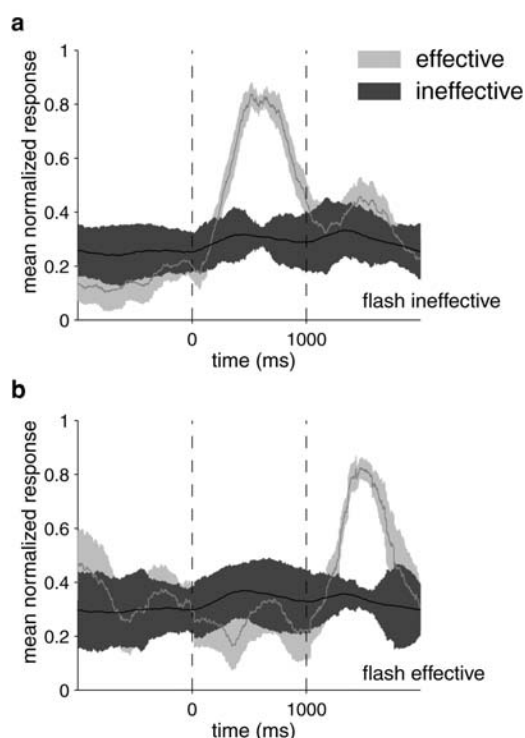

FIGURE 114.3. Averaged normalized spike density functions of 12 MTL neurons in human patients during flash suppression that followed the percept. These cells responded selectively to a specific face or image in the test set (as in Fig. 114.2). The light trace corresponds to the response for all trials when a stimulus from the cell's effective category was shown monocularly for 1 second (*A*) or during the 0.5 second long flash presentation period (*B*). The dark trace corresponds to the response to all other (ineffective) stimuli (shaded regions are the 95% confidence intervals). As all subjects perceive the effective stimuli during the monocular presentation (in *A*) or during flash suppression (in *B*), the cellular responses closely follow the subject's conscious visual experience. (From Kreiman et al., 2002.)

of the neurons in V1 directly correlates with what we consciously see.

Our reason is that at each stage in the visual hierarchy the explicit aspects of the representation we have postulated are recoded. We also assumed that any neurons expressing an aspect of the NCC must project directly, without recoding, to at least some of the parts of the brain that plan voluntary action—that is what we have argued seeing is for. We think that these plans are made in some parts of frontal cortex (see below).

The neuroanatomy of the macaque monkey shows that V1 cells do not project directly to any part of frontal cortex (see the references in Crick and Koch, 1995b).

The strategy used to verify or falsify this and similar hypotheses is to relate the receptive field properties of individual neurons in V1 or elsewhere to perception in a quantitative manner. Ultimately, this correlation has to be made on an individual trial-to-trial basis. If the structure of per-

ception does not map to the receptive field properties of V1 cells, it is unlikely that these neurons directly give rise to consciousness. In the presence of a correlation between perceptual experience and the receptive field properties of V1 cells, it is unclear whether these cells just correlate with consciousness or directly give rise to it. In that case, further experiments need to be carried out to untangle the exact relationship between neurons and perception.

Psychophysical evidence is broadly consistent with our proposal. The study by He et al. (1996) exploits a common visual aftereffect. If a subject stares for a fraction of a minute at a horizontal grating, and is then tested with a faint grating at the same location to decide whether it is oriented vertically or horizontally, the subject's sensitivity for detecting a horizontal grating will be reduced. This adaptation is orientation specific—the sensitivity for vertical gratings is almost unchanged—and disappears quickly. He and colleagues projected a single patch of grating onto a computer screen some 25 degrees from the fixation point. It was clearly visible, and their subjects showed the predictable orientation-selective adaptation effect. Adding one or more similar patches of gratings to either side of the original grating removes the lines of the grating from visibility; it is masked. Subjectively, one still sees something at the location of the original grating, but one is unable to make out its orientation, even when given unlimited viewing time. Yet despite this inability to see the adapting stimulus, the aftereffect was as strong and as specific to the orientation of the invisible grating as when the grating was visible. What this shows is that visual awareness must occur at a higher stage in the visual hierarchy than orientation-specific adaptation. This aftereffect is thought to be mediated by oriented neurons in V1 and beyond, implying that the NCC must be located past this stage.

Another case in point is the observation that very-high-frequency gratings that are perceptually indistinguishable from a uniform field nevertheless produce robust orientation-dependent aftereffects (He and MacLeod, 2001). The presence of aftereffects from stimuli that are not consciously perceived (Blake and Fox, 1974) indicates that stimulus properties must be represented outside of awareness. Thus, activity in V1 often does not correlate with awareness.

These inferences from behavior are complemented by direct electrophysiological measurements of neuronal activity in V1 in macaque monkeys. These measurements show that perceptual reports (presumably reflecting awareness) and the mean firing activity in V1 can change completely independently. For example, disparity-selective cells in V1 differentiate between local depth cues even when these do not give rise to an overall depth percept or may respond in an identical manner to two depth cues that yield very different global depth percepts (Cumming and Parker, 1997). This suggests that single V1 cells sensitive to binocular dis-

parity represent a first critical stage for generation of stereo cues but that conscious perception of depth is most likely generated further upstream. A similar lack of correlation between perceptual experience and the response properties of V1 cells can be seen during blinks. They produce profound and frequent interruptions in retinal stimulation, yet barely impinge on our visual experience (Volkman et al., 1980). Cells in the supragranular layers of V1 show responses to visual stimulation that decrease substantially during reflex blinks (Gawne and Martin, 2000), and this reduction is significantly more pronounced than when there is an equally long gap in visual stimulation. Similarly, microsaccades that occur continually do not alter our impression of the world but are reflected in the activity of neurons in V1 (Martinez-Conde et al., 2000). Or, when two isoluminant colors are alternated at frequencies beyond 10 Hz, humans perceive only a single fused color with a minimal sensation of brightness flicker. In spite of the perception of color fusion, color opponent cells in primary visual cortex of two alert macaque monkeys follow high-frequency flicker well above heterochromatic fusion frequencies (Gur and Snodderly, 1997). Lastly the brain automatically, and unconsciously, compensates for the incessant motion of the eyes. As a result, the external world looks stable. Yet V1 neurons can't tell the motion induced by smoothly pursuing a target with the eyes from pure image motion with the eyes stationary, contrary to visual experience (Ilg and Thier, 1996). In other words, neuronal activity in V1 can clearly represent certain retinal stimulation that is not perceived.

Changes in conscious perception can also occur in the absence of concomitant variations of neuronal activity in V1. As mentioned above, the majority of the V1/V2 cells recorded by Leopold and Logothetis (1996) do not covary with the animal's behavior during binocular rivalry. Instead, their firing reflects stimulus properties. Recently, two neuroimaging studies in humans have presented evidence arguing for a stronger role for V1 in binocular rivalry and hence, by implication, visual awareness. The most popular form of functional neuroimaging is blood oxygenation-level-dependent (BOLD) functional magnetic resonance imaging (fMRI). BOLD measures a component of the hemodynamic response associated with local neural activity (for the exact relationship between the two, see Logothetis et al., 2001). Averaged over the whole of human V1, reliable fluctuations in BOLD contrast activity are observed (Polonsky et al., 2000). The amplitude of these fluctuations is about half as large as those evoked by nonrivalrous stimuli, and is even larger in the part of V1 associated with the blind spot representation which contains cells receiving only monocular input from the non-blind spot eye (Tong and Engel, 2001). The reasons for this discrepancy are not yet clear but might well involve the complex nature of the relationship between

single-cell activity and BOLD measurements (Logothetis et al., 2001). In particular, it is possible that feedback activity from higher cortical areas to lower ones does give rise to a metabolic demand in the lower area due to the associated synaptic activity and so results in enhanced BOLD contrast. Yet the feedback is, by itself, not sufficiently powerful to affect spiking in the V1 cells. Other fMRI BOLD studies in humans show a poor correlation between V1 activity and visual awareness (for a review, see Rees et al., 2002).

Note that our hypothesis is not easy to prove, since it applies to all V1 cell populations. We hope that further neuroanatomical work will make our hypothesis plausible for humans. If correct, it would narrow the search to areas of the brain farther removed from the sensory periphery.

The frontal lobe hypothesis

As mentioned several times, we hypothesize that the NCC must have access to explicitly encoded visual information and project directly into the planning stages of the brain, associated with the frontal lobes in general and with prefrontal cortex in particular (Fuster, 1997). We would therefore predict that patients unfortunate enough to have lost their entire prefrontal cortex on both sides (including Broca's area due to the direct interhemispheric input from the right inferior temporal cortex to Broca's area [Di Virgilio and Clarke, 1997]) would not be visually conscious, although they might still have well-preserved, but unconscious, visual-motor abilities. No such patient is known to us (not even Brickner's famous patient; for an extensive discussion, see Damasio and Anderson, 1993). The visual abilities of any patient with frontal lobe damage needs to be carefully evaluated using a battery of appropriate psychophysical tests.

The fMRI study of the blindsight patient G.Y. (Sahraie et al., 1997) provides direct evidence for our view by revealing that prefrontal areas 46 and 47 are active when G.Y. is aware of a moving stimulus.

Findings of neurons in the inferior prefrontal cortex (IPC) of the macaque that respond selectively to faces—and that receive direct input from regions around STS and the inferior temporal gyrus that are well known to contain face-selective neurons—is very encouraging (Scalaidhe et al., 1997). This raises the question of why face cells would be represented in both IT and IPC. It is unlikely that exactly the same information is represented at two different locations, so it will be important to find out in what way they differ.

Large-scale lesion experiments carried out in the monkey suggest that the absence of frontal lobes leads to complete blindness (Gazzaniga, 1966; Nakamura and Mishkin, 1986). One would hope that future monkey experiments will reversibly (by cooling and/or injection of GABA agonists) inactivate specific prefrontal areas and demonstrate the

specific loss of abilities linked to visual perception while visual-motor behaviors—mediated by the on-line system—remain intact.

Some cognitive scientists (in particular, Jackendoff, 1987) have presented an *Intermediate-Level* theory of consciousness in which neither early sensory processing (the *outer world*) nor high-level three-dimensional information or thoughts (the *inner world*) is directly accessible to consciousness. The Intermediate-Level hypothesis raises the intriguing possibility that although much of the frontal lobes might be necessary for consciousness, the NCC might be preferentially located in more intermediate levels of cortex, such as the inferior temporal lobes (for a more detailed discussion of this and some experimental ramifications, see Crick and Koch, 2000).

Where are we and where should we be going?

We have reviewed the evidence in favor of the hypothesis that there might be anatomically localized neurons or neural pathways whose level of spiking activity mediates consciousness. The NCC is not likely to be found in V1, but among neurons in the ventral pathway (in particular in and around area IT) and in its recipient zones in the medial temporal and frontal lobes. Neurons from posterior parietal areas can modulate the competition in this stream without being strictly necessary for conscious perception of color, shape, objects, and form.

It is likely that a conscious percept requires that the relevant activity in the relevant neurons exceed some minimal amount. It is possible that such a threshold can only be exceeded by some type of feedback activity from a higher cortical area (Lamme and Roelfsema, 2000; Pollen, 1999). Furthermore, this minimal activity may have to persist for a minimum amount of time.

Yet the average firing activity need not be the only relevant variable. An alternative hypothesis is that consciousness may be associated with specific types of neural activity, such as oscillatory or synchronized discharges. These two hypotheses are not mutually exclusive, and a combination of synchronous activity and neural spike rates might be an important attribute of the NCC. Indeed, we suggested early on that synchronized oscillations in the broad 40 Hz range may underlie feature integration and form a substrate for visual consciousness, although the idea remains controversial (Crick and Koch, 1990; Engel and Singer, 2001; Chapter 113). In general, a synchronized neuronal population will be more efficient in evoking a strong postsynaptic response compared to a network of independently firing neurons; that is, it carries a more powerful postsynaptic “punch.” The brain may use correlated firing for more than one purpose. In particular, it might embody the effects of top-down attention. As consciousness frequently involves the suppression of competing percepts, such synchronized and oscillatory

firing might often accompany the NCC without being strictly necessary. Conversely, synchronized firing might also underlie other processes, such as figure-ground segregation, so that their mere presence might not reliably indicate a NCC.

At the moment, the most promising experiments used to discover the correlates of visual consciousness are those on bistable percepts, which need to be expanded to include other brain areas (in particular prefrontal cortex) in both the monkey and the human. It is important to discover which neurons express the NCC in each case (which neuronal subtype, in what layer, and so on), how they fire (do they fire in bursts? are discharge patterns across neurons synchronized?), does the time-course of the relevant activity correspond to the temporal dynamics of conscious perception? and, especially, where they project to. To assist this, more detailed neuroanatomy of the connectivity will be needed. It is also important to discover how the various on-line systems work so that one can contrast their (unconscious) neuronal activity with that of the NCC (Koch and Crick, 2001).

It will not be enough to show that certain neurons embody the NCC in certain—limited—visual situations. Rather, we need to identify the NCC for a sufficiently large and representative sample of visual inputs. One popular approach is to study the many visual illusions. For instance, humans clearly perceive, under appropriate circumstances, a transient motion aftereffect. On the basis of fMRI, it has been found that the human equivalent of cortical area MT is activated by the motion aftereffect (in the absence of any moving stimuli; Tootell et al., 1995). The time course of this illusion parallels the time course of activity as assayed using fMRI. In order to really pinpoint the NCC, one would need to identify individual cells expressing this and similar visual aftereffects.

This is not to argue that studying visual consciousness is the one and only means of cracking the mind-brain problem. Investigating other forms of consciousness might have practical advantages (e.g., the awareness of the exact unconditioned-conditioned stimulus contingency relationship during certain forms of associative conditioning; Clark and Squire, 1998). In order to understand consciousness, we need to understand cerebral cortex. We can only hope to achieve this goal by deliberately interfering with cortex and its components in a delicate, reversible, and transient manner. Molecular biology is beginning to provide the relevant tools (e.g., Lois et al., 2002). Whether these tools are best applied to the macaque’s visual system or to another modality in the more accessible mouse remains an open question.

Finding the NCC would only be the first, albeit critical, step in understanding consciousness. The next biggest challenge would be to bridge the gap between correlation and causation. For this to occur, we would need to understand

the postsynaptic action of neurons expressing the NCC, what happens to them in various diseases known to affect consciousness, such as schizophrenia or autism, and so on. And, of course, a final theory of consciousness would have to explain the central mystery: how a physical system with a particular architecture can have feelings and qualia (Chalmers, 1995). After several thousand years of speculation, it would be very gratifying to solve this puzzle.

INDEX

Page numbers followed by *b*, *f*, or *t* denote boxes, figures, or tables, respectively.

A

- Abducens internuclear (AI) neurons, 1416–1417, 1416*f*, 1418*f*
- Abducens nucleus, neurons in, 1416–1417, 1416*f*, 1418*f*, 1424
- Aberration(s)
 - chromatic, 800–801, 805–807
 - adaptive optics and, 805, 807–808, 808*f*
 - axial, 800–801, 805–806
 - and image formation, 800–801
 - transverse, 800–801
 - correction of, effects of, 807–808, 808*f*
 - monochromatic, 796, 800–801, 805–806
 - correction of, effects of, 807–808, 808*f*
 - pupil size and, 799–800, 800*f*
 - and retinal image formation, 795–797
 - trade-off with diffraction, 799–800
 - wave, 795
 - in aberrated eye, 795, 796*f*
 - capture by pupil function, 796
 - in corrected eyes, 807–808
 - decomposition into component aberrations, 795–796, 797*f*
 - in perfect eye, 795, 796*f*
 - in real eyes, 795, 796*f*
 - Zernike modes of, 795–796, 797*f*
- Abney effect, 893
- Absolute disparity, 550, 780, 1303, 1303*f*, 1304
 - response of V1 neurons to, 783
- Absolute threshold. *See also* Detection threshold
 - of cone system, 841
 - dark light and, 816–817
 - in scotopic vision, 838–840
 - aging and, 846
 - in infants, 846
- Absolute threshold problem, 817
- Absorbance of lens, aging and, 208*t*, 208–209
- Abstract concepts
 - honeybees' formation of, 1502–1504
 - prefrontal cortex (PFC) and, 1555
- Accommodation, 1415, 1461–1462
 - ambient annual temperature and, 206, 206*t*
 - and convergence, 1415
 - cross-coupling between, 1301
 - and ganglion cell excitability, 436
 - loss of, 205–208. *See also* Presbyopia
 - neural pathway for, 1425
 - reading and, 207–208
 - vergence and
 - linkage of, 1419–1422, 1420*f*, 1421*f*, 1461–1462
 - synkinesis between, 1461–1462
- Accommodation gain
 - definition of, 1421*f*
 - and vergence gain, relationship between, 1419–1422, 1421*f*
- Acetylcholine, 311–313, 312*f*
 - amacrine cells expressing, 294–295, 295*f*, 312–313, 361, 403–404, 457–458
 - and calcium currents, 432
 - and cortical plasticity, 128, 134–135, 136*t*, 137*f*, 139
 - and direction selectivity, 457–458
 - future directions for study of, 313
 - ganglion cells expressing, 404, 457–458
 - horizontal cells expressing, 370
 - localization of, 311, 312*f*
 - and long-term depression, 134, 136*t*
 - and long-term potentiation, 134, 136*t*
 - metabolism of, 304, 311, 312*f*
 - modulatory actions of, 135
 - neurotrophins and, 55, 56*f*, 60
 - and orientation selectivity, 134, 136*t*
 - peptide action on, 337
 - retinal, 86*f*, 87
 - signals about nervous system state carried by, 134
 - species differences in systems of, 135
 - in synaptic transmission, 294–295, 295*f*, 304, 312–313
 - versus GABA, 312–313
 - transporters of, 311, 312*f*
 - mitochondrial, 312*f*
 - plasma membrane, 311, 312*f*
 - vesicular, 311, 312*f*
- Acetylcholine receptor(s), 311–312, 312*f*
 - heptahelical, 312, 312*f*
 - ionotropic, 311–312, 312*f*
- Acetylcholine receptor antagonists, and cortical plasticity, 134
- Acetylcholinesterase, 311, 312*f*
 - activity, thalamic, 592
 - and cortical connectivity, 151, 152*f*
- Achromatic appearance, 897–898, 897*f*
- Achromatic channel, 1008, 1217
- Achromatic contrast, 882
- Achromatic contrast sensitivity, 177, 186
- Achromatic observers
 - rod saturation in, 841–842
 - scotopic grating acuity in, 843, 844*f*
- Achromatic percepts, constancy of, 904
- Achromatic vision, bidimensional model of, 884–885
- Achromatopsia, 554, 975, 1014, 1015
 - central, 1029
 - cerebral, 1029, 1035
 - pupil responses in, 641–642, 651*f*, 652, 653
 - complete, 976
 - molecular genetics of, 983
 - incomplete, 976
 - autosomal recessive, 983
 - induced by fusiform gyrus lesions, 1034–1035
 - inheritance of, 976
 - transient, 1035
 - variations in, 1035
- Achromats, X-chromosome incomplete, 875
- ACPD (aminocyclopentane-trans-1, 3-dicarboxylic acid)
 - and cortical plasticity, 129, 132
 - and CREB, 132
- Actin filaments, in cones and rods, 216
- Action potential(s)
 - in area MT neurons, 1206

- Action potential(s) (cont.)
 with frequency adaptation, in basket cell, 688
 in ganglion cells
 bursts or events, 427–430, 428*f*, 429*f*
 calculations of, 434
 frequencies of, 415, 422–430
 accommodation and, 436
 calcium modulation of, 436–437
 current transformed into, 423, 424*f*, 425*f*
 currents facilitating, 424
 in dark-adapted retina, 426, 426*f*, 428, 436
 dopamine and, 438–443
 high versus low, 423–426
 Hodgkin-Huxley equations for, 425
 light intensity and, 423–425, 425*f*, 427, 428*f*, 429*f*
 in light-adapted retina, 426, 427*f*, 427–428
 prediction of, 443
 with presentations of flickering checkerboards, 426–427
 with presentations of spatially uniform random flicker, 427
 temporal contrast and, 437*f*, 437–438
 heterogeneity in, 434–435
 in LGN cells
 burst, 575–578, 612, 613*f*, 622
 in waking state, 612
 cortical feedback and, 611–612, 613*f*
 tonic, 575–578, 612, 613*f*
 in long-term depression, 127
 in long-term potentiation, 127
 synchrony of, horizontal cortical connections and, 742*f*, 742–743
 Action spectrum, of horizontal cells, 373, 375*f*
 Active zones, of photoreceptor axon terminals, 245, 247*f*
 Activin
 in retinal cell development, 65
 in retinal cell differentiation, 68
 Activity
 and cortical development, 165, 167, 170
 and cortical plasticity, importance of, 128
 deprivation of. *See* Binocular deprivation; Dark rearing; Monocular deprivation
 and eye-specific lamination in LGN, 109–110, 113–115
 instructive versus permissive role of, 113–115, 117, 122, 123–124, 165, 167, 170
 and ocular dominance column development, 110–115, 147
 and orientation selectivity, 117, 119–121, 121*f*, 147–148
 mechanisms in, 121–124
 spontaneous, of developing visual system, 88–89, 89*f*
 and LGN lamination, 109–110
 and ocular dominance development, 147
 and orientation selectivity, 117, 123–124
 Acuity. *See also* Grating acuity; Hyperacuity; Stereopsis; Vernier acuity; Visual acuity
 in blindsight, 658
 Adaptation, 851–861. *See also* Dark adaptation; Light adaptation; Sensitivity regulation
 to blur, 944–945, 944*f*
 chromatic, 900–902
 to color and luminance variations, 930
 and color vision, 939–942, 940*f*
 contingent, 939
 contrast, 940*f*, 941–942, 942
 and decorrelation, 943, 945
 definition of, 1655
 diagonal model for, 955–957
 evolutionary, of vision, 943
 in face perception, 944–945, 945*f*
 fMRI, 1184
 functions of, 942–943
 and gain control, 942
 to illuminant, 901
 and learning, 943
 to natural color distributions, 929, 943, 944*f*
 and natural visual environment, 943–945
 and normalization, 942–943
 and object recognition, 1650
 orientation plasticity induced by, 1657–1658, 1658*f*
 pattern. *See* Pattern adaptation
 perceptual, 936
 and phenomenology of perception, 945–946
 plasticity induced by, 1655, 1656*f*
 rapid, 1660–1661, 1661*f*
 as psychologist's electrode, 936
 in regulation of salience, 945
 in scotopic vision, 843
 short-term, to varying environments, 943–945, 944*f*
 spatial, rod-cone interactions and, 871
 spatial frequency, 1062
 von Kries, 940, 955–957
 Adaptation pool, 843
 Adaptive optics, and chromatic aberrations, 805, 807–808, 808*f*
 Adaptive staircases, 811–812
 Adenosine triphosphate (ATP)
 in photoreceptor metabolism, 216, 244
 in signal processing, 316
 Adenosine triphosphate (ATP) receptor(s), 316
 Adenylate cyclase
 activation of, 135, 137
 inhibition of, 135
 PACAP coupling to, 336
 peptide action on, 348
 somatostatin coupling to, 340
 stimulation by CRH, 348
 stimulation by VIP, 336, 345–346
 α -Adrenergic receptor antagonist(s), and ocular dominance plasticity, 134
 Adrian, E. D., 16, 23
 Barlow's recollections of, 26–28
 laboratory of, 27–28
 as research supervisor, 27
 Adult plateau of vigor, 210–211
 Affective significance, prefrontal cortex (PFC) and, 1557
 Affordance, 1114
 Aftereffects, 936–938, 943, 1690. *See also* Illusion
 contingent, 939
 face, 945
 interocular transfer of, discordant visual input and, 198
 motion, 1319–1320, 1692
 hMT/V5+ visual area activity during, 1237–1239
 negative, 1628
 of pattern adaptation, 939
 rod, 374–375, 376*f*
 surfaces and, 1131–1132
 tilt, 936–939, 937*f*, 938*f*
 Afterimages. *See also* Aftereffects
 of filled-in surfaces, 1130*f*, 1132–1135, 1133*f*, 1134*f*, 1135*f*
 rod saturation and, 841
 Agatoxin, calcium currents sensitive to, 433
 Age
 and long-term depression, 127–128
 and long-term potentiation, 127–128
 and NMDA receptor levels, 129
 and pupil size, 642, 846
 and scotopic vision, 846–847
 Age-related maculopathy (ARM), versus natural processes of aging, 846–847
 Aging, 205–211
 cellular dichotomy in (nervous versus non-nervous tissue), 209
 constancy of color vision in, 807
 dark adaptation in, 846
 decline of neural components in, 209, 210*t*
 and disease, mathematical analysis of, 210–211
 versus disease processes, 846–847
 environment and, 205–206
 epidemiology of, 205
 lens changes in, 206–207, 207*f*, 846

- errors and variations in, 208–209
- slopes of log magnitude versus log age for, 208, 208*t*
- and light scatter, 799
- linear decline of, 205
- mathematical analysis of, 210–211
- presbyopia in, 205–208
- pupil size in, 642, 846
- scotopic vision in, 846–847
- Agnosia, visual object, 554
- Airy disk, 796*f*, 798, 799

 stratification and organization of, 84–86, 85*f*, 412–413
 in synapse formation, 87
 development of, 36–37, 37*f*, 77
 tangential migration in, 469
 timing of, 77, 78*f*
 differentiation of, 37–38, 66, 68, 72, 77–78, 467
 in inner and outer plexiform layers, 81*f*, 81–86
 diffuse, 411
 direction-selective (DSGCs), 404–405, 451–461
 acetylcholine and, 457–458
 amacrine cells and, 404–405, 456–460, 457*f*, 458*f*, 459*f*
 Barlow and Levick's classic studies of, 451, 452*f*
 Barlow-Levick model of, 453, 455*f*
 challenges in studying, 455–456
 excitatory model of, 453–455, 455*f*
 feedforward inhibition and, 451–452, 454*f*
 fundamental features of, 451
 GABA and, 355, 361, 452, 457
 general requirements for, 453–455
 independence of sign contrast, 451, 454*f*
 inhibitory model of, 453, 454*f*, 455*f*
 lateral inhibition and, 453–455, 454*f*
 mosaic organization and, 466–467
 mosaics of, 466–467
 motion detection and, 453–455, 456–459, 458*f*
 nonlinearity and, 454*f*, 454–455, 455*f*
 nonlinearity in, 454*f*, 454–455, 455*f*
 ON-OFF, 451, 452*f*, 453*f*
 crosstalk between, 457
 physical asymmetry for, 453–455, 454*f*, 455*f*
 alternative anatomical locations for, 459–460
 postsynaptic mechanisms in, 454*f*, 454–456
 postsynaptic model of, 454*f*, 454–456
 presynaptic mechanisms in, 454*f*, 454–456
 presynaptic model of, 454*f*, 454–456
 presynaptic versus postsynaptic computation of, 455–456
 Reichart's model of, 453–455, 455*f*
 responses to light and dark edges, 451, 454*f*
 synaptic connections and, 460*f*, 460–461
 time delay for, 453–455
 tracer-coupling studies of, 466
 discovery of, 410
 dynamic range of, 422, 423, 424*f*, 425*f*
 emergent property of, 255
 excitability of, 260, 422–444
 burst firing in, 427–430, 428*f*, 429*f*
 calcium modulation of, 436–437
 central, 360
 in dark-adapted retina, 426, 426*f*, 428, 436
 depolarization and, 428, 436–438
 dopamine and, 438–443
 fixed versus variable mechanism of, 422
 heterogeneity of, 422, 434–435
 hyperpolarization and, 426, 426*f*, 428, 435–436
 input-dependent, 435, 438–443, 444
 integrate-and-fire model of, 423, 428
 ion conductances and, 422, 424–426, 432–434, 443–444
 in light-adapted retina, 426, 427*f*, 427–428
 linear filter for, 428
 peptides and, 337, 341–342, 342*f*, 344, 346, 349
 response-dependent, 435–438, 444
 somatostatin and, 341–342, 342*f*, 349
 substance P and, 344
 synaptic input and, 428, 434–435
 temporal contrast and, 437*f*, 437–438
 transient responses in, 426–430
 two signal-processing stages of, 428
 VIP and, 346, 349
 functions of, 422
 morphology as guide to, 410
 GABA receptors in, 309, 357, 358, 359, 412, 412*f*
 gain control in, 416, 422, 427, 487
 generalization by, 17–18
 glutamate receptors in, 306, 412, 412*f*, 431–432
 glutamate transporters in, 306
 in glutamatergic pathways, 320–330
 glycine receptors in, 311, 357, 359, 412, 412*f*
 highlight and shadow detection by, 260
 historical perspective on study of, 410
 hue-encoding, 855
 ideal observer analysis at level of, 832
 immature
 chloride concentration in, 87

 contrast-set gain control in, 753, 753*f*
 in cortical feedback system, 614, 617, 621, 622
 direction selectivity in, 617, 1621
 linear and nonlinear properties of, 753
 spatiotemporal mechanisms of, 710–711, 711*f*, 713
 excitatory input to, 696, 697
 input to, orientation selectivity of, 695–697
 invariance properties of, 1610, 1613
 latency shift in, 753–754, 754*f*
 LGN input to, 695–697
 cortical inactivation experiments and, 697–698
 spatial organization of, 697
 strength of, 697
 untuned component of, 699–700
 as linear filter, 750
 with static nonlinearity, 712*f*, 713–714, 717
 linear properties of, 750–751
L-N model of, 712*f*, 713–714, 714*f*, 717
 monocular, 1631
 nonlinear interactions of, 712*f*, 712–713
 nonlinear properties of, 751–754
 temporal dynamics of, 754–759
 null phase position of, 751
 ON/OFF, 118, 118*f*, 123, 123*f*, 270
 pharmacologic blockade of, 273
 orientation selectivity in, 118, 118*f*, 768, 770*f*, 1621
 linear and nonlinear properties of, 753
 orientation tuning of
 contrast invariance of, 699, 699*f*
 dynamics of, 698–699
 prediction of, from spatial organization of receptive field map, 698
 position selectivity in, 1621
 receptive field map, spatial organization of, prediction of orientation tuning from, 698
 receptive fields of, 118, 118*f*, 673–674, 695, 696*f*
 development of, 123, 123*f*
 linear maps of, 708, 708*f*, 709*f*, 709–710, 716–717, 750
 nonlinear maps of, 712*f*, 712–714, 714*f*, 717
 ON and OFF regions of, 673, 674*f*, 768
 space-time inseparable, 709*f*, 710, 713
 space-time separable, 709*f*, 709–710, 713
 spatiotemporal maps of, 709*f*, 709–710
 spatiotemporal properties of, 751
 subregions of, 750
 temporal profile of, 709–710
 ON regions, 695, 696*f*
 response expansion in, 752*f*, 752–753
 response properties of, relation to image representation model, 1609–1611, 1610*f*, 1611*f*
 response rectification in, 751*f*, 751–752
 response refractory period of, 751
 response saturation in, 753, 753*f*
 responses of
 to drifting gratings, 750
 as function of spatial phase, 750
 selectivity of, 18
 spatial frequency selectivity in, 751, 768, 770*f*
 linear and nonlinear properties of, 753
 spatial summation in, 750
 synaptic connections of, with LGN cells, 118, 118*f*
 system structure of, 712*f*, 713–714
 tuning of, 1302
 Simultanagnosia, 1684
 Simultaneous contrast effects, 881–882, 882*f*
 Single-channel system, in scotopic vision, 838
 Singular value decomposition (SVD)
 analysis, of complex cell receptive fields, 716
 Sinusoidal spatial gratings
 for contrast sensitivity measurement, 176–177, 177*f*
 pupil responses to, 645–647, 646*f*, 647*f*, 648*f*
 X and Y cell responses to, 17
Six3 gene
 expression of
 in eye fields, 34, 66
 in optic vesicle, 66
 in optic cup development and regionalization, 35*f*, 36
 overexpression of, 66
 in retinal cell differentiation, 68
 Size-disparity correlation, 1632
 SKF-38393, and ganglion cell excitability, 438
 Sleep
 and cortical plasticity, 128, 134
 pupil constriction during, 642, 653
 Sleepiness, slow oscillations of pupils during, 642, 653, 654*f*
 Slits, and optic chiasm development, 97*f*, 99–100, 100*f*, 101
 Sloan's notch, 1394, 1394*f*
 Sluggish ganglion cells, 255
 Smooth landings, by insects, motion cues for execution of, 1198–1199, 1199*f*
 Smooth pursuit eye movements. *See* Eye movement(s), smooth pursuit
 Smoothness constraint, 1304
 Sodium channels/currents
 in bipolar cells, 263
 cGMP-activated, 431
 dopamine and, 438–439, 441*f*
 epithelial-type, 431
 in ganglion cells, 417, 425–426, 432–433, 435–436
 high-threshold, 432
 low-threshold, 432
 persistent, 432–433
 temporal contrast and, 437*f*, 437–438
 transient, 432–433
 in horizontal cells, 378–379
 voltage-gated, 435
 Sodium ions
 in current flow to photoreceptors, in darkness, 225
 ganglion cell permeability to, 431
 non-synaptic routes for influx of, 431
 Sodium-calcium exchanger, and amacrine cell release of neurotransmitter, 295, 297*f*
 Sodium/potassium transporters, in cone inner segments, 244
 Somatostatin (SRIF)
 amacrine cells expressing, 339*f*, 339–340
 in dendrite-targeting interneurons, 689
 ganglion cells expressing, 340
 in light/dark adaptation, 349
 retinal, 334–335, 336, 339–342, 348–349
 binding sites of, 336, 340
 cellular physiology studies/calcium imaging of, 337, 341, 341*f*
 coupling to adenylate cyclase, 340
 functional studies of, 337, 341–342
 ganglion cell effects of, 341–342, 342*f*, 349
 ion channel modulation by, 341, 341*f*, 342, 348
 localization of, 340
 Somatostatin (SRIF) receptors
 functional, 336
 mRNA of, 336
 retinal, 336, 337, 340*f*, 340–341
 retinal localization of, 337
 sst subtype of, 336, 337, 340*f*, 340–341
 Sonic hedgehog (Shh)
 in eye field separation, 34
 in optic chiasm development, 101
 in optic cup development, 34–36
 in retinal cell differentiation, 37–38, 68, 467
 Space
 encoding of, posterior parietal cortex lesions and, 552–553
 scale and, 1046–1047, 1053*f*, 1054–1055
 Space representation
 in posterior parietal cortex, 1328–1332, 1330*f*
 in visual pathways, 488
 Space-time inseparable receptive fields, 705*f*, 706

and visual target selection, 1369–1371, 1370*f*
- Visual search flicker task, 1526
- Visual streams. *See also* Dorsal stream; Ventral stream
blob, 1625*f*, 1627
and complementary properties, 1624
as independent modules, 1624
interactions of, 1624
processing stages in, 1624
surface, seeing by, 1627–1628
- Visual target(s)
localization of, auditory, 1327, 1329–1330, 1329*f*, 1397, 1397*f*
for pursuit, selection of, 1402–1403
selection of, 1369–1384, 1402. *See also* Saccades, targets for
- Visuosaccadic behavior, in monkey,
neuronal activity in, stages of, 1468–1470, 1469*f*
- Vitreous space, increase in, reading and, 207–208
- Volition. *See also* Executive function
and prefrontal cortex, 1546–1559
- Voltage-clamp amplifiers, for recording ion
conductances in ganglion cells, 434
- Voltage-gated ion channels
and ganglion cell excitability, 424–425, 432–434
in ganglion cells, 435
in horizontal cells, 378–379, 379*f*
von Kries adaptation, 900–901, 940, 955–957
- Voronoi domain analysis, neuronal mosaic
measurement based on, 473
- VOT (ventral occipitotemporal) visual
area, macaque, 510*f*–511*f*, 512
homology with human visual area, 517–518
- VP (ventral posterior) visual area
human, 515, 516*f*

VP (ventral posterior) visual area (cont.)
macaque, 509, 510*f*–511*f*
motion processing in, functional mapping
of, 1235
VTF visual area, macaque, 510*f*–511*f*, 511

W

W cells, 495, 566–567
chromatic sensitivity in, 498
circadian role of, 628
cortical connections of, 499
homology to K cells, 487
parallel projections of, 496, 496*f*
S-cone driven, 502
subgroups of, 499
Waggle dance, of bees, 1197
Waking state, burst firing patterns of LGN
cells in, 612
Wallenberg's syndrome, 1492
Wallpaper illusion, 1302, 1302*f*
Wasp(s), color vision in, 963
Watercolor effect, 1583, 1583*f*
Waterfall illusion, 936, 1505
hMT/V5+ visual area activity during,
1237–1239
Wave aberration(s), 795
in aberrated eye, 795, 796*f*
capture by pupil function, 796
in corrected eyes, 807–808
decomposition into component
aberrations, 795–796, 797*f*
and image formation, 795–797
in perfect eye, 795, 796*f*
in real eyes, 795, 796*f*
Zernike modes of, 795–796, 797*f*
Wavelength
cone sensitivity to, 176, 186, 186*f*
dominant, 892
horizontal cell dependency on, 373–374,
374*f*
and thresholds, 820
Wavelength discrimination, 658, 913, 913*f*.
See also Color discrimination
in dogs, 963, 963*f*
Weber law region, 912
Weber's law, 815–816, 817, 817*f*, 859, 912,
917, 1046, 1046*f*
Weber fraction, 1304
Wertheimer, Max, 1573–1574, 1578, 1585
“What” visual pathway, 489, 495–496

“Where” visual pathway, 489, 495–496
White noise, 1591, 1591*f*
domain analysis with, 748
in ideal observer analysis, 833, 833*f*
in MT speed selectivity analysis,
1206–1207, 1207*f*
as stimuli for mapping receptive fields,
706–707, 714
White-black dimension, 894, 894*f*,
897–898, 897*f*
Whiteness, 1092
Wiesel, Torgsten, 11, 17, 18, 23, 49, 108,
126, 127, 147
Wire volume, retinal, correlation with
information capacity, 245, 255
Wisconsin Card Sorting Test, 1550, 1550*f*
Working memory, 544
in cognitive control, 1547
definition of, 1547, 1551
prefrontal cortex (PFC) and, 1556–1557
prefrontal cortex (PFC) damage and,
1551, 1552
spatial, and MSTd neuronal responses to
optic flow, 1277, 1277*f*
and visual consciousness, 1686

X

X cells, 17, 495, 566–567, 568, 569*f*
cortical connections of, 498–499, 681
firing patterns of, cortical feedback and,
611–612
Golgi, flat-mount image of, 263, 263*f*
homology to M and P cells, 486–487
inhibitory surrounds of, 355
morphology of, 568
ON and OFF, 262*f*, 262–263, 673
axonal arborization in LGN, 271, 271*f*
distribution of, 267–268
parallel projections of, 496, 496*f*
subgroups of, 499
X chromosome
and color vision defects, 975–976
photopigment genes on, 979–980, 980*f*,
1005
expression of, 983–986
X inactivation, 976, 977
X-chromosome incomplete achromats, 875
Xenopus
eye field demarcation in, 33
optic chiasm development in, 99

optic chiasm in, organization of, 94
retinal cell development in, 63, 64–65,
65*f*
retinal cell differentiation in, 79
retinal progenitor cells in, 37

Y

Y cells, 17, 495, 566–567, 568, 569*f*
axonal bifurcations, 527
central projections of, 270
cortical connections of, 498–499, 681
firing patterns of, cortical feedback and,
611–612
Golgi, flat-mount image of, 263, 263*f*
homology to M cells, 486–487
inhibitory surrounds of, 355
morphology of, 568
ON and OFF, 262*f*, 262–263, 673
axonal arborization in LGN, 271, 271*f*
distribution of, 267–268
parallel projections of, 496, 496*f*
subgroups of, 499
Young, Thomas, 3, 12

Z

Zebrafish
astray mutants of, optic chiasm
development in, 100, 100*f*
bipolar axons in, stratification of, 268,
269*f*
cyclops mutant in, 34
lakritz mutants, retina lamination in, 83
ON and OFF pathways in, 266
electroretinogram of, 261, 261*f*
Pax2 (noi) mutants of, optic chiasm
development in, 101
positioning information across retina in,
41
retinal cell differentiation in, 467
young mutants, retina lamination in, 83
Zernike modes
average magnitude in normal population,
796, 797*f*
radial order of, 795–796
of wave aberrations, 795–796, 797*f*
Zinc
GABA receptor response to, 356*t*, 359
glycine receptor response to, 356*t*,
358–359
Zone models, 895–896, 917
