CONTENTS

Preface xiii

I HISTORICAL FOUNDATIONS 1

1. Vision Structure and Function: The Early History *Mitchell Glickstein* 3
2. The Role of Single-Unit Analysis in the Past and Future of Neurobiology
Horace Barlow 14

II DEVELOPMENTAL PROCESSES 31

3. Molecular Regulation of Vertebrate Retinal Development
Colin J. Barnstable 33
4. Neurotrophins, Electrical Activity, and the Development of Visual Function
Nicoletta Berardi and Lamberto Maffei 46
5. Developmental and Genetic Control of Cell Number in the Retina
Robert W. Williams and Sally A. Moody 63
6. Development of the Vertebrate Retina *Rachel O. L. Wong and
Leanne Godinho* 77
7. The Development of Retinal Decussations *Carol Mason and
Lynda Erskine* 94
8. The Development of Eye-Specific Segregation in the Retino-Geniculo-Striate
Pathway *Barbara Chapman* 108

9. The Role of Neural Activity in the Development of Orientation Selectivity
Chiayu Chiu and Michael Weliky 117
10. Mechanisms of Plasticity in the Visual Cortex *Nigel W. Daw* 126
11. Ontogenesis of Cortical Connectivity *Henry Kennedy and
Andreas Burkhalter* 146
12. Neural Limitations on Visual Development in Primates *Lynne Kiorpes and
J. Anthony Movshon* 159
13. Development of Spatial Selectivity and Response Timing in Humans
Anthony M. Norcia 174
14. The Effects of Selected Forms of Early Visual Deprivation on Perception
Donald E. Mitchell 189
15. Toward a Future for Aging Eyes *R. A. Weale* 205

III RETINAL MECHANISMS AND PROCESSES 213

16. Visual Transduction by Rod and Cone Photoreceptors *Marie E. Burns and
Trevor D. Lamb* 215
17. How Retinal Circuits Optimize the Transfer of Visual Information
Peter Sterling 234
18. ON and OFF Pathways in the Vertebrate Retina and Visual System
Ralph Nelson and Helga Kolb 260
19. Retinal Synapses *Martin Wilson* 279
20. Retinal Neurotransmitters *Robert E. Marc* 304
21. Excitation in the Retina: The Flow, Filtering, and Molecules of Visual Signaling
in the Glutamatergic Pathways from Photoreceptors to Ganglion Cells
David R. Copenhagen 320
22. Peptide and Peptide Receptor Expression and Function in the Vertebrate Retina
Nicholas C. Brecha 334
23. Inhibition in the Retina *Malcolm M. Slaughter* 355
24. Anatomy, Circuitry, and Physiology of Vertebrate Horizontal Cells
Ido Perlman, Helga Kolb and Ralph Nelson 369
25. Retinal Amacrine Cells *David I. Vaney* 395
26. Ganglion Cells in Mammalian Retinae *Paul R. Martin and
Ulrike Grünert* 410
27. Retinal Ganglion Cell Excitability *Andrew T. Ishida* 422

PREFACE

Perhaps the most remarkable thing about vision is the utter simplicity of the act of seeing. We open our eyes and a three-dimensional panorama of colored images—some stationary, others in motion—unfolds before us. In most cases, the brain makes sense of this information seemingly instantaneously, allowing us to function reasonably well under a wide range of lighting conditions. The retinal image is constantly changing as we move about and yet the objects around us are perceived as stable. This seemingly effortless nature of sight beguiles the profound complexity of the processes underlying the perception of even the simplest visual stimulus. Indeed, no machine can currently perform the myriad visual recognition tasks we normally take for granted, and it is still unclear whether such technology will become available in the foreseeable future.

Vision is the dominant sense in humans and other primates, with nearly 30% of our cortical surface representing information that is predominantly visual. Reflecting the importance of vision to the formation of human experience, more effort has gone into studying the visual system than any other sensory modality. As a consequence, we have accumulated an impressive amount of information about vision at many different levels, ranging from genes and molecules to theoretical computations. Our long-term objective is to explain how the brain transforms the spatiotemporal patterns defined by the photons impinging on the retina at any given moment into a coherent visual world. The information derived from understanding these basic processes will ultimately help us prevent and treat the many disorders that impair our ability to see.

Almost 10% of people living today suffer from a visual disorder stemming from a defect of the retina or the visual centers of the brain. Effective treatment of these visual impairments is possible in only a few types of cases because we lack the basic knowledge to understand the dysfunction underlying these disorders. Although we have made significant progress in the visual neurosciences, much remains to be done. The scope of the overall effort has intensified in recent years, reflecting in part, the advent of new technologies, ranging from those of modern molecular biology to the functional imaging of the human brain. Such methodologies have now made it possible to pursue a host of previously unanswerable questions.

There is a plethora of professional journals devoted to vision research, and a number of excellent books dealing with perception as well as the neural bases of vision. No single source, however, has attempted to provide a comprehensive and authoritative account of the visual neurosciences. In an attempt to remedy this situation, we invited 100 of the world's leading researchers in this field to summarize their area of specialization in a manner understandable to the nonspecialist. The response by our colleagues was immensely gratifying. Virtually everyone invited agreed to participate, and some suggested the inclusion of additional chapters, so the final number of contributions was increased to 114.

Each chapter was reviewed by other experts, and authors made revisions based on their feedback. As editors we strove to preserve the individual “voice” of each author, and we also agreed to tolerate a certain degree of redundancy across chapters, provided they

offered valuable insights into the topic under consideration. *The Visual Neurosciences* is a work in progress so some disagreement was expected among authors regarding specific issues. We made little attempt to broker a compromise between dissimilar viewpoints held by different authors, as long as these were supported by empirical evidence. Controversy is what often makes science fun, and we leave it for future generations to decide the relative merits of currently held positions.

The Visual Neurosciences begins with two historical chapters and an appraisal of the prospects for single-unit approaches in neurobiology. They are followed by Chapters 3–15 on Developmental Processes. This section, as in the book as whole, is organized from molecules to pathways to systems. The section on Retinal Mechanisms and Processes (Chapters 16–29) presents the current state of knowledge on phototransduction, retinal synapses, and physiology, with authors explaining how these mechanisms ostensibly optimize the processing of visual information. These chapters set the stage for the next section on the Organization of Visual Pathways (Chapters 30–34) and the subsequent elaboration of projections for Subcortical Processing (Chapters 35–40) and for Processing in Primary Visual Cortex (Chapters 41–49). Most of the chapters in these first six sections provide an anatomical and physiological context for understanding the psychophysical, perceptual, and neurophysiological chapters that follow in the next four sections, beginning with Detection and Sampling (Chapters 50–55) and proceeding to higher-level processing of Brightness and Color (Chapters 56–67), Form, Shape, and Object Recognition (Chapters 68–79), and Motion, Depth, and Spatial Relations (Chapters 80–89). These chapters illustrate how 20th Century neuroscience unraveled many phenomenological conundrums of the 19th Century. Of course, 20th Century psychology raised still other challenges for neuroscience, including the role of nonsensory variables in perception and cognition. Sections on Eye Movements (Chapters 90–99) and Attention and Cognition (Chapters 100–104) address these questions with detailed accounts of the coordination of eye position and information processing by subcortical and cortical circuits underlying cognitive phenomena. The final section, Theoretical and Computational Perspectives (Chapters 105–114), provides an integration of ideas from neuroscience, psychology, and computer science that are likely to guide future discoveries in the visual neurosciences.

For an undertaking of this scope, the entire project went remarkably smoothly. For this we thank all of the authors for adhering good-naturedly (in most cases) to the rather tight schedule. We also thank the countless anonymous reviewers, members of the Editorial Advisory Board for their input at all stages of this undertaking, and Barbara Murphy, our editor at the MIT Press, for her support and keen professional advice. It is our hope that *The Visual Neurosciences* will serve to motivate and inspire the next generation of researchers, whether they are currently beginning students, clinical practitioners, or established researchers in other fields of endeavor.

Leo M. Chalupa and John S. Werner

I HISTORICAL FOUNDATIONS

1 Vision Structure and Function: The Early History

MITCHELL GLICKSTEIN

Introduction

This chapter deals with the early history of the study of visual processing by the eye and brain. I begin by considering the first recognition of how images are formed in the vertebrate eye and early contributions to understanding the structure and function of the retina. I go on to discuss the connections from the retina to the cortex by way of the lateral geniculate nucleus (LGN), and the evidence that led to the recognition and spatial mapping of the visual fields on the primary visual cortex. Finally, I describe some of the studies that began to reveal the multiplicity of visual cortical areas and their functions. Because of space limitations, many interesting aspects of the history, such as color vision, visual reflexes, subcortical visual structures, and the controversies over the interpretation of macular sparing after visual cortex lesions must be beyond the scope of this chapter. The emphasis is on fundamentals of structure and its relation to visual function.

Image formation

The cornea and lens form an inverted image of the visual scene at the back of the eye. The optics of image formation in the vertebrate eye were unknown until the theoretical and experimental advances of the seventeenth century. Prior to that time, scientists were troubled by the idea of an upside-down image in the eye even though they knew of the *camera obscura*, a dark chamber with a pinhole aperture that admits light and forms an inverted image of an illuminated scene. As early as the eleventh century, Ibn Al-Haithem, an Arab scholar (cited in Polyak, 1941), wrote a treatise in which the principles of image formation by the camera obscura were clearly described. Even though the optics of the camera obscura appeared to be similar in some ways to that of the eye, inversion of the image troubled earlier thinkers. Leonardo da Vinci (sixteenth century; Windsor Collection) tried to construct a scheme whereby an inverted image would first be received somewhere in the lens and then reinverted to form an upright image at the back of the eye. He wrote:

No image, of however small a body, penetrates into the eye without being turned upside-down and, in penetrating the crystalline sphere, it will be turned the right way again.

The true nature of image formation by the eye was first put forward by Kepler (1604) on theoretical grounds and confirmed experimentally by Scheiner (1619 and 1652), who removed some of the opaque tissue at the back of an excised eye and directly demonstrated the inverted image. The principle of image formation by the human eye was beautifully illustrated by Des Cartes (1677; cited in Polyak, 1941).

The retina

Following Kepler's analysis and Scheiner's demonstration, the inverted image became an accepted fact. There was, however, little understanding of how the pattern of light and darkness in the image is converted into a signal by the retina. Thomas Young (1802) speculated that there must be a finite number of receptor types, say three, which would be sufficient to account for human color vision. But the actual structure of the retinal elements remained poorly understood. Invention of the compound microscope in the early nineteenth century led to an explosion of new knowledge about the structure and function of tissues in general and of the retina in particular. Among the most important of the early contributors was Max Schultze (1866), who described clearly the three major cell layers of the retina, with special attention to the distribution and morphology of the rods and cones (Fig. 1.1). He noted that there is a predominance of thin, rod-like receptors in the retina of strongly nocturnal animals and of thicker, cone-like receptors in diurnal animals. On the basis of comparative evidence and the distribution of receptors in the human eye, Schultze suggested that the two distinct classes of receptors might be associated with vision under two different conditions of illumination.

Schultze and his contemporaries were vague about the connections between the successive elements of the receptors and the ganglion cells. The prevailing view of nervous tissue in general, and the retina in particular, was that it has a reticular structure in which successive elements are continuous and fused. The three prominent cell layers of the retina were thought of as swellings on optic nerve fibers. The anatomic research of Santiago Ramon y Cajal changed that view. Cajal first saw an example of the then new Golgi

FIGURE 1.1. Schultze's drawings illustrating the structure of the retinal elements, with special reference to the morphological difference between rods and cones. Cones and rods are shown with their fibers up to the inner nuclear layer of the human retina. All of the figures, with the exception of Fig. 8, are drawn at a magnification of 500x. Figs. 1-8 are taken from teased pieces of retina which were placed in osmic acid for 24 hours (1:700). They were from a fresh healthy eye. Figures 9-12 were from an eye with an atrophied optic nerve which was hardened in Müller's solution. *a* always refer to the external limiting membrane, *b* the rods, *c* the cones, *b'* the rod nuclei on the inner part of the external granular layer, *c'* the cone nucleus, and *d* the inner nuclear layer. The outer segments of the cone are incomplete since they were shriveled by the osmic acid. The outer segments of the rods are shown as they would appear in a fresh condition.

Fig. 1. From the peripheral region of the retina. The space between *a* and *d* is completely filled by the rod and cone nuclei (the latter are always adjacent to the external limiting membrane). In the figure, a place has been selected in which the individual rod nuclei are removed in order to make the course of the fibers which remain apparent throughout their entire length. The cone nuclei end in a cone-shaped swelling that breaks up into fine fibers at the upper border of the inner nuclear layer. The rod fibers, which have exquisite fine varicosities, also end in the internal granular layer in an expanded varicosity at the point at which they make connections.

Fig. 2. The same elements from a region outside of the macula lutea. The fibers of the cones and rods have become measurably longer, but their associated nuclei remain in the same relative position, so that now in the external granular layer *d*, there is a region without nuclei that consists only of the radial fibers of the external granular layer, which can reach an even greater length than the figure illustrates. It is this same place which H. Müller says appears to arise as a thickening of the inner nuclear layer and which Henle calls the *external fiber layer* of the retina.

Fig. 3. A region of the retina which is closer to the macula. In the inner part of the external granular layer there is a change

of direction of the fibers away toward the ora serrata. With a reduction in their number, the rods have the same course as the adjacent cone fibers. Otherwise, all courses are as previously described.

Fig. 4. At the border of the macula lutea. The diagonal course of the rod and cone fibers is even more marked.

Figs. 5-7. These figures show the cones in the macula lutea and the fovea centralis. *a* is the outer limiting membrane in all cases next to the cone nuclei. As was partly seen earlier, the cone nuclei appear to follow a radial course. The fibers become so long before they reach the inner nuclear layer that a complete depiction is not possible. The one illustrated is six times longer than the one in Fig. 4. The outer segments of the cones, as stated previously, are shriveled.

Fig. 8. (*a*) A cone from the peripheral region of the retina fixed in osmic acid and enlarged 1000-fold. The outer segment is shriveled. The inner segment and the cone nucleus have a fine fibrous structure, somewhat like that of the substance of the central ganglion cells. This apparently stops at the nuclear swelling of the cone just under the external limiting membrane, only to reappear in the cone fiber, where it is continuous with the end swelling. (*b*) This is an equivalently magnified rod, but without its outer segment: *b'* is the nuclear portion of the rod fiber, the so-called rod nucleus.

Figs. 9-12. These figures show cones and rods of the macula lutea and its surroundings from a thin retina hardened with Müller's fluid and then teased with needles. The preparation is shown to illustrate the fact that even if the rods and cones themselves are not present, the nuclei of the rods and cones (*b'* and *c'*) can be distinguished, and those connected to the thin cones of the fovea centralis are similar to the nuclei of peripheral cones. But the preparation is not suitable to illustrate the cone fibers, which may be attributable to their long immersion in Müller's fluid or else to a pathological condition. The eye had been excised because of intercalary staphyloma, and showed atrophy of the optic nerve and ganglion cells. (From Schultze, 1866.)

staining technique when he visited his colleague in Madrid, Don Luis Simarro, in 1878. Struck by the beauty and promise of the method, he began to apply the Golgi staining technique systematically to the study of the vertebrate retina and brain. Cajal's classic monograph on the retina was published in French (1892) and translated into English (1972) (Fig. 1.2). Cajal was convinced that the reticular theory of organization of the nervous system was wrong. The retina, as well as the brain and spinal cord, he argued, are made up of individual elements, later called *neurons* by Waldeyer. Neurons may touch one another, but they do not fuse. In his monograph, Cajal described in detail the major cell types in all three retinal layers. He emphasized that the direction of conduction is from the receptors, through the horizontal, bipolar, and amacrine cells of the inner nuclear layer, ultimately to the ganglion cells, whose axons constitute the optic nerve. Cajal's descriptions have remained the basis for all subsequent anatomical studies.

On the central course of the optic nerve fibers and the pattern of decussation in the chiasma

Early anatomists saw a prominent nerve exiting the back of each eye directed toward the brain. It was usually assumed that the nerves originated in the brain and extended out to the eye. The fibers arising from each eye appeared first to unite and then to cross the midline in the X-shaped optic chiasm. With earlier techniques of crude dissection, the pattern of crossing was not clear, so the true picture was not accepted until the late nineteenth century. The rearrangement of fibers in the chiasm was briefly described by Isaac Newton in his second book on optics (1704). Newton wrote:

Are not the Species of Objects seen with both Eyes united where the optick Nerves meet before they come into the Brain, the fibres on the right side of both Nerves uniting there, and after union going thence into the Brain in the Nerve which is on the right side of the Head, and the fibres on the left side of both nerves uniting in the same place, and after union going into the Brain in the nerve which is on the left side of the Head, and these two Nerves meeting in the Brain in such manner that their fibres make but one entire Species or Picture, half of which on the right side of the Sensorium comes from the right side of both Eyes through the right side of both optick Nerves to the place where the Nerves meet, and from thence on the right side of the Head into the Brain, and the other half on the left side of the Sensorium comes in like manner from the left side of both Eyes. For the optick Nerves of such Animals as look the same way with both Eyes (as of Men, Dogs, Sheep, Oxen & cet.) meet before they come into the brain, but the optick Nerves of such Animals as do not look the same way with both Eyes (as of Fishes and of the Chameleon) do not meet, if I am rightly informed.

Although he incorrectly assumed that the origin of the optic nerves is within the brain, Newton described correctly

the course of the optic nerves in the optic tracts, and he was also aware of differences in the pattern of decussation in animals with laterally placed eyes. But despite Newton's scientific authority, the true picture failed to penetrate to the medical or biological literature. Over 100 years later, William Wollaston (1824), describing his own temporary hemianopia, wrote:

It is now more than twenty years since I was first affected with the peculiar state of vision, to which I allude, in consequence of violent exercise I had taken for two or three hours before. I suddenly found that I could see but half the face of a man whom I met; and it was the same with respect to every object I looked at. In attempting to read the name JOHNSON over a door, I saw only SON; the commencement of the name being wholly obliterated to my view.

Unaware of Newton's suggested scheme for the course of the optic nerves, Wollaston wrote:

It is plain that the cord, which comes finally to either eye under the name of the optic nerve, must be regarded as consisting of two portions, one half from the right thalamus, and the other from the left thalamus nervorum opticomum. According to this supposition, decussation will take place only between the adjacent halves of the two nerves. That portion of the nerve which proceeds from the right thalamus to the right side of the right eye, passes to its destination without interference: and in a similar manner the left thalamus will supply the left side of the left eye with one part of its fibres, while the remaining half of both nerves in passing over to the eyes of the opposite sides must intersect each other, either with or without intermixture of their fibres.

Wollaston rediscovered hemidecussation by observing his own transient hemianopia. Despite Newton's scientific authority and Wollaston's evidence, the pattern of hemidecussation was still largely unrecognized. Wollaston's report was cited one year later by a news item in the Boston Medical and Surgical Intelligencer as an isolated curiosity in the same paragraph that described a boy in Philadelphia who allegedly saw a candle flame upside down. As late as 1880, H. Charlston Bastian (1880), Professor of Pathological Anatomy and Medicine at University College London (I blush), could still write:

Although the subject is by no means free from doubt and uncertainty, the weight of the evidence seems now most in favour of the view that decussation at the Optic Commissure is as complete in Man as it is known to be in lower Vertebrates.

In spite of Dr. Bastian's opinion, within a few years the true picture was soon clarified. By the time Gowers wrote his Textbook of Neurology (1892), the pattern of decussation and visual loss associated with lesions of the optic tract, the visual radiations, or the striate cortex was widely accepted.

On the termination of the optic tract fibers in the lateral geniculate nucleus

Vision, like all sensory inputs, except for olfaction, is relayed to the cerebral cortex by way of the thalamus. The thalamic relay for vision is the LGN. The LGN in humans and Old World monkeys has an obvious striped appearance, with six layers of neurons separated by interleaved fiber layers. Although, by the end of the nineteenth century, it was clear that the eye projects to the LGN, the pattern of termination of optic tract fibers was not well understood. The true picture was revealed by study of transneuronal atrophy and degeneration. Cells in the LGN that are deprived of their input from the eye shrink or die. Mieczyslaw Minkowski (1920), working in Zurich, studied the LGN of a monkey that had had one eye removed 8 months earlier and that of a 75-year-old woman who had had amblyopia due to a unilateral cataract for 38 years before she died. Minkowski saw that cells in the LGN layers opposite the blind eye, layers 1, 4, and 6, were atrophied. In the ipsilateral LGN, layers 2, 3, and 5 were affected. The technique of studying transneuronal atrophy has revealed the organization of the LGN in a large number of mammals. The six-layered pattern is virtually identical in the apes and the Old World primates.

In some cases, the existence of a hidden laminar pattern can be revealed by transneuronal atrophy. For example, in the squirrel monkey, *Saimiri*, the dorsal parvocellular region of the LGN is not obviously laminated. One year after unilateral enucleation, a clear six-layer pattern emerges which is similar to that of the Old World primates (Doty et al., 1966).

On the representation of the visual fields in the LGN and cortex; orthograde and retrograde degeneration in the visual system

In the 1920s and 1930s, anatomists (e.g., Brouwer and Zeeman, 1926) studied orthograde projections from the retina to the LGN by making restricted retinal lesions and identifying degenerating fiber terminals in the LGN using the Marchi stain. Geniculocortical projections were studied by making lesions of the primary visual cortex and mapping retrograde degeneration of cells in the LGN (e.g., Clark, 1932). These anatomical studies confirmed that there is an orderly projection from the retina to the LGN and from the LGN to the visual cortex. Neighboring points in the visual fields are represented at neighboring points on the cerebral cortex. In later studies (Van Buren, 1963), it

FIGURE 1.2. Cajal's drawings showing the cell types in the mammalian retina. This is Cajal's description (from Thorpe and Glickstein's 1972 translation). All figures show cells from the mammalian retina with the exception of Fig. 1, which shows the nerve cells from the chicken retina.

Fig. 1. *A*, ganglion cell destined for the first sublayer; *B*, ganglion cell destined for the second sublayer; *C*, small ganglion cells with granular clusters which spread in the fourth sublayer; *D*, multipolar cell destined for the second sublayer; *E*, a cell which forms two horizontal plexuses—one below the fourth sublayer and another in the third sublayer; *F*, small cell with two fine plexuses—one in the second sublayer and the other in the fourth sublayer; *G*, giant cell which forms three plexuses—in the second, third, and fourth sublayers; *H*, bistratified amacrine cell; *J*, cell with an extremely fine plexus destined for the third sublayer; *K*, cell which arborizes in the fourth sublayer and whose branches interlace with the end branches of an amacrine cell lying in the same layer; *a*, centrifugal fibers; *b*, another centrifugal fiber whose termination extends horizontally above the inner plexiform layer.

Fig. 2. A section through the retina of an adult dog. *a*, cone fiber; *b*, cell body and fiber of a rod; *c*, bipolar cell with an ascending cluster destined for the rods; *d*, very small bipolar cell for the rods with a sparse upper cluster; *e*, bipolar cell with a flat cluster destined for the cones; *f*, giant bipolar cell with a flat cluster; *h*, diffuse amacrine cell whose varicose branches lie, for the most part, just above the ganglion cells; *i*, ascending nerve fibrils; *j*, centrifugal fibers; *g*, special cells which are very rarely impregnated; they have an ascending axis cylinder; *n*, ganglion cell which receives the terminal cluster of a bipolar cell destined for the rods; *m*, nerve fiber which disappears in the inner plexiform layer; *p*, nerve fiber of the optic fiber layer. *A*, outer plexiform layer; *B*, inner plexiform layer.

Fig. 3. Horizontal cells from the adult dog retina. *A*, outer horizontal cell; *B*, middle-sized inner horizontal cell with no descending protoplasmic processes; *C*, another, smaller inner horizontal cell; *a*, horizontal cell axis cylinder.

Fig. 4. Nerve cells from the ox retina. *a*, bipolar cell with an ascending cluster; *b*, bipolar cell with a flat upper terminal cluster destined for the cones; *c*, *d*, *e*, bipolar cells of the same type whose lower cluster, however, arborizes in the more external sublayers of the inner plexiform layer; *g*, bipolar cell with a flat cluster of enormous extent; *f*, another bipolar cell with a giant upper cluster characterized by the rich, irregular arborization formed by the ascending processes; *h*, oval cells lying outside the outer plexiform layer; *i*, amacrine cell located within the second sublayer of the inner plexiform layer; *j*, amacrine cell occupying the third sublayer; *m*, another amacrine cell whose branches apparently disappear in the third and fourth sublayers.

Fig. 5. Horizontal axis cylinder from the outer plexiform layer. *a*, terminal arborization as seen from the side; *b*, nerve fiber.

Fig. 6. Another terminal arborization of the same type.

Fig. 7. Nerve elements from the ox retina stained with chromium-silver according to the double impregnation method. *A*, semilunar amacrine cell whose enormously long branches arborize in the first sublayer; *B*, large amacrine cell with thick branches in the second sublayer; *F*, another amacrine cell, which is rather small and arborizes in the second sublayer; *D*, amacrine cell with a stellate cluster destined for the third sublayer; *G*, *H*, amacrine cells destined for the fourth sublayer; *E*, large amacrine cell destined for the fifth sublayer; *C*, special type of amacrine cell with very thin branches which spread preferentially in the first and fifth sublayers. *a*, small ganglion cell destined for the fourth sublayer; *b*, ganglion cell whose branches form three superimposed plexes; *c*, small ganglion cell with branches arborizing in the first sublayer; *d*, middle-sized ganglion cell with branches in the fourth sublayer; *f*, ganglion cell which is similar to the multilayered cells (branching in three sublayers) in the reptile and bird; their branches form two plexes—one in the fourth sublayer and another in the second sublayer; *e*, giant ganglion cell destined for the third sublayer.

Fig. 8. Amacrine cells and ganglion cells from the dog retina. *A*, stellate amacrine cell destined for the first sublayer and a portion of the second sublayer; *B*, giant amacrine cell of the third sublayer; *C*, *G*, stellate amacrine cells destined for the second sublayer; *F*, small amacrine cell destined for the third sublayer; *E*, amacrine cell destined for the fourth sublayer; *D*, unstratified amacrine cell; *a*, ganglion cell whose upper cluster spreads in the second sublayer; *b*, giant ganglion cell destined for the second sublayer; *e*, small ganglion cell whose cluster spreads in the fourth sublayer; *f*, middle-sized ganglion cell which arborizes in the first and in a portion of the second sublayers; *g*, ganglion cell which arborizes in the third and a portion of the fourth sublayers; *i*, two-layered cell (*cellule bistratifiée*).

Fig. 9. Ganglion cells from the dog retina. *a*, giant ganglion cell whose cluster spreads in the first and a portion of the second sublayers; *b*, small ganglion cell whose multiple processes disappear in the fifth sublayer; *c*, giant cell whose cluster seems to spread mainly in the second sublayer; *e*, giant ganglion cell of the second sublayer; *d*, *g*, small ganglion cells with clusters in the fourth sublayer; *f*, middle-sized ganglion cells destined for the first sublayer; *h*, another ganglion cell destined for the second and partially for the first sublayer; *i*, unstratified ganglion cell; *A*, *B*, *C*, spongioblasts (amacrine cells); *L*, lower terminal arborization of a bipolar cell. (From Cajal, 1892.)

was discovered that in addition to retrograde degeneration in the LGN that is caused by cortical lesions, there is also transneuronal degeneration in the retinal ganglion cell layer after lesion of the cerebral cortex.

On the primary visual cortex

By the end of the eighteenth century, the gross structure of the cerebral cortex was beautifully illustrated in anatomical texts, but the cortex was portrayed as structurally homoge-

neous. One part of the cortex was depicted as looking like any other. The first recognition that the cerebral cortex is not uniform in structure was made by an Italian medical student, Francesco Gennari, working in the newly re-founded University of Parma (Gennari, 1782; Glickstein and Rizzolatti, 1984). Gennari packed brains in ice, which allowed him to make clean, flat cuts through them. He noted a thin white line, and sometimes two lines within the cortex, running parallel to and about halfway between the pial surface above and the white matter below. The line coalesces

into a prominent single stripe in the caudal part of brain, “in that region near the tentorium.” Gennari first saw the stripe in 1776 and described it in his monograph *De Peculiari* (1782) some 6 years later (Fig. 1.3).

Gennari’s monograph was published in a limited edition and he came from what was then an obscure university, so although it was cited by some authors, it was often ignored. The same cortical stripe was discovered independently a few years later by the more eminent anatomist Vicq D’Azyr. The stripe was described in his *Traité D’Anatomie* (1786) 3 years later. It was the Austrian anatomist Obersteiner (1888) who found Gennari’s earlier description of the white line and named it the *stripe of Gennari*.

Although regional variability in cortical structure was soon accepted, there was no agreement about possible differences in the functions of different cortical areas. Two of the major authorities at the beginning of the nineteenth century, Gall (Gall and Spurzheim, 1810–1819) and Flourens (1824), held opposing views. Gall and his followers, the cranioscopists/phrenologists, asserted that the cerebral cortex is made up of a number of individual areas, each associated with a specific personality characteristic. If a person has a good memory, for example, the memory area of the cortex is relatively enlarged. Enlargement of a cortical area is associated with corresponding change in the shape of the skull, hence a bump on the head. Person-

ality, ability, and character could be read by palpating the head.

The earliest experimentalists failed to confirm Gall’s views. In a typical experiment, Flourens (1824) made lesions in the brains of birds and mammals and observed the resulting effects on the animals’ behavior. Although Flourens was convinced that the cerebral cortex is responsible for sensation, movement, and thought, he could find no evidence that any of these functions is localized to a particular site on the cerebral cortex.

In later years, evidence began to accumulate in favor of functional localization in the cerebral cortex. A series of postmortem observations of focal injuries in the brains of patients who had lost the power of speech culminated in Broca’s (1861) description of the lesion in the left frontal lobe of the patient “Tan,” a man who had been unable to say any word other than *tan* for the past several years. The evidence for brain localization of speech was soon accepted, and within a few years experiments began to provide additional evidence that different areas of the cerebral cortex are specialized for different functions. The single most important experiment that led to modern understanding of the localization of motor and sensory functions in the cortex was done by Gustav Fritsch and Eduard Hitzig (1870). They electrically stimulated restricted regions of the frontal lobe of a dog and elicited movement of the face or limb on the opposite side of the body. Fritsch and Hitzig’s discovery of a specifically motor area of the cortex was instrumental in prompting a search for other functions, including vision. There had been indications (Panizza, cited by Mazzarello and Della Sala, 1993) that lesions in the caudal part of the brain are associated with visual deficits, but the clearest and most influential evidence for the visual function of the occipital lobe was provided by Hermann Munk, professor of physiology in the Veterinary Institute in Berlin. Munk (1881) made lesions in the occipital lobe of dogs and monkeys. He reported that if he destroyed one occipital lobe, the monkeys became hemianopic. Bilateral lesions caused blindness (Fig. 1.4).

Munk’s discovery focused the attention of clinicians and scientists on the role of the occipital lobe in vision. Salomon Henschen (1890) summarized the postmortem findings in a group of patients who had suffered from hemianopia as a result of a stroke. He compared these patients with a similar number who had sustained a comparable loss of brain tissue that had not become hemianopic. Henschen confirmed the location of the primary visual area, and he suggested a scheme for the way in which the visual fields are mapped on the primary visual cortex. Henschen recognized that the left hemisphere receives its input from the right visual field and the upper bank of the calcarine fissure from the upper retina, hence the lower visual field. But Henschen also suggested that the periphery of the visual field is projected

FIGURE 1.3. The first recognition of the presence of a fiber layer within the cerebral cortex (labeled *l* in the picture) which Gennari described as being “particularly prominent in that region near to the tentorium.” (From Gennari, 1782.)

FIGURE 1.4. Munk clearly illustrates the locus of the visual area of the monkey cortex. Unilateral occipital lobe lesions cause hemianopia. (From Munk, 1881.)

onto the caudal end of the striate cortex, with the fovea represented anteriorly. In this, he was in error.

Henschen's error is understandable, since the lesions in the brains that he studied were diffuse. What was needed to establish a more accurate spatial mapping was evidence of partial field defects, scotomas, caused by smaller, subtotal lesions of the striate cortex. Such lesions, regrettably, arise in wartime. One of the earliest clear pictures of the representation of the peripheral-central visual field representation was made by a young Japanese ophthalmologist, Tatsuji Inouye (Glickstein and Whitteridge, 1987; Inouye, 1909). Inouye was in the medical service of the Japanese Army during the Russo-Japanese war of 1904–1905. His responsibility was to evaluate the extent of visual loss in casualties of the war. Inouye used the opportunity to study the visual field defects caused by penetrating brain injuries. In that war the Russians used a newly developed rifle which fired small-caliber bullets at high velocity. Unlike most bullets used in previous wars, these bullets often penetrated the skull at one point and then exited at another, making a straight path through the brain. Inouye devised a three-dimensional coordinate system for recording the entry and exit wounds. He then calibrated the course of the bullet through the brain and estimated the extent of the damage it would have caused to the primary visual cortex or the optic radiations. Based on his study of visual field defects in 29 patients, Inouye produced a map of the representation of the visual fields on the cortex. The central fields were now placed correctly in the most caudal part of the striate cortex, with the peripheral visual fields represented anteriorly, and there was an over-representation of the central visual fields in the primary visual cortex.

Based on his studies of the visual field defects sustained by soldiers of the First World War, Gordon Holmes (1918a) produced a more accurate and detailed map of the representation of the visual fields on the striate cortex, which still forms the basis for interpreting partial visual loss in humans.

Confirmation of the map by electrical stimulation and recording of evoked potentials

In the period between the First and Second World Wars, the basic arrangement of the visual fields was confirmed in studies using electrical stimulation of the brain in neurosurgical patients. Ottfried Foerster (1929) operated under local anesthetic on patients who suffered from seizures caused by focal scarring of the brain. Electric current was applied at a specific site on the cerebral cortex, and the resultant sensation was reported by the patient. Electrical stimulation of the cortex at the occipital pole caused phosphenes that were centered in front of the patient. Stimulation of the upper lip of the calcarine fissure 5 cm anterior to the occipital pole produced a phosphene that was centered in the lower visual field opposite the side of the brain that had been stimulated. Foerster's studies, and later those of Wilder Penfield (Penfield and Rasmussen, 1952), confirmed the representation of the visual fields on the human striate cortex that had been revealed by the analysis of the scotomas caused by focal lesions.

Electrical recording of neural activity in the primary visual cortex

In the 1930s Philip Bard (1938) and his collaborators, one of whom was Wade Marshall, began to record the electrical

activity that is evoked on the surface of the cerebral cortex of experimental animals by stimulation of the body surface. The electrodes at the time were too large to record the activity of individual neurons but small enough to detect focal activity in a restricted group of cells. There is an orderly representation of the body surface on the primary somatosensory cortex, with neighboring points on the body represented at neighboring points on the brain. Marshall later collaborated with William Talbot in studying the activity evoked on the striate cortex of cats and Old World monkeys. They focused small spots of light on the retina of a monkey and marked the locus of maximal evoked activity on the cerebral cortex. Figure 1.5 is from their report.

Talbot and Marshall's recordings were limited to the dorsolateral surface of the macaque cortex, comprising only roughly the central 10 degrees of the visual field. The work was extended by Peter Daniel and David Whitteridge (1961), who recorded more anterior cortical areas within the calcarine fissure of baboons, extending the mapping into the peripheral visual field.

The evidence from visual loss in humans and monkeys caused by cortical lesions, electrical stimulation of the cortex in humans, and recording in monkeys was all consistent. The visual fields are represented in an orderly way on the primary visual cortex.

Early electrical recording from visual areas outside of the primary visual cortex

Early workers had suggested that the regions outside of the primary visual cortex might have a related visual function. Hermann Munk (1881), for example, labeled a region outside of the primary visual cortex in dogs as an area con-

cerned with the storage of visual memories. William Talbot (1942) made a brief report to the Federated Society for Experimental Biology and Medicine which initiated modern study of the way in which the visual fields are represented beyond the primary visual cortex. Talbot recorded potentials evoked by vision from the surface of a cat brain. As expected, he found that the visual field is mapped in an orderly way on the primary visual cortex, with neighboring points in the visual field represented at neighboring points on the cortex. As Talbot continued to record lateral to the representation of the vertical meridian, he found that the cortex was still activated by focused spots of light, but from increasingly peripheral regions of the visual field. Talbot had discovered a second visual area, later called *Visual Area 2*, which is mapped on the cortex like a mirror image of the primary representation. Talbot had started a growth industry. Some years after Talbot's report, Margaret Clare and George Bishop (1954) described another visual area that is located on the lateral suprasylvian gyrus of cats, in which flash stimuli evoke a gross potential. Although the pioneering work of electrical mapping was done in cats, the visual cortex in these animals is not "primary" in the sense that it is in monkeys and humans. In monkeys and humans, the overwhelming majority of geniculocortical fibers terminate in the striate cortex. In cats, Visual Area 2 receives a direct and equally powerful input from the LGN (Glickstein et al., 1967).

In the 1950s, techniques were developed for isolating the activity of individual neurons, and single-unit recording has since become a standard method of studying visual processing by the brain. The contribution to our understanding of vision from single-unit recording is described in this book by Horace Barlow (Chapter 2). Here we note

FIGURE 1.5. Mapping of the visual fields onto the monkey striate cortex revealed by evoked responses to small, focused spots of light. (From Talbot and Marshall, 1941.)

briefly the way in which these studies increased the number of recognized visual areas in the cerebral cortex. After Talbot's discovery of Visual Area 2 and Clare and Bishop's description of the lateral suprasylvian visual area, David Hubel and Torsten Wiesel (1965) identified another area by recording from cells on the medial bank of the lateral fissure of cats, an area they called *Visual Area 3*. A few years later, John Allman and Jon Kaas (1971), studying the owl monkey *Aotus*, and Semir Zeki (1978), studying Old World macaques, identified more extrastriate visual areas, each of which appeared to be specialized for analyzing color, motion, or form. By a count made in 1992, there are no less than 32 visual areas in the monkey brain (Van Essen et al., 1992). There are doubtless at least as many in the human cortex.

Early behavioral evidence for the functions of extrastriate visual areas

In humans and monkeys the striate area is virtually the sole cortical target of cells in the LGN, but the cortex adjacent to the primary visual cortex is also dominated by vision. An estimated one-third or more of the monkey cerebral cortex is devoted to visual processing. There are two large groupings of visual areas outside the primary visual cortex (Glickstein and May, 1982; Ungerleider and Mishkin, 1982), a medial group centered in the parietal lobe and a lateral group centered in the temporal lobe.

The visual areas of the parietal lobe

In monkeys, all of the parietal lobe cortex from the primary visual area as far rostrally as the intraparietal fissure has direct or indirect input from the primary visual cortex. The angular gyrus is a major part of this area. When David Ferrier stimulated the angular gyrus of the monkey brain electrically, he observed that the stimulation caused eye movements. When he ablated the region, the monkey appeared to be blind. Ferrier concluded that this region must be the primary visual cortex (Ferrier, 1876; Glickstein, 1985) (Fig. 1.6).

Ferrier's first experiments were done in the 1870s, prior to the widespread use of antiseptic techniques in experimental surgery. His animals were killed 3 days after he operated on them, since longer survival times inevitably led to infections. In later experiments, Ferrier adopted the sterile surgical techniques of his colleague at King's College London, Joseph Lister. His animals could now live for weeks, months, or years after the operation. With Gerald Yeo he replicated his studies of the behavioral effect of angular gyrus lesions. They now reported that his animals were not blinded by the angular gyrus lesion but suffered a *temporary* loss of vision (Ferrier and Yeo, 1884). Ferrier's protocols

demonstrate that rather than blindness, his monkeys suffered a severe impairment in guiding their movements under visual control. Virtually identical symptoms were described by Rudolf Balint (1909) in a patient who had suffered bilateral lesions of the parietal lobes and by Gordon Holmes (1918b), who studied casualties among British soldiers in the First World War. Ferrier's monkeys, Balint's patient, and Holmes's soldiers were all unable to guide their movements accurately under visual control. The visual areas of the parietal lobe are principally concerned with spatial localization in the visual field (Ungerleider and Mishkin, 1982) and the visual guidance of movement (Glickstein and May, 1982).

On visual deficits following lesioning of the temporal lobe

Temporal lobe lesions cause an impairment in recognizing and remembering forms. In early studies of the effects of large temporal lobe lesions in monkeys (Brown and Schäfer,

FIGURE 1.6. Lesions of the angular gyrus of the parietal lobe. Ferrier initially interpreted the resultant deficit as blindness. His later study (Ferrier and Yeo, 1884) shows that the monkey was not blind but had a profound deficit in visual guidance of movement following bilateral angular gyrus lesioning. (From Ferrier, 1876.)

1888; Klüver and Bucy, 1938) in addition to other symptoms, there were visual deficits. The specifically visual function of the inferotemporal cortex was further clarified when animals were tested after smaller, more restricted lesions of the temporal lobes were produced. K. L. Chow (1951) showed that lesions of the inferotemporal cortex cause a specific impairment in the acquisition and retention of visual discrimination learning. Mishkin (1966) demonstrated that the essential input to the inferotemporal cortex is by a series of corticocortical connections originating in the striate cortex.

A note on the aims of this chapter and its sources

This chapter has attempted to outline some of the major questions and discoveries that led from the first understanding of image formation by the eye, the recognition of the nature of the photoreceptors, and the connections from the eye to the primary visual cortex. The single most useful volumes for exploring the topics presented here are the two masterful scholarly works of Stephan Polyak, *The Retina* (1941) and *The Vertebrate Visual System* (1957). Both have extensive bibliographies and references which are invaluable for finding the early literature. An excellent source for the history of neuroscience in general is Clarke and O'Malley (1968). Useful also are Von Bonin's (1950) translations of several of the papers cited here. I recognize that there are many other aspects of the history of the study of vision that are of equal interest and relevance. For example, the fascinating story of color vision has only briefly been touched on in the reference to Thomas Young (1802). There is also a tradition based on the subjective study of visual phenomena that began with Goethe, was powerfully advanced by Purkinje and Hering, and contributed to the later understanding of color coding by the brain. While apologizing for these omissions, I hope I have given an outline of some of the early contributions that formed the basis for much of the material to be covered in this volume.

2 The Role of Single-Unit Analysis in the Past and Future of Neurobiology

HORACE BARLOW

Introduction

This chapter starts with a brief history of single-unit recording, biased, I am afraid, toward recounting the parts I know best, namely, those that interested me or those I took part in. It stops well short of the present, except for a brief account of some studies on MT neurons in awake behaving monkeys that I believe point the way ahead. The quantitative statistical approach of signal detection theory should enable one to follow a single quantity, the signal-to-noise ratio, through all stages from the sensory stimulus itself, through single-neuron responses at all levels, to reports of perceptual experiences or other behavioral responses. But statistical arguments have pitfalls. First, the source or sources of limiting noise must be correctly identified; second, they are good for establishing limits to what is possible but not very good as a basis for direct models because we know so little about how the brain computes statistics. I think the implications of statistical measures are most easily understood in terms of rules stating when signal-to-noise ratios are conserved, how they can be increased, and when they decrease. Using the rules, statistical arguments can give much insight into the role of single units in sensory systems, for neurons are the only elements capable of collecting together the information relevant to a particular task, which in turn is the only way to obtain high signal-to-noise ratios.

I believe we need to open our eyes to the much more complex types of computation that, as cell biology is beginning to show, might be accomplished by single neurons, so I could not refrain from speculating about this at the end of the chapter. Finally, at the editor's instigation, I have recounted in an Appendix some of my personal experiences in the remarkable department, created by Lord Adrian, in which I had the extraordinary good fortune to grow up scientifically.

This, then, is a personal view. Please do not read this chapter in the hope of finding a complete historical account that leads to a balanced view of the role of single units in vision; desirable though that would be, it is not what the title proclaims and it is not what you will find.

History

By the beginning of the twentieth century, the basic layout of the sensory systems of the brain, including vision, was surprisingly well understood. If, for example, one reads Schäfer's account of the cerebral cortex in his two-volume *Textbook of Physiology* (1900), at first one cannot fail to be amazed by how much was known. There is a good deal about cortical localization, the neuron doctrine was in place, and there were Cajal's beautiful pictures of neurons with all sorts of shapes and sizes, sometimes with putative circuits showing how messages flowed into the dendrites through synapses and out along axons to distant destinations. But on reflection one becomes aware of what was then missing, for the nature of the activity that was localized, and the nature of the messages that passed from place to place in the brain, were quite unknown. Müller's doctrine of specific nerve energies was based on the similar sensation produced whenever a given type of sensory nerve fiber was excited, regardless of the means employed to excite it. It was sometimes taken to imply that the messages were different in different fibers, rather than that the same message had different meanings when carried by different fibers, but with no knowledge of the nature of the messages, this misunderstanding is perhaps not surprising. The all-or-none law had been formulated for heart muscle, but it was not known to apply to nerve impulses; indeed, it was not clear that nerve messages were composed of impulses. In other words, it was well understood that nerve fibers were communication channels, but it was not understood at all how or what they communicated.

The reason for this ignorance is simple: there were no methods available either for isolating the activity of an individual nerve fiber or for detecting and recording the activity if it had been isolated. Intracellular recording was unheard of, and as we now know, the potential from an impulse that can be recorded through an external electrode placed close to a nerve fiber is a brief (<1 msec) triphasic pulse, often no more than a few microvolts in amplitude. Until these pulses could be amplified electronically, there was no way they could be detected. Action potentials from the synchronized syncytium of muscle fibers in the heart could

be recorded, as could the synchronized action potentials from an electrically stimulated peripheral nerve, but in spite of interesting and ingenious technological devices such as the capillary electrometer, string galvanometer, and rheotome, no method combined the speed and sensitivity required to detect single nerve impulses. The nature of the nerve impulse as a locally generated, self-propagating, all-or-nothing electrical disturbance traveling down individual nerve fibers was soon to be established, perhaps chiefly by Keith Lucas (1909) in a series of closely argued and compelling experiments, but the arguments were indirect: he never recorded all-or-none impulses from single fibers.

PERIPHERAL SENSORY NERVE FIBERS The vacuum tube amplifier, or thermionic valve, was invented in the early 1900s by Fleming and De Lee Forest, and this provided the answer. Among the earliest users in physiology were Gasser and Newcomer (1921), and a year or two later, E. D. Adrian (Keith Lucas's student and colleague) wrote to Gasser asking for details of his amplifier; he then constructed one, and in 1925 for the first time recorded action potentials traveling in sensory nerve fibers. By 1928, after collaborations with Sybil Creed (*née* Cooper), Rachel Matthews (*née* Eckhardt), and Yngve Zotterman, he had recorded from nerves carrying sensory messages from many different types of sensory endings and was able to write *The Basis of Sensation* (Adrian, 1928), a book of only 120 pages telling us that all sensory messages are composed of trains of all-or-none nerve impulses. They vary in frequency according to the intensity of the stimulus; they often (but not always) adapt, that is, the frequency of the train declines over time when the stimulus intensity is sustained; and sometimes they are highly regular (for instance, from the stretch organs of muscle) and sometimes highly irregular (for instance, from taste endings in the tongue). These were exciting years; see Hodgkin (1979) for a fuller and more detailed account of Adrian's early work.

Adrian's main method of isolating the activity of a single nerve fiber was to place a complete peripheral nerve on a pair of recording electrodes and then cut away at the nerve between the electrodes and sensory endings until there was only a single sensory fiber remaining to conduct impulses from sensory ending to recording site. He judged when this had been accomplished by observing that all the action potentials reaching the electrodes became uniform in height and shape, and those from some endings were also regularly spaced in time. This method did not always work. In the experiments that are most relevant for this chapter, on the optic nerve of the eel (Adrian and Matthews, 1927a, 1927b, 1928), they were not successful in recording from single active fibers. Their three papers illustrate their resourcefulness when they could not achieve what they wanted, and they had many indirect results foreshadowing later work, but

discussion of recordings from retinal ganglion cells will be deferred.

I said above that the vacuum tube amplifier provided the answer that overcame the problem of recording from single neurons, but it only provided the tool to obtain the answer. The choice of biological tissue, of the arrangements for recording from the nerve, of the means of stimulating sensory endings, and, above all, of the controls needed to show that the weak potentials recorded really were from sensory fibers—all these depended on the experimenter. Adrian's papers describe with transparent simplicity and directness what he and his colleagues did, why they did it, what they observed, and what this means. It all seems so simple that one asks oneself, "Why are not all papers this easy to follow and understand?" I think the answer is that Adrian was skilful enough to make critical observations whose message was clear without elaborate interpretation. He did not waste time describing results whose meaning was not clear, and when there was any doubt about what they meant, he refused to speculate further. For more than 20 years, important results from him and a galaxy of internationally famous collaborators tumbled out of his laboratory, and he remained at the forefront of neurophysiology, but little of this work involved single units and it will not be described here. He gave up experimental work only when his laboratory was flooded in 1958, and for many years afterward he continued to fill influential and important administrative positions. At the editor's suggestion, I provide a few reminiscences about him and his lab in the Appendix.

RETINAL GANGLION CELLS By 1930, then, the neural code used by peripheral nerve fibers had been broken, but there were 10^{10} neurons in the central nervous system busy communicating with each other, and it was far from certain that they used the same code. The next major step toward resolving this question came in the late 1930s, when Keffer Hartline in Philadelphia and Ragnar Granit in Stockholm recorded from retinal ganglion cells, which are separated by at least two synapses from the sensory cells themselves. Granit and Svaetichin (1939) used platinum-tipped glass electrodes about 15 μm in diameter to record extracellular potentials, and sometimes the action potentials from a single retinal ganglion cell could be isolated (see Rushton, 1949). The development of this method of recording from neurons, in which Gunnar Svaetichin also had a hand, was an important advance, and with minor modifications provided the main means of recording from single neurons in sensory systems until brain slices and patch electrodes were developed many years later.

The physiological aspect of Granit's work on the retina (Granit, 1947) was not so successful. He chose to attack the color problem, using large-area, spectrally pure stimuli, and

he described units with broadband *dominator* and narrower-band *modulator* spectral sensitivity curves. The dominators were relatively stable in position and had scotopic spectral sensitivity curves in dark-adapted conditions and photopic curves in light-adapted conditions. The modulators were not stable and seemed to come in many different varieties. They probably correspond to the spectrally opponent units recorded many years later from fish retina (Svaetichin and MacNichol 1958; Wagner et al., 1960) and from monkey lateral geniculate nucleus (LGN) (DeValois et al., 1967), but it was not really until this later work accrued that progress was made on the color problem.

Hartline developed a technique for raising optic nerve fibers onto recording electrodes as they ran on the surface of the retina from the ganglion cells in the periphery toward the optic disc. His beautiful papers (Hartline, 1938, 1940a, 1940b) give a first insight into how a couple of layers of synaptic connections and lateral interactions create a pattern of activity in the retinal ganglion cells that constitutes a spatiotemporally transformed version of the optical image. He observed that different ganglion cells respond to different temporal phases of the stimulus, some at “on,” some at “off,” and some at both phases. He defined *receptive fields*, noting that they are so large that there must be extensive overlap between the receptive fields of neighboring retinal ganglion cells, and he emphasized the exceptional sensitivity of many cells to movement of the light stimulus. Curiously, he did not discover lateral inhibition in the vertebrate retina, though he certainly would have done so if he had extended his studies of spatial summation to larger diameters of stimulating spots. Instead he switched to the *Limulus* preparation and described it there (Hartline, 1949), so lateral inhibition in the vertebrate eye was left to Kuffler (1952, 1953) and I (Barlow, 1950, 1953) to discover in the cat and the frog, respectively.

SINGLE NEURONS IN THE CENTRAL NERVOUS SYSTEM The task ahead, breaking the code of the 10^{10} neurons of the brain, was a daunting one, not only because of the technical difficulties of recording from them one at a time, but also because of the sheer numbers: How could one possibly hope to sample the activity of a sufficient number of these cells to form an impression of their overall state of activity? And anyway, what guarantee was there that the output of a single cell was at all meaningful by itself? To break the code, it might be necessary to take into account the simultaneous activities of other cells, the details of which would, of course, remain unknown if the cells were recorded one at a time. But the results sketched above convinced some people that single-unit recording was a viable and illuminating technique, and more results followed during the next two decades.

Lettvin and his colleagues (1959) argued that the frog’s retina and superior colliculus extracted behaviorally impor-

tant features from the retinal image. Hubel and Wiesel (1959, 1962, 1968) showed that neurons in the cat’s (and later the monkey’s) visual cortex were sensitive to the orientation of stimuli, and color opponency of neurons in fish retina and monkey lateral geniculate were sorted out (DeValois et al., 1967; Svaetichin and MacNichol, 1958; Wagner et al., 1960). Enroth-Cugell and Robson (1966) applied systems theory to retinal ganglion cell responses and unexpectedly revealed a strong distinction between *X cells*, which behaved linearly, and *I cells*, which behaved nonlinearly, in the way they responded to sinusoidal spatial gratings. Other varieties of selectivity in single units were described and analyzed, such as selectivity for direction and velocity of motion in the rabbit retinal ganglion cells (Barlow et al., 1964) and for disparity in the cat visual cortex (Barlow et al., 1967; Pettigrew et al., 1967). In addition, it was found that the sensitivity of single neurons often approached that of the whole animal quite closely (Barlow et al., 1957, 1971). There were also reports of pattern selectivity in the responses of optic nerve fibers in crustaceans (Wiersma and Yanigasawa, 1971; Wiersma et al., 1961).

In 1972 (Barlow, 1972) I reviewed much evidence showing that single neurons had sensitivity, selectivity, and reliability of an order that would have been considered out of the question 20 years earlier. The results suggested that sensory representations are sparsely coded, that is, only a small proportion of all available sensory neurons are active at any one time in the representations that are responsible for perception. With such sparse coding, single neurons carry a much greater burden in classifying and representing our sensations and perceptions than had previously been supposed, and their ability to respond in a highly selective manner to their inputs becomes crucial. It is sometimes suggested, however, that the early promise of single-unit analysis has not been fulfilled, because units at higher levels responding to more and more specialized features of the environment have not been found. This deserves a comment.

UNITS CAN BE VERY SELECTIVE, BUT THEY ALSO GENERALIZE Perhaps the most striking feature of the early results from single-unit recording was their selectivity: a retinal ganglion cell responds better to a spot of light in exactly the right place on the retina than it does to flooding the whole retina with light, a cortical neuron responds poorly even to a well-placed spot but instead requires a line of the right orientation, and some neurons require a line in the right position in each eye. Some of the *local edge detectors* described by Levick (1967) in the rabbit retina are extraordinarily difficult to excite and characterize. They do not fire spontaneously, nor to whole field illumination, nor even to a line if it is too long, and they ignore their favorite stimulus, a small spot of light, if it is moving too fast. I recall, with some qualms,

leaving Bill Levick just after he had isolated a unit, and coming back an hour and a half later after a good lunch to find that he had made only limited progress toward characterizing it. “I know the receptive field is somewhere near here,” he said, pointing to a mark on the plotting screen, “but there’s something special about its trigger feature.” Then, after perhaps another hour’s further work, he demonstrated that a short black edge at the right orientation, moved very slowly, would invariably elicit a vigorous response, but very little else that could be done on the plotting screen had any detectable effect on that particular unit.

The existence of this degree of selectivity, even in the retina, makes one appreciate how difficult it must have been for Gross and his colleagues (1972) to characterize trigger features as complex as their *hand detectors* or *face detectors* in the inferotemporal cortex of monkeys, or for Rolls and colleagues (Mora et al., 1976; Rolls et al., 1979) to demonstrate *food object detectors* in lateral hypothalamus. These reports were in fact treated with very great skepticism in the early days, though the repeatability of the findings has now established their validity beyond reasonable doubt; one wonders how many more examples of comparable selectivity are waiting to be discovered. But the main point I want to make is that although single-unit results sometimes do show amazing selectivity, they also show evidence of another process—generalization.

One of the surprises in Hartline’s results was the large size of the receptive fields: a retinal ganglion cell collects the activity not just from its fair share of photoreceptors, but from a vastly greater number. Complex cells described by Hubel and Wiesel (1962) in V_1 were orientationally selective but did not have receptive fields that could explain this property, as those of the simple cells could. They proposed that complex cells collect the outputs of many simple cells, thereby retaining the pattern-selective property but generalizing it for position over a small region of visual space. Levick and I found the same in the direction-selective ganglion cells of the rabbit retina (Barlow & Levick, 1965): they apparently collect the outputs of subunits that are selective for the same sequence of activation occurring in their inputs at different positions. This work also showed that selectivity is not necessarily achieved by AND-type logic, but can result from inhibition “vetoing” responses to a subset of stimuli. Another recent example of the way neurons achieve selectivity and generalization is to be found in the work of Thomas and colleagues (2002) showing that some cells in V_2 of monkey are selective for the relative disparity of stereoscopic stimuli; this is thought to be achieved by the appropriate pattern of connections to V_1 cells having absolute disparity selectivities.

The answer to the question raised in this subsection is therefore that cells do become more selective at higher levels, but they also relax their response requirements and gener-

alize in appropriate ways. Selectivity and generalization seem to be the basic operations needed to generate the mythical grandmother cell; the final cell must be selective enough for details so that it responds to a particular elderly lady, not just any elderly lady, but it must also generalize for the dispositions of these details so that it can recognize grandmother in all her possible poses, positions, gestures, and clothing. One can grasp in outline how a hierarchy of neurons, each capable of both selectivity and generalization, might trace a path through the jungle of possibilities resulting from the combinatorial explosion, culminating in a neuron with the properties of a reasonable object detector. I don’t, however, think this has yet been demonstrated in detail in any specific instance as complex and arbitrary as a grandmother cell—if indeed neurons with this degree of selectivity and arbitrariness exist.

The discovery of these unexpected attributes of brain cells obviously took one a step forward, and a sizable fraction of the rest of this book includes later results of single-unit recording in the visual system. I regard this work as the “present” of single-unit analysis and shall not attempt to review it in this chapter, but there is a group of experiments that I shall return to since they are, in my opinion, showing the way ahead. These use statistical measures that can be applied to the sensory signals used to drive the neural responses, to the responses they evoke from single units, and to the behavioral responses of an animal or human observer. First, the approach itself must be described.

The power and pitfalls of the statistical approach

Developments in electronic engineering not only brought us the tools for recording the activities of single neurons, they also brought into prominence the problem of *noise*, the random stochastic voltages that interfere with the *signal* one is interested in and ultimately set a limit to its detectability. But the problem the electrical engineers introduced us to attracted the attention of statisticians, who have provided us with the concepts needed for measuring and understanding signals and noise.

These are the concepts of statistical decision theory (Neyman and Pearson, 1933), which also formed the basis of signal detection theory and which were, in turn, imported into psychology for measuring psychophysical performance within an absolute framework (Swets, 1964). The key advance here was to emphasize signal-to-noise ratios (SNRs) rather than thresholds. Whenever a signal is being detected against a background of noise, there comes a point, as you reduce the signal intensity, when its presence or absence cannot be decided reliably. Before the days of signal detection theory, this was regarded as the threshold of perception, but there is a range in which it can be shown that the value of this threshold is dependent on the number of

false-positive responses the subject makes. From both a theoretical and a practical viewpoint, it is preferable to use a measure that is not dependent on the false-positive rate, and this is provided by the measure that an engineer would naturally use when specifying the magnitude of a signal in a noisy background, the SNR. This is the ratio of the response to the signal divided by the standard deviation of the responses with no signal present. The measure d -prime in signal detection theory estimates from the psychometric responses the SNR of the representation of the stimuli on the decision variable.

The reason this measure is so valuable depends first on the fact that it can be applied equally well to the signals being used as sensory stimuli, to data obtained from the neural firing rates of individual neurons, and to data derived from perceptual responses of human observers or from behavioral responses of animals. It can thus provide the common currency for establishing quantitative relations all along the way from the initial stimulus itself, through single-unit responses, to final behavioral output.

A second reason for attaching great importance to these measures is that the statistical aspects of perceptual performance are in many ways the ones of greatest interest. This cannot be argued here in detail, but my reading of the lesson to be derived from nearly 50 years of work in computer vision is that natural visual systems effortlessly and efficiently extract signals from noisy backgrounds, while computer systems initially struggle to do so. However, once a visual task has been defined in sufficient detail, it can usually be performed as well or better by a computer system. The visual system's superiority seems to lie in the selection of tasks it performs well, for these tasks are just those required to enable an animal to survive and flourish in a competitive, inherently variable, barely predictable environment that has the statistical characteristics of the one we experience. Perhaps one should not be surprised at this, considering that the animals do survive, but one cannot help being impressed.

THE IMPORTANCE OF EXTRINSIC NOISE The ability to detect specific signals buried in extrinsic noise, with an efficiency not far below the theoretical limit, is central to such tasks. The first pitfall is to ignore this, but there is an excuse for doing so because it was none other than J. von Neuman (1956) who suggested that the main problem was to understand how the brain achieves reliable performance using noisy components. Noise is certainly generated inside the brain by neurons themselves, so there is no doubt that intrinsic noise is a problem, but it makes no sense to regard it as the most important one simply because picking out the signal from the extrinsic noise has to be done whether the components are noisy or noiseless. Intrinsic noise is not the essential problem, it is an additional one.

It is extremely difficult to find and isolate the signals from the environment that are necessary for performing a task such as driving a car down a busy street, because of the clutter of other very similar signals that is continuously bombarding the sensory system. Solving the similar problems that arise for prey and predator in the jungle would bring great competitive advantages, and sensory systems must surely have evolved mainly under this pressure. Intrinsic noise is interesting and is probably the limiting factor at the absolute threshold of vision, but quantum fluctuations and extrinsic noise are surely the limiting factors in a much wider range of conditions. One should see how this is handled before worrying too much about intrinsic noise, for this becomes important only when it produces effects comparable in magnitude to those of extrinsic noise, and this tends to occur only when extrinsic noise is artificially reduced to a very low level. For instance, the thermal stability of rhodopsin is probably important at the absolute threshold of vision; but otherwise, the ability to catch the largest possible fraction of quanta is much more important (Barlow, 1956).

THREE RULES ABOUT SNRS Attaining the high SNRs that are needed for reliable behavior in a noisy environment is not an easy task, and the following three rules may help to understand the process better, and thereby illuminate how sensory mechanisms achieve the high standard of performance required for survival in a competitive world.

Rule 1. Noise cannot be removed from a message once it has been added to it. Since signal can easily be lost and more noise can easily be added, this sets a one-sided limit. SNRs decline for any of a large number of possible reasons, but it is hard to sustain them at the same value and still harder to raise them. Note that one immediate and obvious implication of this rule is that you can never obtain a message with a higher SNR than that present in the stimulus delivered, provided that all the available information from the stimulus has already been utilized. Following the SNR through the system can therefore tell the inquisitive neurophysiologist how much irretrievable information loss occurs and where it occurs. We shall see later that there is suggestive evidence that the losses, up to the level of single-unit responses in MT, can be low (Mogi and Barlow, 1999) and that for the most favored types of stimulus, not much more is lost even up to the level where behavioral decisions are made (Barlow and Tripathy, 1997).

Rule 2. The only way to raise an SNR is by adding further relevant information. Relevant information usually means other messages with new signal from the same source, but with noise that is independent (at least partially) of that contained in the original message. The optimal way of incorporating new information is considered below, but

note here that the signal parts of the original and new messages add directly, while it is the variances of the noise parts that add, not their standard deviations, so the combined standard deviation rises more slowly than the signal—hence the possibility of improving the SNR.

Rule 3. The optimal SNR for a given target with graded parameters is obtained by matching all the parameters of the detector to those of the stimulus. This matching assigns weights to the messages from different parts of the target, each weight being proportional to the SNR contributed by that particular part of the target. It can be shown that this maximizes the signal collected and minimizes the noise that accompanies it. Obviously this is an important rule for understanding how a sensory system should design detectors for the features in the environment that are important for its survival, and it adds much significance to the receptive field of a neuron, for its shape, considered as a weighting function, tells one the target for which it is an optimally matched detector.

Recall that the parameters of receptive fields, even those in the same column, differ from each other considerably, so each is a matched detector for a different target; in general, any two neurons in MT are likely to have only moderate overlap of response regions in the multidimensional space defined by the selectivities of the neurons (see Lennie, 1998). Note also that neurons are the only components we know of in the brain that might combine messages in the appropriate way to obtain optimal improvements in SNRs. There are other methods of combining signals, such as picking the maximum, or so-called probability summation, but in general, these are suboptimal.

Experimental statistical studies

With this theoretical background, the history of experimental studies of single neurons can be resumed. Among the earliest uses of signal detection theory in visual neurophysiology were FitzHugh's studies (1957, 1958) of the threshold responses of cat retinal ganglion cells. These and other studies showed how the maintained discharge of neurons constitutes noise limiting what can be detected (Barlow and Levick, 1969; Kuffler et al., 1957; Werner and Mountcastle, 1963). Good neurophysiological SNRs can be obtained for stimuli that are of the same order of magnitude as behavioral or psychophysical absolute thresholds (Barlow et al., 1971). The power of using the approach at several successive levels in the same visual pathway was shown by Laughlin (1973, 1974a, 1974b), who demonstrated the improvement that occurs as information from several insect photoreceptors is brought together on a single higher level neuron.

Note that noise may be represented in other than ways as a variable neural discharge rate. Intracellular biophysical variables often depend on rather small numbers of molecules, implying a high level of random variability which is certainly liable to interfere with the processing of sensory information. On the other hand, a high level of variability does not necessarily limit performance: this will occur only when the intrinsic variability is comparable to or greater than the variability arising from the extrinsic noise which enters with the sensory stimulus.

I learned this lesson in Kuffler's lab. Before going there, I had been struggling to establish that noise was important in human vision (Barlow, 1956, 1957), and I was expecting it to be similarly inconspicuous neurophysiologically. I could not believe my ears when I heard the dreadful irregular cacophony produced by a cat's retinal ganglion cell, and it took some time for Steve and Dick to convince me that this noisiness was not an artifact (Kuffler et al., 1957). The apparent paradox became clear when we measured the ganglion cell's sensitivity to light (Barlow et al., 1957), for like a good radar operator or ham radio enthusiast, the retina turns up the gain far enough to make the noise easily detectable but not so far that it swamps the signal. I strongly suspect that MT does a similar job with correspondence noise.

USING BOTH NEURAL AND BEHAVIORAL RESPONSES Mountcastle (1984) defined three stages of analysis of sensation, in the last of which single units were recorded in alert animals while doing sensory discriminations. The studies of this sort that I think show most promise for sorting out the roles of single units in vision are those on the detection of coherent motion by neurons in MT of the monkey, and I shall concentrate on the following five papers: those of Britten et al., (1992, 1993, 1996), Celebrini and Newsome (1994), and Shadlen et al. (1996). These are referred to collectively as "work from Newsome's lab."

Using alert, trained macaques, these authors recorded the responses of single neurons in MT while the monkey was performing a behavioral discrimination task and signaling its apparent result. The task chosen was to discriminate between two opposite directions of motion of a random dot kinematogram in which the proportion of dots moving coherently in one direction could be varied. The recordings from the isolated neurons gave the distributions in numbers of impulses for different coherence levels for movements in both preferred and null directions, while the behavioral responses gave the proportions with which the monkey correctly identified the direction of motion in their forced-choice task.

The authors plotted the behavioral results as the percentage correct at the varying coherence levels and found that, like humans, the monkeys could perform this task very well, achieving 82% correct responses at coherences

of 10% or less. The criterion of 82% they chose for threshold corresponds to a d -prime value of 1.13 and can be obtained directly from the percentage correct in a two-alternative forced-choice task (e.g., from Elliott's tables in Swets, 1964).

To obtain comparable curves for the neural responses, they used the following method: they assumed that there was another neuron, which they called the *anti-neuron*, with exactly the same properties as the one they were recording from but having a reversed directional preference; they then took the number of impulses in each trial, and said that it signaled the preferred direction if it was a number more likely to have been generated by preferred direction trials at that particular coherence level and null if it was more likely to have been generated by null direction trials.

There are two slight problems with this way of making unit responses comparable with psychometric responses. First, there is little if any evidence that the monkey brain actually uses an anti-neuron in making its decisions, and it is a pity for such an uncertain feature to be so deeply embedded in the comparisons and models made. Second, the authors' neurometric curve shows the performance expected of two neurons, the hypothetical anti-neuron as well as the one they actually recorded from, and this is, of course, better than that expected from a single neuron, provided that, as they assume, the neurons give independent information about the signal.

There seems no good reason to avoid expressing a single neuron's performance directly as an SNR in the way an engineer would naturally express measurements of a signal variable, that is, as the difference between the mean responses at a given coherence and at zero coherence, divided by the standard deviation of the response at zero coherence. This is merely a step in thinking clearly about what can and cannot be done with signals such as those that have been recorded, and it does not necessarily entail the assumption that the brain actually uses the expected response to zero coherence in making its decisions. The unit's SNR at the coherence required for an 82% correct behavioral threshold can be compared directly with 1.13, the value of d -prime for their psychometric measure at 82% correct.

It is worth pointing out that the two-alternative forced-choice task the monkeys performed is a method devised by psychophysicists to determine the ratio of signal response on the decision variable to the noisiness of that representation—that is, its standard deviation. The neuron/anti-neuron artifice seems to be a way of doing this in reverse, going from recorded signal responses back to expected psychophysical-like performance, but why do this? The neurophysiologist has, or hopes he is going to have, access to the signals from which decision variables are constructed, so why go backward? Why use psychophysical performance as the currency for comparisons?

The main result of their study was to show an astonishing agreement between the psychometric curves obtained behaviorally and those obtained from single units using the anti-neuron method. It is true that there was a large range in sensitivities, the ratio of neurometric to psychometric threshold varying over a 10-fold range, with many neurometric sensitivities exceeding the psychometric sensitivity, but the mean ratio was close to 1. Furthermore, the agreement extended to the slopes of the curves as well as to their means. Note, however, that these exact agreements depend in part on the assumption that the decision is based on the use of all of the 2000-msec responses collected from the neuron; this is implausible, for the monkey's life must often depend on much more rapid responses to moving stimuli. Departing from this assumption is likely to spoil the exactness of the agreement, but the change would probably not be large enough to alter the main conclusion—that MT neurons can signal the direction of coherent motion in a random dot kinematogram with a sensitivity comparable to that attainable by the whole animal. This is in agreement with a good body of other work showing that single neurons are very sensitive, and I personally think it is about as far as their results take us at present. But there is hope of further progress from measurements of *choice probabilities* (called the *sender operating characteristics* in Celebrini and Newsome, 1994, and the *predictive index* in Shadlen and Newsome, 2001).

Choice probability is a measure of the way the monkey's behavioral responses covary with the neural responses of a recorded neuron, and it is related to the area under the receiver operating characteristic (ROC) curve in signal detection theory. It represents the probability of determining the behavioral response correctly from an optimal analysis of a particular single unit's responses. If the neural response fully determined the behavioral response, choice probability would have a value of 1, whereas if there was only a chance relationship, it would have a value of 0.5. In fact, the authors found that the average value for all neurons analyzed was significantly above 0.5, though not by very much. A few neurons seem to have had considerably higher values, but they imply that these were untrustworthy chance results. Higher average values have been reported from other experiments on MT (Dodd et al., 2001), in which many neurons seemed to have values above 0.8, and Shadlen and Newsome (2001) and Horwitz and Newsome (2001a, 2001b) have also obtained much higher values in parietal cortex and superior colliculus, where they actually used a much shorter analysis period.

From the point of view of SNR analysis, the choice probability is a measure of the amount of noise added between unit response and behavioral choice: high choice probabilities near 1 are evidence of little added noise, whereas low probabilities near 0.5 are evidence of much added noise.

The trouble is that a high choice probability does not prove that a neuron did actually determine the behavioral response; it only proves that it could have done so, and the possibility that other neurons actually did so is not excluded. Similarly, a low choice probability near 0.5 does not prove that the neuron played no role at all in the behavioral response, for it may have stepped in and caused a correct response on rare occasions when no other neuron was able to do so. What a low choice probability does prove is that that particular neuron, by itself, could not have been responsible for all the correct decisions made behaviorally, and this remains true even if the neuron's SNR was as high as or higher than that given by the psychometric results. It is an important additional measure that has to be taken into account in figuring out how single units control behavior.

In the final paper of the series, Newsome's group tried to model how the brain derives the decision variable underlying the behavioral responses from a set of neural responses and choice probabilities such as those they recorded, but although I admire the attempt, I feel it is not the final solution for the following five reasons:

1. It fails to take into account the fact that, if the conclusion reached by Barlow and Tripathy (1997) is accepted, *correspondence noise*, which is extrinsic, is a major factor limiting the performance of the MT system. Correspondence noise arises from the correspondence problem—that is, from the lack of information about which dots are to be considered as pairs in successive frames of a random dot kinematogram. If we know how such stimuli have been generated, its magnitude can be calculated (Barlow and Tripathy, 1997). Human coherence thresholds behave as if they were limited by it over wide ranges of variation of the principal parameters of the target stimulus, and under optimum conditions, statistical efficiencies for detecting coherent motion are quite high. Newsome's group does recognize the problem of correlations between responses of MT neurons, but this measure does not seem to differentiate between correlations due to the signal being shared and correlations due to the noise being shared, yet these have very different implications.

If correspondence noise is the major natural problem in detecting and analyzing motion signals, one is unlikely to understand how the visual analysis of motion is organized without taking it into account. It is also a pity not to exploit the possibility of estimating SNRs on the stimulus as well as on the responses, for this enables one to follow the losses of efficiency directly. It is these losses of efficiency that are of most practical importance to the monkey, since they have the greatest effect on the utility and survival value of the system for detecting coherent visual motion.

2. One can expect to be able to derive the behavioral decision variable from the neural responses only if the

measure of these responses that is used for the analysis actually corresponds to the measure that the brain uses. The only measure of the neural responses Newsome's group used was the total number of impulses over 2000 msec, but it seems unlikely that an animal that spends its life jumping around in the treetops uses only 2000-msec totals for controlling its responses to motion signals that might save its life if reacted to quickly. Bair and Koch (1996) have shown that the temporal frequency response of the motion detection system peaks at around 3 Hz, so perhaps the monkey makes a decision every 300 msec, and, if forced to wait before responding, bases its delayed response on some kind of probability summation among the stored results of these previous decisions, or perhaps simply uses the most recent, up-to-date one. The decrease in efficiency of psychophysical performance for durations above about 400 msec (Barlow and Tripathy, 1997), together with the margin by which the performance of many neurons exceed their behavioral performance, suggests that it would be hard to exclude such a possibility.

3. The neuronal data the authors used to model the formation of the final decision were collected for stimuli that were only approximately optimal for each of the individual neurons. No signal can be optimal for all the different neurons, even those in a single column, but the extent of the loss of performance from mismatching is obviously hard to estimate. Note particularly that the importance of disparity selectivity was not fully recognized when the data were collected, so this parameter was not optimized.

4. I think that at this stage of our understanding of the problem, we should use statistical arguments to derive limits on what is possible, and it is premature to attempt a direct model. The three rules stated earlier make it fairly easy to derive such limits. Note that if the statistical efficiency of the early stages is as high as some estimates indicate (Mogi and Barlow, 1999), the limits become more stringent and are more informative about which models are viable and which can be excluded.

5. At present, we have very little understanding of the way the brain does its statistical computations, important though these are for all decisions. Advancing knowledge of the cell biology of cortical neurons suggests that they may be able to do computations we have not hitherto suspected, as described in the final section of this chapter. It is not clear how this will affect the problem, but it seems unwise to pin one's faith (or one's model) on the assumption that they can do little more than compute weighted sums of impulse numbers, even though this is a crucial step in collecting the evidence needed for good decision making.

It's evident that the last two objections are swayed by prejudice and stylistic preference. Further analysis (Gold and Shadlen, 2000, 2001) shows interesting convergence with independent psychophysical measurements (Carpenter

and Williams, 1995; Reddi and Carpenter, 2000), and may well prove these and my other doubts to be unfounded. Whatever happens in the future, Newsome's group has already shown that statistical analysis of single-unit responses greatly improves our understanding of behavioral decisions; including the role of extrinsic noise in this analysis will surely bring further insight into this crucial aspect of perceptual decision making.

Why study single neurons?

Different people would answer this question in different ways. For instance, Adrian (1932) clearly regarded himself as an empiricist, saying:

In all branches of natural science there are two methods of approach, that of the strategist who can devise a series of crucial experiments that will reveal the truth by a sort of Hegelian dialectic, and that of the empiricist who merely looks about to see what he can find.

In his hands, "merely looking about to see what one can find" was astonishingly fruitful, but I confess that I have often aspired to the more theoretical approach that Adrian described first in the above passage. As a research student I was intrigued by information theory and cybernetics, which were then coming to the fore (Shannon and Weaver, 1949; Wiener, 1961), by early work on computer pattern recognition (Grimsdale et al., 1959; Selfridge and Neisser, 1960), and by the ideas of ethologists about *fixed action patterns* and *innate releasing factors* that were being popularized by Niko Tinbergen (1953) and Konrad Lorenz (1961) at about that time. But theories can close your eyes as well as open them.

One of the first experimentally satisfactory experiments I did on the frog's retina gave a result that made nonsense of the theory I was testing, but I was so fixated by the theory that I nearly missed an important new fact that was staring me in the face. Having previously mapped the receptive field of a retinal ganglion cell, I measured its sensitivity to circular spots of increasing size. My theory predicted that while it was within the receptive field, sensitivity would rise either in proportion to the area of the stimulus spot or in proportion to its square root, depending on the type of unit. My theory attached great importance to which of these rules it followed, but the results showed that the sensitivity rose at a rate almost exactly halfway between the alternatives expected. I went home late at night in great gloom, thinking the experiment had failed and was not worth repeating. It was only as I was falling asleep that I remembered that the sensitivity had plunged to a nonsensical-seeming near-zero value for the largest spot size when it spread outside the excitatory receptive field. I then realized that this unpredicted near-zero result actually provided direct evidence for

something more interesting than my previous theorizing: it strongly suggested that the retinal ganglion cell had an inhibitory surround, a new fact that was only later described by Hartline (1949) and Kuffler (1952).

This event might justify ignoring theoretical and philosophical issues altogether, but, of course, the real lesson is to stay awake and be ready with a new theory whenever the facts demand it.

For Steve Kuffler, linking single-unit function to known (or discoverable) anatomical structure was probably the main inspiration, as it was for his most famous followers, David Hubel and Torsten Wiesel. Their school of thought was extraordinarily influential, for it diverted the main efforts of neurophysiologists in the United States away from the study of evoked potentials and massed responses to single units. Single-unit recordings are never going to make much sense unless they are related to the anatomy, but this needs no further emphasis.

Obviously, one important aim of neuroscientists is to explain subjective experience, and the role of single neurons in mediating this process adds much zest to their investigation. However, I think this appeal has been seductive rather than productive. We know so little about the nature of conscious experience that it would not help very much even if we were able to establish tight relations with single-unit activities. Instead, the qualitative parallels are weak and tend to fall apart when closely examined, so I shall not discuss them further, feeling that the quantitative parallels that signal detection theory has established are far more significant. There has, however, been one very simple and direct demonstration of the relation between subjective experience and single impulses in a single unit.

Vallbo and colleagues (see Valbo, 1989) demonstrated that human subjects (actually, the experimenters themselves) can detect the occurrence of a single impulse in a single sensory fiber. They inserted a fine metal microelectrode, insulated up to its tip, into the nerve that runs from the hand to the spinal cord and then connects to the brain. With fortunate placement of the electrode it is possible to record the activity of just one fiber, and in such a case a certain region on the hand or finger may be found that, when touched, causes a succession of brief, equal-sized pulses to appear on the oscilloscope screen and to be heard through the loudspeaker as a volley of brief clicks. These action potentials come from a single sensory fiber, and one can reduce the intensity of the mechanical stimulus until it only causes, on average, a single action potential. Will this minimal response ever be felt? For some types of touch receptors at the fingertip, it can: it is felt as a brief and very light touch. For other types of receptors, and at other positions on the skin, this is not the case, and even where it is, one is not forced to conclude that conscious awareness accompanies a single impulse, for it is quite possible that a single one in the peripheral fiber causes several

impulses at later stages. All the same, these facts do seem to show that sensory experience does not necessarily depend on hundreds of impulses in hundreds of fibers: a single impulse in a single fiber sometimes makes a perceptible difference.

For myself, the reason for retaining a keen interest in single neurons is simply that they are the main computing elements of the brain, and I cannot believe that we shall get our models right until we understand them better; the properties of neurons define the work that a network can do, whereas the network connections only permit (or prevent) that work being done.¹ So at this point I shall indulge in some guesswork about how our notions of pyramidal cells may evolve over the next decade or so.

A glimpse of the future

This section is obviously speculative, but there is one feature of the brain that may make speculations more reliable than you would expect. Pyramidal neurons occupy a specific place in a highly organized system, so we know quite a lot about the nature of their inputs. Advances in understanding of their cell biology can only reinforce what existing results already suggest—that neurons are capable of more complex computations than we previously thought. Now, assuming constant requirements for speed and accuracy, an increase in computational capacity is not much use unless there are more data to be handled, but we already know that most data arrive along the inputs to the neuron in question. If nodes can handle more data than we used to think they could, what are these extra data? Where do they come from?

The first possible answer that ought to be considered is that neurons use information that is not often mentioned, namely, knowledge of the time of day. Many cells in the body that have no part in generating the overall circadian rhythm nevertheless have most of the biochemical machinery of the circadian clock (Hastings and Maywood, 2000), and cortical neurons are among them. The timing of the clock in a group of cells is indicated by the phase at which the *mPer1* and *mPer2* genes are expressed, and this can be determined by *in situ* hybridization. If one compares a diurnally active animal (ground squirrel) with a nocturnally active one (hamster), the clocks in their suprachiasmatic nuclei are both found to be synchronized with the overall light/dark cycle, *mPer1* and *mPer2* expression peaking about 5 hours after the beginning of the light cycle. Now their motor cortices also show a diurnal rhythm, but this is not

synchronized with the suprachiasmatic nucleus (Mrosovsky et al., 2001). In the hamster it peaks at the time when its normal period of *nocturnal* motor activity is starting at the start of the dark period, 5 hours after the *mPer1* peak in the suprachiasmatic nucleus; and in the ground squirrel it peaks at the start of its normal period of *diurnal* motor activity, some 4 hours before the *mPer1* peak in its suprachiasmatic nucleus.

It is not yet known how the phase of the local clock is determined, but it is tempting to suppose that the local activity of the cells provides a synchronizing signal to the cell's cycle, so that *mPer1* expression comes to coincide with the expectation of activity—an increase in the prior probability that a particular cortical neuron will be activated, based on the proportion of activations at that time 24, 48, 72, and so on hours earlier. This machinery in our dog's cortical neurons could presumably become synchronized with the important daily events of her life, thus preparing her to bark at the arrival of the postman or to roll on her back when one of us comes home. Time is only a single variable, but the daily cycle of expectations, signaled intraneurally, might form a nontrivial addition to each cortical neuron's data input.

The second possible answer is that neurons use more thoroughly the data we already know that they receive through ordinary input channels: perhaps they store their inputs temporarily and operate on the temporal patterns and sequences they contain, not just on the present input and that of the very recent past. I shall try to show in the next few paragraphs that the idea that the main job of cortical neurons is to exploit, for the benefit of the brain's owner, the absolute time and the relative timing of sensory signals is a very reasonable extension of our current concepts of what they do, though I think it may take a while to get used to it.

HOW BIOPHYSICAL KNOWLEDGE OF PYRAMIDAL CELLS HAS EVOLVED Our knowledge of the biophysical processes that occur in pyramidal cells has increased enormously since Cajal drew those beautiful pictures of them, but our concept of what they do to help their owner survive in a hostile world has not kept pace. I don't think anyone now accepts the challenging notion of Pitts and McCulloch that they are elementary AND, OR, and NOT logic elements whose task is perform more complex logical functions. We have also progressed from the Sherringtonian model of a neuron that "integrates" central excitatory and central inhibitory states, through Eccles' simple integrate-and-fire model controlled by excitatory and inhibitory synaptic potentials, then through Rall's compartmental treatment of proximal and distal dendrites, and have reached the elaborated compartmental model (Koch and Segev, 1998) by including many different forms of ion channels, including voltage-sensitive

¹There is, however, an intriguing possibility that network studies will tell us what neurons *should* do to make the whole brain able to compute what cognitive studies show that it *does* compute.

ones. These provide a formidable battery of possible biophysical mechanisms, but what do they all add up to? What functions do these cells perform that aid the survival of their owner?

By far the most significant functional addition has been the modifiable synapse postulated by Hebb. This not only adds the function of memory to the nodes, but also increases their computational capacity by an enormous factor. Without memory, a neuron can exist in only two states, on or off, and it cannot change between them in less than about 1 msec. That's not much of a unit, and a cell with, say, 10,000 synapses, each of which can be in several different states, certainly commands much more respect. But there are more additions.

Nerve cells have second messenger systems, working on slower time scales than transmitters that operate on ionic membrane channels. In addition, they have calcium-induced calcium release (CICR) which can not only produce powerful effects at the locality in the dendrite where it occurs, but can also propagate down the endoplasmic reticulum of a dendrite at a speed of about 40 $\mu\text{m}/\text{sec}$ (Jaffé and Brown, 1994). It is remarkable that this striking mechanism has not yet been shown to be responsible for a correspondingly striking functional process in neurons, though there are hopes (Barlow, 1996; Euler et al., 2002) that it may turn out to be responsible for directional selectivity. When considering the time scale on which pyramidal neurons operate, one should realize that metabotropic glutamate receptors activated at the tip of a 2 mm long apical dendrite might initiate a wave of CICR that would produce powerful effects in the soma nearly a minute later!

We do not know what these intracellular processes achieve any more than we know what the various channels in the elaborated compartmental model neuron achieve; they are potential mechanisms, and we still have to find tasks whose performance we can pin on them. It is certainly worthwhile to look at what such mechanisms are known to achieve in *Escherichia coli* and other simple systems. Bray (1990, 1995) has pointed out several instances of biochemical pathways interacting to form control systems that would require many interacting nodes in a network model. But instead of occurring in a whole network of different nodes, in *E. coli* these occur inside a single small cell that is about the size of a synaptic bouton of a pyramidal cell. It would take about a quarter million *E. coli* to fill the whole cytoplasm of a pyramidal cell.

The potential computational capacity of these intracellular mechanisms is hard to assess; they are slower to switch than the ionic channels of membranes, but there are potentially so many of them, all reasonably well isolated from each other, that the complexity of the computations the whole cell might achieve must be increased by a huge factor (Barlow, 1996).

PHASE SEQUENCES AND PYRAMIDAL CELLS Now let us consider what has to be explained by the actions of pyramidal cells. Donald Hebb (1949) was the first person to discuss seriously how the properties of neurons might explain psychological function, and his landmark book made the influential proposal that memory, or information storage, occurs at modifiable synapses. But another influential concept he introduced, that of *cell assemblies*, has not fared so well. As Hebb explained, the reason he advanced this idea was that times of the order of hundreds of milliseconds seemed to be involved in the *phase sequences* that were being discussed by psychologists at that time (see Lashley, 1951), whereas a nerve impulse was very brief and could not produce a sustained effect. He therefore postulated that a group of neurons sustains an excitatory input for the required duration by reverberatory, self-reexcitatory action. There can be little doubt that sequences of activity in the brain follow each other not as independently excited events, but rather as chains in which one event prepares the brain for the next: the sensory stimuli and motor actions at one choice point in a maze prepare the rat for the next choice point, hearing one syllable of a word or one note of a tune prepares the brain for the next, and so forth. But, Hebb argued, nerves work on a very rapid time scale; a mechanism is needed to make excitation persist long enough to carry over to the next element in a phase sequence, and that is what his self-reexciting cell assemblies were supposed to do.

This argument does not really stand up. Even in a peripheral nerve, the passage of an impulse allows sodium ions to enter, and the time constant for pumping them out is much longer than the times Hebb was concerned about. At synapses, as we have seen, there are second messenger systems and CICR that occur slowly. The principal reason Hebb gave for postulating the existence of cell assemblies, the evanescent nature of nerve activity, is no longer convincing, nor is there good experimental evidence for self-reexciting chains performing the function he postulated. All the same, we should not disregard the need he saw for slow processes. Instead, we should ask: is it possible that pyramidal cells on their own can work on the slow time scale appropriate for phase sequences?

Given that pyramidal cells have Hebbian synapses modifiable by experience, this question resolves into two different ones. First, might pyramidal cells be capable of responding selectively to much more complex spatiotemporal patterns than our present concepts would allow? Might they detect a whole tune rather than the separate notes of a tune? The second question follows naturally: if they can detect and discriminate such spatiotemporal patterns, could they acquire these abilities through experience? I think it is plausible to suggest that the answer is "Yes" in both cases, and shall briefly discuss these possibilities.

RADICAL INSEPARABILITY The first proposal moves almost as far away as possible from the integrate-and-fire model. This dealt primarily with the integration of inputs to the neuron through different synapses, which I shall call *spatial integration*; temporal integration could occur through the persistence in time of postsynaptic potentials, but differences in times of persistence were assumed to be unimportant, and so far as this assumption was valid, one could regard spatial and temporal integration as separable processes.

It has actually been clear for a long time that this simplification is not valid. Temporal and spatial summation in vision are not independent of each other (Barlow, 1958), and even in comparatively simple neurons such as retinal ganglion cells, direct measurements of responses to sinusoids of different temporal and spatial frequencies have shown nonseparability (Enroth-Cugell et al., 1983). Furthermore, inseparability in time and space have been shown to be characteristic properties of the neurons in V_1 that are directionally selective (DeAngelis et al., 1995).

Let us suppose that separability is completely wrong, and that the synapses of each neuron have time courses and/or delays that differ from each other, influence each other, and fall into perhaps a dozen or more different categories. It's clear that this neuron is far more complicated than a simple integrate-and-fire neuron, but it can also achieve much more. Directional selectivity would be easy to obtain with only two different categories of synapses having two different positions and delays; so would velocity selectivity. Acceleration, deceleration, and change of direction would require at least three. Oscillatory motions, which are often characteristics of innate releasers, could be detected with rather more, as could the sequences of syllables in a word or of the notes and rhythm of a tune. These and many more are surely possibilities to which we should be opening our eyes.

SUPER-HEBBIAN SYNAPSES Could a pyramidal cell learn to combine information from its many synapses in this radically inseparable way? Recent evidence (Bi and Poo, 1998; Feldman, 2000; Markram et al., 1997) shows that the timing of pre- and postsynaptic activity determine the polarity of the change in synaptic effectiveness that results from joint activity: this is increased when presynaptic firing occurs first and is decreased when it occurs after the postsynaptic firing. But is the time at which the switch occurs always the same at all synapses? Could it be different for synapses located on different parts of the dendritic tree? Is it even possible that there are different mechanisms at the same synapse that are reinforced at different pre-post intervals (Barlow, 1996)? Either of these mechanisms could enable a neuron to learn the spatiotemporal pattern of a movement sequence, a speech sound, or a tune.

Other possibilities will surely appear as we learn more about the cell biology of the large neurons of the brains of higher animals, but at the moment, the difficult problem seems to be that of determining their functional significance. Maybe we need to turn to simpler animals, with simpler behavioral repertoires, to bridge this gap between cell biology and cognition, for I think it is clear that a cell with the kinds of capacities I have sketched above would be a useful component at many levels of behavioral complexity. Such capacities are, however, unlikely to be discovered by experimenters who confine their attention to a brain slice in a dish.

If even a few of these possibilities turn out to be true, the neurophysiology of the cortex is going to be an exciting field over the next few decades. Single neurons are not just the elements whose activity represents what is happening in the outside world; they are also the elements that do the computation in the brain. So their analysis should tell us not only how experience is represented, it should also tell us how it is computed.

Appendix: recollections of Lord Adrian

I was one of Lord Adrian's very small number of graduate students. The Ph.D. was not a popular degree in Cambridge until well after the Second World War, and especially in physiology, even those going into academic research more often took a medical degree, as I had done myself. But when I qualified in 1947, I was faced with the choice of many years of internships and residencies to climb the medical ladder or having a go at physiological research, and I chose the latter. I needed a research studentship, so I came to Cambridge to explore the possibility of getting one.

The first problem was to find Adrian, as he was universally known, both before and after his elevation to the peerage. I knew he was in Cambridge, and often in the Physiological Laboratory, but whenever I called he was not in his office. After several visits his secretary rather reluctantly admitted that he was probably downstairs in his lab, but when I asked if I could find him there, her jaw dropped and she said, "Well, er . . ." I got the message but went down to look for him all the same. The entrance was guarded by his assistant, Leslie, who said, "He's in there with a pony² and does not want any visitors." This time I took the hint, but as I was leaving the lab I met one of my former lecturers (Tunncliffe) and explained my problem. He at once told me I was not alone in finding it difficult to catch Adrian, but, he

²There is some artistic license here—it may have been a hedgehog. But he certainly did do an experiment, singlehanded during the anesthetization, on a Shetland pony at around this time (Adrian, 1946).

said, "He usually goes to Trinity on his bicycle around lunch time, and if you stand in front of him he won't run you down." So I lurked around the lab entrance for a few lunchtimes, and the tactic worked: as I stood triumphantly over the front wheel of his bike he said, "Come to my office at 2 o'clock."

There he asked if I had any ideas I wanted to work on, quickly demolished the ones I proposed, but then said I might be interested in looking at the paper by Marshall and Talbot (1942) on small eye movements to see if there was anything in their idea, and, by the way, he thought he could get me a research studentship from the Medical Research Council. The total duration of the interview was certainly no more than 5 minutes; Adrian believed in getting a lot done in his time outside the lab as well as inside it.

I read the paper, and although it was not the beginning of my interest in vision, it probably was the beginning of my realization that visual motion is an important topic. When I reported for work a few days later, Adrian seemed surprised to see me, and even more surprised when I asked him what I should do, but he said something like "We've discussed that—Marshall and Talbot, don't you know." I was beginning to get the hang of things and quickly got out some words like "I need apparatus—a recording camera, don't you know," whereupon he said "Leslie will see to that." I still had absolutely no idea of what I was expected to do, but ended up the next day in possession of a beautiful mahogany-cased 35mm cinecamera of 1920s vintage with a manual crank for driving it and no lenses, and, of course, no film. It was fun converting it to record eye movements, and I eventually got some film, but I was very glad I was never asked to return the camera in full working order.

ADRIAN AS A RESEARCH SUPERVISOR He mainly left me to find my own way and did not give me very much direction or advice, but the advice he did give was always direct, to the point, valuable, and correct, even if it was often a bit discouraging. I remember him suggesting relevant references and pointing me to various people who might help with problems I was encountering. When I was massacring the movie camera he pointed me to Bryan Matthews, and it was he who explained to me what the unexpected cylindrical lens near the image plane in a recording camera does. Another was Andrew Huxley on a statistical problem, and I remember him explaining patiently that the variances of independent samples add, so my problem became instantly soluble.

After about a year, I knew a good deal more about how much the human eye moves: it moves a lot, but not in ways that make sense for Marshall and Talbot's hypothesis. I realized I was not going to discover much more and wanted to move on, so when Adrian popped his head round my

door a week or so later, I explained where I had got to with eye movements and told him that I wanted to repeat some of Hartline's experiments on the frog's retina because I was puzzled by the very large receptive fields he had described. Adrian's immediate response was, "Oh, I wouldn't do that—Hartline's a very clever chap, you know." But I persisted, driven largely by the theoretical drive that told me the frog's eye would not work very well if there was no more to it than Hartline had described, so I wrote him a note a few days after his visit about the equipment I needed.

At that time, one could buy war surplus electronic equipment at absurdly low prices. It was sold by weight, and one could buy a photon multiplier complete with all circuitry for about 25 cents. I reckoned that with the help of others who had followed the same path, I could build a suitable amplifier for less than 20 dollars. I wrote Adrian a letter asking if I could go ahead and pick it all up from London the following week, but got the letter back the next day with a note scribbled on the back: "Is this a request for leave of absence or something?" I think he was actually more worried about my spending all my time on the equipment (a real danger) than about my wasting the lab's money, and I got the stuff anyway.

A month or two later, I had got it all assembled and in sometimes-working condition when Adrian came unannounced into my lab with a visitor smoking a large cigar and speaking completely incomprehensible English.

A few minutes before their arrival I had dropped the electrode on the floor. I had just remounted it and was lowering it onto a frog retina, without much hope of success, when they came in, so I turned on the light and started explaining what I was trying to do and how. At this point, the visitor was standing under the room light and took a deep puff from his cigar. As he exhaled the smoke, its shadow fell on the preparation and it gave a long, vigorous "off" discharge. Ragnar Granit, for that was who it turned out to be, was astonished. So was I, and his English became at least partly intelligible as we discussed the technicalities of what makes a good electrode and so forth.

ADRIAN'S LABORATORY Adrian definitely did not like visitors in his laboratory, and I only entered it once or twice. I think the first time was when Leslie took me round to see what recording cameras were available. It was a large room, 600sq ft I would guess, completely full of tables with apparatus on them, with more bits and pieces stacked around the walls. The room was in the basement, and in my memory it has a mud floor with no tiles, boards, carpet, or anything luxurious. That is probably wrong, but superficially it was indistinguishable from a mud floor. I remember the frame of a motor bike without its engine resting under one window, and then noticing the engine under an operating table being used as a respiration pump.

I was fascinated, trying to guess what all the old equipment had been used for, but had to attend to the job in hand. Leslie wanted me to take a *falling plate camera*, a device with dashpots and levers and a wooden frame that fell at a controlled speed when one pushed the trigger, but I asked what recording material it used. "It takes a glass plate," said Leslie. "Are they available?" I asked. "Well," said Leslie, "we have many of the glass plates, and you can coat them yourself." That explained why Leslie wanted to get rid of the camera, but it did not make it into a good choice for me, so after a few more false starts I got the beautiful camera I described above, delivered the next day by Leslie after he had checked that it was okay for me to have it.

I recall only one other very brief visit, for a purpose that I cannot recall, when Adrian was actually doing an experiment. Now whenever he was in the physiology lab, Adrian was always moving, never at rest, always reacting. His body movements were like saccadic eye movements, jerking incessantly from one object of attention to another. Ordinarily these movements, while much more frequent than most people's, were quite well spaced out and synchronized with other events occurring around him, so that he surprised one with an unexpected shift of attention only, say, once every 30 seconds or so. But in his own laboratory they seemed to occur every second, and each of one's own movements elicited a response. On the occasion of my visit, he was doing an experiment on a monkey that was infected with amebic dysentery—the reason, he explained, why he was able to get hold of it. If I turned toward the table to ask a question, he seemed to jump to intervene between me and the monkey, and my attention was so riveted by his heightened state of reactivity that I could take in nothing about his laboratory or the experiment he was conducting.

He was an amazing person, and I have never met anyone who had more than a very superficial knowledge of him who was not similarly amazed. I'm sure he broke all records for the number of sound decisions per minute that he could make. I shall tell one more story about him that reveals an aspect of his character of which he was certainly himself aware, and which may have contributed a lot to his success both as a scientist and as an administrator.

After his wife died he came to live in Trinity College, and as the senior fellow he often presided after dinner, when fellows and their guests meet to converse over more wine and cheese. On these occasions those who serve the wine and cheese leave quite early, and it is left to the last departing fellow to extinguish the candles and lock up the room. On one occasion when Adrian was presiding I had consumed a fair amount of port, but considered that I was still well able to perform these functions and indicated to Adrian that I would do so. In spite of this he followed me around, checking every candle and testing the door I had just locked as we left. I suppose I was a little marked by this and turned to him,

saying, "Good heavens, I wish I had ever had a colleague in the lab who was as meticulous and careful as you are!" I don't think I used the word *obsessional*, but it was certainly in my mind and, equally certainly, he knew it. But he turned to me and said with a smile, "Yes, there are not many like us, are there?" Of course, that made my day—and makes it again whenever I recall it.

The Physiological Laboratory at Cambridge in the 1950s was a truly remarkable place, but it's only years later, when I think about the scientific achievements of Adrian, Rushton, Hodgkin, and Huxley, that I realize just how extraordinarily fortunate I was to be there.

II DEVELOPMENTAL PROCESSES

3 Molecular Regulation of Vertebrate Retinal Development

COLIN J. BARNSTABLE

Introduction

For well over a century, the retina has been a favorite model system for experimental studies of the central nervous system (CNS). Anatomical studies, including the pioneering studies of Ramon y Cajal, have identified the ordered laminar arrangement of the five neuronal and two glial cell types, as well as the numerous subclasses of each cell type (see Chapter 20). The retina has also been used extensively by experimental embryologists, and we now have a detailed description of how many of the cell types of the retina are formed from a sheet of primitive neuroepithelium. Such a rich background of information has made it possible for more recent biochemical studies to explain many of these events in molecular terms.

In the plane of the retina, many cell types form a mosaic whose spacing and connectivity patterns vary with position. Retinal position also dictates the topographical connectivity of ganglion cell terminals. Here too, classical anatomical and physiological studies have defined the timing and specificity of this connectivity, and recent studies in the retina have now begun to suggest molecular pathways by which positional specification might be effected.

This chapter will discuss the major steps of retinal development in molecular terms. In particular, it will try to show that several general principles govern many steps of development. First, many developmental steps consist of transcriptional changes in response to one or more morphogenetic gradients in the concentration of diffusible factors (usually peptides). Second, transcription factors that delineate tissue compartments often reciprocally inhibit transcription factors in adjacent compartments. As described later, a combination of these two principles leads to the formation of sharp boundaries. Third, the same families of molecules, even the same molecules, are used at multiple stages of development. This has the experimental advantage that understanding how one retinal cell type is formed can provide many clues about the mechanisms involved in the formation of other retinal cell types.

While our understanding of the molecular mechanism of retinal development has advanced dramatically in recent years, we probably have only the crudest outline of the

whole process. Nevertheless, this outline seems to be robust, and new information is likely to expand, not replace, our current view.

Initial demarcation of eye fields

The developing neural plate acquires an anterior-posterior axis using the same cues as the rest of the early embryo. This axis provides positional information to cells of the developing neuroepithelium. At the anterior edge of the neural plate, a patch of cells becomes specified to develop into the neural components of the eye—the eye field. These cells of the eye field are morphologically identical to surrounding cells but can be characterized by the expression of a variety of transcription factors. The two earliest genes expressed in the eye field are both paired-like homeodomain genes, *Rax/Rx* and *Pax-6* (Furukawa et al., 1997; Hill and Hanson, 1992; Mathers et al., 1997). Both can be detected in mouse by embryonic day 8.5 (E8.5) and in *Xenopus* by stage 12.5 (Furukawa et al., 1997; Hirsch and Harris, 1997). *Pax-6* first appears as two lateral stripes that pass through presumptive forebrain, midbrain, and hindbrain. *Rx* or *Rax* also first appears in areas that will give forebrain and midbrain structures. *Pax-6* expression is maintained in many regions throughout development whereas *Rax/Rx* expression rapidly becomes restricted to the developing eye field. Whether one of these two genes regulates the other or whether they represent parallel developmental pathways with separate functions is not entirely clear. Experimentally it has been found that in *Pax-6* mutants *Rax/Rx* shows normal activation in the anterior neural plate. In *Rax/Rx* mutants, on the other hand, *Pax-6* is not upregulated in the presumptive eye fields (Zhang et al., 2000). This suggests that *Rax/Rx* is an earlier determinant of retina or eye formation.

In recent years there has been a lot of discussion on whether a single gene can trigger complete eye development and thus be thought of as a *master gene*. In a series of elegant experiments, Gehring and his colleagues showed that expression of *Pax-6* in *Drosophila* imaginal discs changed the fate of cells such that ectopic eyes were formed on legs and antennae (Halder et al., 1995). In vertebrates the situation is clearly more complex. First, other cells in the neural plate

express *Pax-6* and do not form eyes. Second, ectopic expression of *Xenopus Pax-6* can induce ectopic eyes but only in certain regions of the head (Chow et al., 1999; Hirsch and Harris, 1997). One convenient synthesis of these findings is that *Pax-6* can specify eye formation in the unique environment of a *Drosophila* imaginal disc but that in the more complex developing neural tissue of the vertebrate, it is one of a series of molecules that are all essential for eye formation.

After expression of *Rax/Rx* and *Pax-6*, three other genes are switched on in the early eye field region. These are *ET*, *Six-3*, and *Optx*, all of which are also transcription factors (Li et al., 1997; Toy et al., 1998). *Pax-6* can induce all three of these genes, suggesting a hierarchical relationship among this set. It is likely that each of these transcription factors regulates the activity of a number of other genes, but these have not been identified.

The next stage in retinal development is the separation of the single eye field into two distinct eye primordia. This is controlled by the underlying prechordal mesoderm. The separation itself is caused by the migration and growth of neuroepithelial cells into the midline region rather than any change of fate in eye field cells. This process is part of the maturation of a dorsoventral axis in the developing brain and is controlled by a number of soluble factors. One of the best characterized of these, sonic hedgehog (Shh), is released from the prechordal mesoderm. Defects in Shh signaling lead to the *cyclops* mutant in zebrafish in which the separation into two eye fields does not occur (MacDonald et al., 1995). Other secreted factors that regulate the dorsoventral patterning, most notably bone morphogenetic proteins 4 and 5, can also disrupt eye field separation and lead to a cyclopean phenotype (Golden et al., 1999).

By this stage of retinal development, cells have undergone substantial molecular changes in response to two sets of external stimuli, but they remain morphologically identical to the surrounding neuroepithelial cells. At the next step, however, a morphologically distinct structure begins to form.

The optic cup and regionalization

The first morphological specialization detectable in the formation of a retina is the outgrowth of a neuroepithelial sheet from the ventrolateral wall of the forebrain vesicle. This occurs before the neural tube has closed at its anterior end and can be detected in rats at E9.5. This outpocketing grows out and up between the forebrain and the surface ectoderm, forming the optic vesicle. Although both layers of the optic vesicle are a single cell thick, the presumptive retina facing the surface ectoderm already looks thicker.

The next major morphological event is the invagination of the optic vesicle to form the optic cup. This is a complex series of events involving both the neuroepithelium and the

surface ectoderm. The surface ectoderm expands and forms a lens vesicle. The neuroepithelial sheet invaginates, and the two layers become even more distinct. The presumptive retina becomes a pseudostratified epithelium with many layers of nuclei, whereas the presumptive retinal pigment epithelium remains as a monolayered epithelium. The optic cup remains connected to the forebrain by the cells of the optic stalk. As indicated in Figure 3.1A, the optic vesicle is all dorsal to the optic stalk. As the optic cup develops, growth and movement of the neuroepithelial sheet extend down below the stalk to form a disc with the stalk approximately in the center. The optic fissure formed when the two edges of the optic cup meet then fuses to form continuous retinal and *retinal pigment epithelium* (RPE) layers.

At the molecular level, the optic vesicle begins to express new transcription factors and to show a patterned expression of others. Among the new gene products expressed in the optic vesicle is that of the homeodomain transcription factor gene *Vax-1*, a close relative of the *emx* and *Not* genes that play important roles in the patterning of many forebrain regions (Hallonet et al., 1999). *Vax-1* is expressed in the basal forebrain and the optic stalk. Other genes that are expressed at this time include *Pax-2*, which is expressed in the ventral optic vesicle and then becomes restricted to the optic stalk, and *MITF*, a basic helix-loop-helix (bHLH) transcription factor gene that regulates many other genes including the enzymes involved in pigment formation in the RPE. *Otx-2*, a transcription factor important in early forebrain vesicle development, becomes restricted to the presumptive RPE region of the optic vesicle at this stage. If we were able to look at the expression of *Vax-1*, *Pax-2*, *MITF*, and *Pax-6* in a single section of the early optic cup we would see some differences, with *Vax-1* and *Pax-2* in the stalk and ventral regions and *Pax-6* in the dorsal surface layer, but there would be extensive overlap. With maturation of the optic cup this changes such that *Pax-6* is restricted to the front (retinal) layer of the optic cup, *MITF* is restricted to the back (RPE) layer, and *Pax-2* and *Vax-1* are found only in the optic stalk (Fig. 3.1B). Such a change from an overlapping distribution to separate domains of expression is a relatively common feature in the developing nervous system. There is increasing evidence that this refinement of territories of transcription factor expression occurs by reciprocal inhibition (Fig. 3.2). For example, *Pax-2* and *Pax-6* show reciprocal transcriptional repression (Schwarz et al., 2000). *Vax-1* also inhibits expression of *Pax-6* (Hallonet et al., 1999). Similarly, *Pax-6* and *MITF* have a positive feedback effect on their own transcription but can inhibit the activity of the other (Planque et al., 2001). The midline secreted factor Shh can increase expression of *Vax-1* and thus might be responsible for a cascade that helps form distinct regions within the optic cup. Of course, a single factor initiating such a cascade

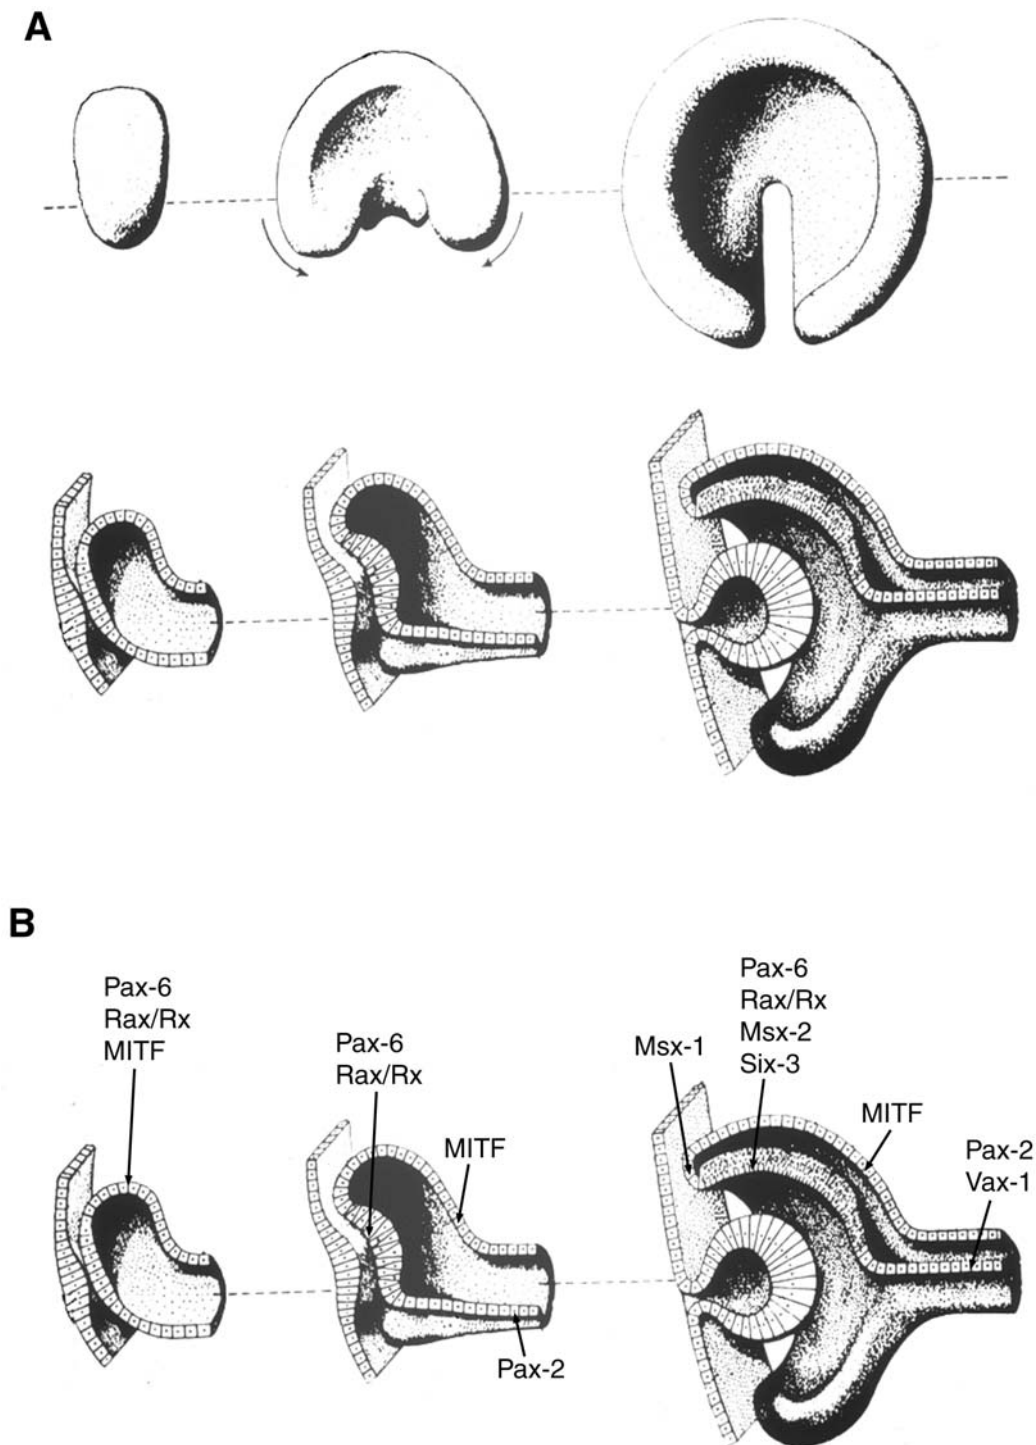

FIGURE 3.1. *A*, Diagrammatic representation of optic cup development showing the outgrowth of the optic vesicle (*left*), the invagination (*middle*), and the downward movement to form the ventral portion of the cup (*right*). This process takes place at the same time that the surface ectoderm is bulging in to form a lens vesicle and mesenchymal cells are beginning to form vascular and other structural components of the eye. *B*, Expression patterns of

transcription factors in the optic vesicle and optic cup. Many of the factors are initially expressed over much of the optic vesicle neuroepithelium but gradually become restricted to specific compartments. In the mature optic cup, the optic stalk, retinal pigment epithelium, ciliary margin, and retina can all be recognized both morphologically and biochemically.

FIGURE 3.2. *A*, Diagrammatic representation of transcription factor interactions in the developing optic cup. *B*, Extrinsic factors can influence transcription factor expression.

might result in the whole optic cup taking on properties of the optic stalk, that is, elevated Pax-2 and Vax-1 expression and suppressed Pax-6 expression. It is likely that a second gradient exists in the opposite direction. One candidate for this is the fibroblast growth factor (FGF) family, possibly FGF8. FGFs can increase expression of retinal transcription factors and thus might work to counterbalance the effect of Shh.

Similar pathways of repressive interactions probably refine the expression patterns of other regulatory molecules. For example, two members of the Msh-like family of transcription factors, Msx-1 and Msx-2, are important markers of optic cup regionalization. Msx-2 is initially expressed in both layers of the optic vesicle but only in the retinal layer of the optic cup (Monaghan et al., 1991). Msx-1 is expressed only in the margins of the optic cup that will go on to form the ciliary epithelium. Many of the transcription factors also stimulate expression of other transcription factors. Pax-6, for example, regulates expression of other transcription factors including *Six-3* and *optx*, the functions of which are unknown.

The regionalization that began in the optic vesicle is now complete, with gene products including Pax-6, Rax/Rx, Six-3, and Msx-2 demarcating the retina, Otx-2 and MITF the RPE, Msx-1 the ciliary margin, and Vax-1 and Pax-2 the optic stalk. The relationships between the multiple markers of each compartment are not entirely clear. While they might be part of a single linear developmental pathway, some evidence favors the idea that they are carrying out separate functions in parallel pathways. In the RPE layer of the optic cup, mutations in MITF lead to lack of further development such that the cells remain as an

immature epithelial monolayer. Loss of Otx-2 in addition to MITF, however, leads to a change in cell phenotype such that the cells turn into retina (Bumsted and Barnstable, 2000).

In all of the dramatic changes of morphology and transcription factor profiles leading up to the optic cup, there is no evidence yet for expression of what can be thought of as retina-specific genes. If no retina-specific genes are expressed, could we define an isolated cell as belonging to retina as opposed to any other part of the nervous system? The answer is a qualified yes. Although each gene we know to be expressed in the retinal epithelium is also expressed at other places and times in development, there are few if any other cells in the embryo that contain the same spectrum of expressed genes. Thus, definition of a cell or tissue type can be achieved through the use of a spectrum of markers rather than a single molecule. Individual markers are more characteristic of the more specialized cells of the terminally differentiated derivatives of the optic cup. The first such signs of terminal differentiation can be detected in the RPE layer with the formation of pigment granules following the expression of tyrosinase and in the retinal layer with the formation of the first postmitotic neurons.

Retinal neurogenesis

The order in which postmitotic cells are formed in the retina, and the relationships between them, have been studied using a variety of tracers. The formation of retinal neurons has been studied using thymidine or BrdU to label cells during their terminal mitosis. All vertebrate retinas studied to date generate retinal cell types in the same order and at approximately the same time when expressed as a proportion of total gestation. All mitoses occur at the ventricular edge of the retinal epithelium, the edge facing the RPE. The space between the two layers is continuous with the forebrain ventricle at the optic vesicle stage, so the retina is like other parts of the CNS in having a proliferative ventricular layer. The other surface of the retina, the vitreal surface, is topologically equivalent to the pial surface of other brain regions.

The major classes of retinal neurons and their laminar arrangement are indicated in Figure 3.3. Ganglion cells become postmitotic in the mouse over the period E12–E15. Beginning just after this, but showing considerable overlap, cone photoreceptors and horizontal cells are generated. In the middle period of development, another major class of retinal interneurons, the amacrine cells, are generated. During the early postnatal period, the last three retinal cell types are formed. These are rod photoreceptors, their post-synaptic targets bipolar cells, and the intrinsic glial cell of the retina, the Müller cell. In addition to the temporal overlap in the generation of retinal cells, there is substantial

spatial overlap such that different cell types are being formed in close proximity to each other. There is a time delay between development of central and peripheral retinas, with central retina several days more advanced in mice and rats. Thus, at any one point on the retina, a spectrum of cell types is being formed, and in adjacent regions a slightly different spectrum is being formed. Such complexity suggests that development is not tightly controlled by an extrinsic factor but rather that much of the timing of cell formation is under intrinsic control.

To determine whether retinal cell types are generated from specific progenitor lines or from common progenitors, lineage tracing has been performed using markers that label dividing cells. Studies using retroviruses in mice or labeled dextrans in *Xenopus* have indicated that multiple cell types can be formed from a single proliferating progenitor cell (Holt et al., 1988; Turner and Cepko, 1987; Turner et al., 1990; Wetts and Fraser, 1988). This means that the fate of cells is not determined in the early epithelium but at a later stage, probably as cells enter their final mitosis. Most current evidence supports the idea that the pool of proliferating progenitor cells is not the same throughout retinal develop-

ment. This means that the vast majority of mouse retinal progenitors at E13 cannot make rod photoreceptors and the progenitors at postnatal day 1 (PN1) cannot make ganglion cells.

Thus, the model we have of early retina is a sheet of neuroepithelium that is distinct from neighboring areas in which each cell initially has the ability to form any retinal cell type but, with time, its potential for development becomes more restricted. Much of the ongoing control of retinal neurogenesis must be intrinsic to the tissue because isolated embryonic retinas can continue to generate all the cell types on an almost normal schedule (Sparrow et al., 1990).

Differentiation of inner retinal cells

In *Drosophila*, neurogenesis in the eye imaginal disc occurs as a wave across the tissue. At the active site of this wave, the morphogenetic furrow, precursor cells differentiate into a regular mosaic of photoreceptors in ommatidia. The secreted protein hedgehog regulates this morphogenetic furrow. There is no morphogenetic furrow in vertebrate retinas, but some studies suggest that the process of retinal

FIGURE 3.3. The five major classes of neurons in the retina form a laminated structure that contains the radial pathway from rod or cone photoreceptor, through bipolar cell, to output ganglion cell and the lateral modulatory pathway consisting of horizontal cells in the outer retina and amacrine cells in the inner retina.

neurogenesis may have some similarities. It appears that one or more of the vertebrate hedgehog isoforms is produced by the RPE and influences the spread of neurogenesis from a small central area outward to the periphery (Neumann and Nusslein-Volhard, 2000; Stenkamp et al., 2000).

We do not yet know how hedgehog proteins influence retinal neurogenesis. There are, however, clues to two important parts of the process. Both of these were first characterized in the development of the *Drosophila* nervous system. The membrane receptor protein Notch and its ligand Delta play an important role at the time a dividing precursor chooses to divide again or to spin off a differentiated daughter cell. Activation of Notch by Delta decreases the production of retinal ganglion cells, and decreasing Notch activity increases the production of ganglion cells (Austin et al., 1995). The Notch system is active throughout retinal development, and changing the activation of Notch can affect production of late-generated cells such as rod photoreceptors and Müller glial cells. Most of the available evidence suggests that the Notch system dictates a differentiation/no differentiation switch, with Notch activation maintaining a cell in an undifferentiated state, but does not control what cell types are formed. At present, we also do not know what controls the selective activation of Notch. One way in which Notch can act is by altering expression of a set of transcription factors essential for triggering the movement of a progenitor into a differentiation pathway. In *Drosophila*, a set of proneural genes of the *aschaete-scute* complex and *atonal* are essential for the development of neural competence by proneural cells. These genes encode proteins of the bHLH class, named for the structural characteristics of their DNA-binding domains, and a number of vertebrate orthologs are known to be important in retinal development. The mouse ortholog of *atonal*, *Math5*, is transiently expressed in developing mouse retinas beginning at E11, a time coincident with the onset of ganglion cell differentiation. Mice in which *Math5* had been deleted showed >80% loss of ganglion cells and an increase in amacrine cells (Wang et al., 2001). In *Drosophila*, *Notch* acts as a negative regulator of *atonal* and it is tempting to speculate that a similar relationship holds for *Notch* and *Math5* in the mouse. Other genes may cooperate with *Math5* in triggering ganglion cell differentiation. For example, *Otx-2* also shows transient expression in ganglion cells just after they become postmitotic (Baas et al., 2000). Whether *Math5* and *Otx-2* are acting in concert or in independent pathways is not known.

Among the earliest markers of ganglion cell differentiation are the POU-domain transcription factors of the *Brn-3* family. These can be detected soon after the ganglion cells have become postmitotic and before they have migrated to

the ganglion cell layer. *Math5* can transactivate a gene coupled to a *Brn-3* promoter (Liu et al., 2001).

Taking all the above results together, we can suggest a pathway in which the process of differentiation from competent precursors is initiated by the action of Shh. This factor influences the pattern of Notch activation, and in cells in which Notch is not activated *Math5* is expressed. This, perhaps in conjunction with other factors like *Otx-2*, irreversibly triggers cells into a ganglion cell fate and promotes expression of characteristic genes such as *Brn-3*. This is clearly an oversimplification and ignores interactions with other cells undergoing other fate choices. A related bHLH protein, NeuroD, is vital for amacrine cell formation. *Math5* can inhibit expression of NeuroD. Thus, in addition to promoting ganglion cell formation, *Math5* is inhibiting amacrine cell formation. By analogy with the mechanisms of optic cup regionalization discussed earlier, we should perhaps be looking for more examples of reciprocal inhibition of bHLH genes involved in specifying retinal cell types and for other extrinsic factors that can initiate a cascade of these reciprocal interactions.

Just as important as the mechanisms initiating cell differentiation in retina are those that regulate the number of each cell type produced. There is abundant evidence for a negative feedback in the production of ganglion and amacrine cells. In many species of fish and amphibians, the retina continues to grow throughout life by adding new cells at the tissue margin. Thus, the radial dimension from center to periphery recapitulates the developmental history of the retina. Dopaminergic amacrine cells are normally formed at the retinal margin at a constant density. Destruction of these cells with 6-OH-dopamine, followed by a sufficient recovery period, led to production of a higher than normal density of new dopaminergic cells (Negishi et al., 1982). Similar experiments in larval frogs gave essentially identical results (Reh and Tully, 1986). In an extension of these experiments, other retinal cell types were destroyed by treatment with kainic acid, and the number of new cells formed was increased in proportion to the damage to the differentiated neurons (Reh, 1987). The conclusion from these studies was that an inhibitory feedback signal was produced by differentiated cells that limited the number of that cell type produced. This possibility has been explored in more detail using retinal cultures. In reaggregate cultures using retinal cells of different ages, differentiated amacrine cells were found to inhibit the production of amacrine cells by embryonic cells (Belliveau and Cepko, 1999). Similarly, ganglion cell production was reduced in cultures of chick embryonic retinal cells when cultured adjacent to older retinal cells (Waid and McLoon, 1998). This type of experiment suggests that the inhibitory signal is diffusible, although its identity has yet to be established.

Differentiation of outer retinal cells

We know more about the differentiation of rod photoreceptors than about any other CNS neuron. The extensive background of molecular information derived from numerous studies of phototransduction has provided an excellent set of markers, and the medical importance of photoreceptor degenerative diseases has spurred extensive studies of this cell type. As indicated earlier, most rods become postmitotic near the end of retinal development, in the first few postnatal days in mice and rats. A few rods can be labeled by thymidine injection as early as E14, although they show further signs of differentiation at the same time as the vast majority of rods born later (Morrow et al., 1998). This suggests that the events occurring during the final mitosis can be separated from those of overt differentiation. Rods are formed from late progenitors, some of which can also form bipolar cells and Müller glial cells.

The visual pigment protein opsin is one of the earliest markers of rod differentiation and, because its early appearance is under transcriptional regulation, it has frequently been used to designate rod formation (Treisman et al., 1988). If retinal cells from postnatal rats or mice are plated in dilute monolayer culture, they form many opsin-expressing rods. If cells from early or midembryonic stages are plated, no opsin-positive rods are detected. On the other hand, if the embryonic tissue is maintained as an explant culture or dissociated and allowed to reaggregate, opsin-positive rods are detected at a time equivalent to the normal time of expression. This suggests that the information required to generate rods is intrinsic to the retina but that it needs cell-cell interactions for expression. Embryonic cells mixed with neonatal retinal cells (that are at their peak of rod differentiation) form more rods but only after the appropriate number of days in culture (Watanabe and Raff, 1992). These and related experiments suggest that there are factors present within retina that can promote formation of rod photoreceptors, but only when the progenitor cells are competent to respond to them. At present, the relative roles of factors located on the cell surface and secreted factors are unknown. Numerous factors including FGFs, retinoids, and even compounds like taurine can increase opsin expression in culture. There is, however, little direct evidence that any of them act directly on cell determination or opsin transcription pathways. It is more likely that they have relatively nonspecific effects that make the cells more healthy and better able to express differentiated functions.

In contrast to the positive effects of the growth factors mentioned above, treatment of retinal explants with cytokines of the interleukin-6 (IL-6) family, such as ciliary neurotrophic factor (CNTF) or leukemia inhibitory factor (LIF), completely inhibits the production of rod photore-

ceptors, as judged by opsin expression (Ezzeddine et al., 1997; Neophytou et al., 1997). These cytokines are known to bind to multisubunit membrane receptors and activate a tyrosine kinase. The intracellular transduction pathways activated by cytokine binding include those characterized by MAPK and STAT proteins. Activation of either of these can lead to changes in transcription. By using pharmacological blockers of MAPK and viruses expressing either constitutively active or dominant negative STAT proteins, we have shown that the MAPK pathway is likely to be involved in Müller glial cell formation and the STAT pathway (specifically STAT3) in rod formation. Activation of STAT3 leads to a change in expression of several key transcription factors. Most relevant are increases in the levels of Otx-2 and HES-1. Otx-2 is thought to play a role in the decision of progenitors to become either bipolar cells or rods. Since reduced levels of Otx-2 lead to production of more rods, it is reasonable to assume that elevated levels will help prevent rod formation. *Hes-1* is an important regulator of development in a number of tissues, is a bHLH protein homologous to the *hairy* and *enhancer of split* genes of *Drosophila*, and generally acts as a repressor of transcription. Its expression can be increased by activation of the Notch pathway. We do not yet know whether the cytokine-induced increase in Hes-1 expression is mediated through a Notch signaling pathway or whether this is another example of regulation through two independent pathways.

Positive regulators of rod formation include a number of bHLH transcription factors. The best studied of these is *Neuro D*, the same gene that influences amacrine cell production. Transfection of *Neuro D* into retinal cultures can increase the number of rods formed, and blocking of *Neuro D* can diminish rod production. *Hes-1* inhibits *Neuro D* expression; thus, this pathway may be responsible for the cytokine-induced inhibition of rod formation.

At present, we do not know how *Neuro D* facilitates rod formation. It does not appear to have a direct effect on the *opsin* gene, suggesting that there must be several steps between *Neuro D* expression and *opsin* expression. It has also been found that inhibition of *Neuro D* function increases the production of Müller glial cells. This suggests that *Neuro D* functions at the time a retinal progenitor is making a choice of cell differentiation pathway.

Molecular regulation of opsin expression

Promoter mapping studies using transgenic mice have suggested that all the information for correct temporal and spatial regulation of *opsin* expression is contained in about 1.5 kb of DNA 5' to the *opsin* gene. Most of the information is in the first few hundred bases 5' to the transcription start site. *Opsin* is a classical gene with a full TATA box for

assembly of the transcription complex. In a region just upstream of this is a region of DNA that appears to become completely covered with transcription factors, several of which have now been identified (Fig. 3.4). RET-4 has been defined as a nuclear protein binding site at -39 to -52, although the identity of the binding protein is unknown. Nrl is a zinc-finger protein that binds at -55 to -70 in the rat rod opsin promoter. Crx is a homeodomain protein that probably binds to the BAT-1 site at -82 to -98 on the opsin promoter. A key promoter site for regulation of opsin expression lies at -110 to -37. This site, labeled RET-1 or PCE, is found in a number of other rod photoreceptor genes, suggesting that a common transcriptional regulatory pathway may exist (Morabito et al., 1991). Its importance is also suggested by the finding that *opsin* genes from species as diverse as humans and *Drosophila* have RET-1/PCE sites in their promoters. Although high levels of Crx can activate transcription from this site, other transcription factors act with higher efficiency. Among these are other homeodomain proteins including *Rax* and another member of the *emx* family *Vax-2* (Kimura et al., 2000; Martinez and Barnstable,

1998). Since neither of these show peak expression in the mature photoreceptor layer, it is likely that either a still undescribed protein is important in *opsin* gene transcription or the affinity of another protein such as Crx can be altered by complex formation with another protein. The transcription factors necessary for *opsin* expression all seem to have different developmental profiles, suggesting that different pathways regulate their expression. What we do not have at present is evidence for a single trigger for rod photoreceptor differentiation, though *Neuro D* may serve this function in some way.

Maturation of retinal cells

The complex set of interactions that trigger the appearance of characteristic molecules is only the first step in the formation of a fully differentiated retinal cell type. Rod photoreceptors undergo a major developmental step of outer segment formation about a week after opsin expression can first be detected. Rod outer segments represent a complex morphological specialization and contain the light-sensing

FIGURE 3.4. Comparison of the sequences upstream of the *opsin* gene of various vertebrates. Homologous regions are boxed, and known transcription factor or nuclear protein binding sites are labeled in order from the transcription start site. 1, TATAA box; 2, Ret-4; 3, NRE; 4, BAT-1; 5, Ret-1; 6, Ret-2.

and transduction machinery. It is not surprising, therefore, that outer segment formation is accompanied by the de novo expression of a large number of rod-specific genes. Among these are the structural proteins involved in maintaining rod disc shape, such as peripherin and Rom-1, and components of the transduction cascade, such as transducin, phosphodiesterase (PDE), and the cGMP-gated cation channel. Although most of these appear to be regulated at the transcriptional level, we have little idea of the transcription factors regulating their expression. Both in vitro and in vivo studies have shown that the presence of an RPE cell layer is vital for the full development of outer segments but not for their initiation. Explants of retinas from many species will develop normally up to the stage of forming outer segments but then stop. In the *mi/mi* mutant mouse, an RPE layer is present but the cells remain in an immature state. The retina adjacent to this does not develop normally. Electron microscopy has shown that the rod photoreceptors begin to make membrane expansions that are the beginning of outer segments, and molecular studies have shown that several transduction genes are turned on. Thus, it appears that the RPE does not provide a triggering signal for outer segment formation but is vital for continued growth. Whether it provides important nutritional factors or mechanical support is not yet known.

The role of glia in retinal development and function

Most vertebrate retinas contain three types of glial cells. Müller glia are intrinsic glia that span the whole width of the tissue and are derived from the same set of progenitors as the retinal neurons. Astrocytes that reside in the optic nerve fiber layer migrate in through the optic stalk. Microglia also migrate into the retina, and many move from the ganglion cell layer to a position just below the outer plexiform layer. The timing of this migration coincides with the wave of developmental cell death that occurs during postnatal maturation, and these cells are thought to be intimately involved in removing dead cells from the tissue.

Müller glia serve a variety of roles. They form the inner and outer limiting membranes at either side of the retina and thus serve an important barrier function for substances moving into and out of the retina. Through their glycogen stores and their ability to process transmitters such as glutamate and GABA, they play a vital role in retinal metabolism. They also clearly serve a structural role, and defects in Müller cells can lead to severe disruptions and rosette formation in the photoreceptor layer. Müller cells are also capable of producing a variety of important peptide mediators. In response to lack of oxygen, Müller cells can produce vascular endothelial growth factor (VEGF) that can act on adjacent blood vessels and stimulate their growth. Müller cells can also produce trophic factors such as CNTF

and FGF. Experimentally, this production is usually seen after an insult such as bright light exposure or excitotoxin treatment. It is thought that the Müller cell response may be part of a homeostatic mechanism to lessen the deleterious effects of these insults. Since a number of aspects of retinal development involve similar trophic factors, it is tempting to think that Müller cells, or their precursors, also release these factors as key developmental regulators.

Positional information across the retina

The developmental mechanisms discussed so far in this chapter can begin to explain how distinct cell types arise from an initially uniform epithelium. They cannot, however, account for differences within the same cell class seen in central versus peripheral retina. Some differences, such as the size of the dendritic field or changes in the spacing of an orderly mosaic of cone photoreceptors, are intraretinal, but others, such as the position of synaptic targets in other visual areas, require translation of retinal position into complex patterns of growth and connectivity. It is important to try to distinguish those events in which position is reflected in expression of unique or unique amounts of particular molecules from those that arise as epiphenomena of other processes. One of the most dramatic differences seen in dendritic field morphology is in bipolar cells and retinal ganglion cells where in the human fovea a cone photoreceptor interacts with one or two bipolar cells but in the periphery hundreds of photoreceptors converge onto a single bipolar cell. We do not know whether this difference is inherent in molecular differences between the cells, a consequence of developmental processes that affect relative cell numbers, or a late event that changes from an initially more uniform pattern. Although these intrinsic retinal properties reflect positional information, the axes are more commonly defined by readout, as defined by the retinotopic mapping of ganglion cell axon terminals in target areas such as the superior colliculus.

Many studies have attempted to define the molecular correlates of retinal position. A number of molecules can be found in gradients. Some surface proteins and carbohydrate groups can be found in a dorsoventral gradient (Constantine-Paton et al., 1986; Trisler et al., 1981). Some transcription factors seem to divide the retina into nasal and temporal halves (Hatini et al., 1994). To date, however, only two classes of retinal gradient are known to convey positional information. The first is retinoic acid, which is present in a gradient along the dorsoventral axis created by corresponding gradients in synthetic enzymes with different substrate affinities (Drager et al., 1998). Retinoic acid is critical for the formation of ventral retina in zebrafish (Hyatt et al., 1996). In addition, the gradient of retinoic acid may be used in mouse retina for patterning different cone types.

The other classes of molecules found in a graded distribution are the Eph receptor tyrosine kinases and their ephrin ligands (Flanagan and Vanderhaeghen, 1998). This ligand receptor family was originally identified using a culture assay to measure topographic modulation of the growth of retinal ganglion cell axons (e.g., see Ciossek et al., 1998). Ephrins were isolated as molecules that could inhibit growth by inducing growth cone collapse. The receptor EphA3 is expressed in retinal ganglion cells as a temporal-nasal gradient, and its ligand ephrin A2 is expressed in a posterior-anterior gradient in the tectum. A second tectal ligand for EphA3, ephrin A5, is also expressed in a graded fashion in the tectum. A variety of *in vitro* assays, knockouts, and ectopic expression studies have provided strong evidence for the role of this receptor-ligand system in retino-tectal connectivity. For example, in ephrin A5 and ephrin A2 knockouts, retinal ganglion cell axons terminate in more posterior locations exactly as predicted if a repulsive influence was removed (Feldheim et al., 2000).

There is still debate whether ephrins and Eph receptors are important in both retinal axes. EphB2 and EphB3 receptors show a dorsoventral gradient of expression in the retina, and ephrin B ligands show a medial-lateral gradient in the superior colliculus. The importance of this group of ephrins and their receptors in retinotopic mapping is currently unknown.

As well as interpreting molecular gradients, tissues such as the retina need a molecular mechanism for their establishment. As discussed earlier, the transcription factor Vax-2 is preferentially expressed in ventral retina. In Vax-2 mutant animals, ephrins and their receptors show altered gradients in both nasal-temporal and dorsoventral axes, suggesting that this transcription factor is one specifier of axial polarity in the retina (Mui et al., 2002). Exactly how Vax-2 can produce different levels of expression in different cells is not known.

The gradients described to date cannot fully explain the formation of topographic maps. Unless there is some mechanism for producing and sensing absolute levels of a receptor or ligand, a single gradient is unlikely to be able to give a clear topographic organization. It has often been suggested that a pair of gradients in opposite directions is a more efficient mechanism because it allows the sensing of relative levels to determine position. It seems likely that this other gradient is attractive rather than repulsive, although its nature has yet to be characterized.

Retinal cell survival and cell death

Understanding the ways in which retinal cells develop is very important for providing therapies for diseases that lead to retinal cell death. Use of growth factors to promote cell survival, use of transplanted retinal cells as replacement

therapy, and even use of retinal stem cells all require a knowledge of pathways that regulate retinal cell phenotypes.

The most common forms of blindness occur through the death of retinal ganglion cells or photoreceptors. Loss of ganglion cells is the defining characteristic of glaucoma, which remains one of the leading causes of blindness in adults (Quigley et al., 1995). Loss of photoreceptors can involve rods, as in retinitis pigmentosa; or cones, as in macular degeneration; or both, as in rod-cone dystrophies and various syndromes.

A major risk factor for glaucoma is elevated intraocular pressure, which is thought to cause mechanical deformation as the ganglion cells axons leave the eye. This deformation may prevent the retrograde transport of neurotrophic factors. Based on developmental studies showing that brain derived neurotrophic factor (BDNF) is a vital neurotrophic factor for ganglion cells, it has been suggested that BDNF, or agents that mimic BDNF at later points in its pathway of action, might have therapeutic benefit. A second major cause of ganglion cell death in glaucoma is thought to be excitotoxic injury caused by excess glutamate. This might occur as a result of ischemic damage from elevated intraocular pressure or from other retinal defects in cases where pressure seems normal. Excess glutamate has been measured in glaucomatous eyes, and experimental application of glutamate can certainly induce ganglion cell death (Dreyer et al., 1996; Otori et al., 1998). One mechanism that might account for abnormal glutamate metabolism is abnormal uptake or handling by Müller glial cells (Kawasaki et al., 2000). Although glaucomatous eyes do appear to have lower levels of the Müller cell glutamate transporter, it has yet to be shown that this is a primary cause of the disease. Defects at other steps in the glutamate pathway, including glutamine synthetase and glutamine transporters, are also candidates for causing glaucoma. Since several of these molecules show regulation by extrinsic molecules such as corticosteroids, changes in their function could arise from a number of causes. The differences between normal and diseased retinas may initially be very slight. In addition to defects in specific molecules, overall developmental differences that, for example, alter the relative numbers or spacing of ganglion cells and Müller glial cells could influence the tissue's ability to metabolize glutamate.

Retinitis pigmentosa (RP) is an inherited condition in which loss of rod photoreceptors leads to loss of night vision and, later, deleterious secondary changes in cone photoreceptors (Berson, 1993). A wide array of genes have been identified as causing RP including most of those specific to the phototransduction cascade. Some are loss of function, such as mutations in the cGMP phosphodiesterase; some are structural, such as mutations in the rod outer segment protein peripherin; and still others are "metabolic," such as mutations in the visual pigment protein *opsin* that seem to

clog up the Golgi apparatus of the cell. Mutations in the *CRX* transcription factor gene can cause loss of rods, and later of cones as well (Freund et al., 1997). Thus, many of the molecules that are thought of as developmental regulators may also play a role in later disease. Trophic factors are thought to play an ongoing role in rod photoreceptor survival. In mouse and rat models of RP, it has been shown that some of the same trophic factors important in rod development and survival can prevent cell death for extended periods (LaVail et al., 1998). Interestingly, one of the factors that helps is CNTF, a factor that can completely block rod formation during development. Such a difference emphasizes that the same molecule can have very different functions at different stages of development.

Only a few clearly inherited forms of macular degeneration (MD) have been described. MD is generally much later in onset and can probably result from many different initial causes (Stone et al., 2001). Most vision loss in MD is caused by rapid proliferation of blood vessels between the RPE and the photoreceptor layer of the retina. This is thought to occur as a secondary consequence of changes in the RPE layer, the photoreceptor layer, or both. It may turn out that the majority of cases of MD are due to defects in the RPE layer. As expected for such a late-onset disease, most forms of MD do not show clear patterns of inheritance. This is probably due to the influence of multiple genes. The best-studied examples of gene mutations that cause MD suggest that abnormal handling of retinoid metabolism in the visual cycle can lead to deposits that cause cone photoreceptor death. It remains to be seen whether mutations in transcription factor genes, such as the homologs of *CRX*, can also cause specific cone diseases.

One of the therapies under investigation for photoreceptor degenerative disease is transplantation or cell replacement. For this to be effective, it is essential to know how to treat tissue so that photoreceptors survive and remain functional. We still need to know much more about the factors regulating formation of photoreceptors, particularly those regulating outer segment development. With the increased interest in and potential of stem cell therapies, it is essential that we understand the nature and sequence of factors necessary to turn a cell from a multipotential stem cell or progenitor into the desired phenotype of photoreceptor.

Conclusions

This chapter has presented a very narrow view of retinal development in terms of a series of biochemical pathways. Prior to the completion of the sequencing of the human genome, it was often argued that the complexity of the nervous system arose because of the existence of a vast number of "brain-specific" genes. This does not appear to be the case. Many of the genes used in neural development

are also used in other organs. Many of the genes are also used in multiple regions and at multiple times. Thus, using different combinations of molecules, or the same combinations in temporally and spatially distinct compartments, can generate complexity in the organization of regions of the nervous system. A number of examples of this in retinal development have been discussed. Gene products such as Pax-6 are important in the development of multiple brain regions. Nevertheless, this molecule is critical for eye formation and, in the correct environment, can initiate the whole process of optic vesicle formation. The protein Otx-2 is used in both RPE and retinal compartments, but these are made distinct by expression of other molecules. Otx-2 is also expressed during the development of several retinal cell types but, since these develop at different times from different sets of progenitors, its functions at each stage are unique.

Retinal development does not stop with the events of neurogenesis and maturation described in this chapter. There is obviously much more that could be written about the mechanisms of process growth within, and outside of, the retina and the molecular mechanisms governing synaptogenesis. These phenomena can be studied at the same level of molecular detail as earlier developmental stages. In the foreseeable future, we should have a reasonably complete description of retinal development. If the past is any guide, insights that arise from these studies will be of great value in understanding not only other parts of the visual system, but also other parts of the brain.

4 Neurotrophins, Electrical Activity, and the Development of Visual Function

NICOLETTA BERARDI AND LAMBERTO MAFFEI

Introduction

Vision in mammals is very poor at birth and develops over a relatively long period (weeks, months, or years, according to the species; Fig. 4.1A) in parallel with the anatomical and functional maturation of the visual system, particularly the visual cortex. If visual experience is altered during this period, called the *critical period*, dramatic consequences follow both in visual cortical development and in the development of vision. For instance, if during the critical period one eye is deprived of patterned vision, as with unilateral congenital cataract, the great majority of visual cortical neurons stop responding to the deprived eye, being driven only by the normal eye, and vision for the deprived eye develops poorly (amblyopia). There seems to be a close link between visual cortical development, critical period duration, and maturation of some visual functions, as shown in Figure 4.1A: the closure of the critical period for monocular deprivation roughly coincides with completion of visual acuity development in a number of species, from rat to monkey to human.

Manipulations of sensory experience also have been shown to affect the development of auditory and somatosensory systems, leading to the widely accepted assumption that the final stage of development of neural connections in sensory systems is under the irreplaceable control of sensory experience. The studies then converged into what may be the various stages for the fulfillment of the task initiated by sensory experience.

The first link in the chain is likely to be electrical activity, the language into which sensory experience is translated, which is already known to guide nervous circuit rearrangements and synapse formation. Here we reexamine the role of electrical activity, both spontaneous and visually driven, in the “construction” of the visual system by analyzing the interactions between electrical activity and neurotrophins in the completion of visual function development. Neurotrophins are an essential link in the chain of events leading to maturation of visual connections, a link so necessary that electrical activity in the absence of neurotrophins fails to drive developing visual cortical circuits into their final functional state. For instance, even if visual experience is normal,

development of visual function is abnormal if specific neurotrophins are missing. Surprisingly, neurotrophins also seem sufficient to drive the development of some aspects of vision in the absence of visual experience.

In presenting the fascinating story of the role of electrical activity and neurotrophins in the development of the visual system, studies which blossomed in the past 10–15 years, we shall follow an historical criterion, which allows us to introduce the various experimental paradigms and the experimental models used. (For recent reviews, see Berardi and Maffei, 1999; Cellerino and Maffei, 1996; McAllister et al., 1999; Pizzorusso and Maffei, 1996).

The neurotrophins

Neurotrophins have usually been considered for their involvement in the development of the nervous system and for the differentiation and maintenance of specific functions of certain classes of neurons (see Box 1). The neurotrophins so far identified in addition to NGF, which is the progenitor of the entire family, are BDNF, NT4-5, NT3, and finally NT6, which has been described only in fish (Lewin and Barde, 1996). The action of neurotrophins requires their binding to particular receptors. Each neurotrophin binds to a specific tyrosine kinase receptor (trk) through which it exerts its biological functions. These specific receptors are trkA for NGF, trkB for BDNF and NT4-5, and trkC for NT3 (Bothwell, 1995). Neurotrophic factors also bind to the low-affinity receptor p75, the role of which has been studied particularly in relation to the ligand NGF. Where NGF is concerned, one of the roles of p75 is to augment trkA function, lowering the concentration of NGF necessary for signal transduction. In addition to this role, p75 can act as an inducer of apoptosis.

The classical neurotrophic hypothesis was that developing neurons compete for target-derived neurotrophic factors which are produced in limited amounts by nonneuronal targets (the skin for sensory neurons, the muscle for proprioceptive neurons); neurotrophins bind to their receptors, are internalized, and are transported retrogradely to the neuronal soma, where they promote neuronal survival. If one neurotrophin or its receptor is antagonized or missing,

A

B

FIGURE 4.1. *A*, The development of visual acuity for man, monkey, cat, and rat is reported as a function of age and compared with the critical period for monocular deprivation. By the end of the critical period visual acuity reaches its final value, indicating that maturation of sensory functions and decline of experience-dependent plasticity are two closely interconnected processes based on the maturation and activity-dependent stabilization of neural connections in the visual cortex. A variation of the critical period duration implies a variation of the rate of visual function development (see Fig. 4.8). *B*, Activity-dependent synapse stabilization. The crucial elements for the new neurotrophic hypothesis are depicted

here: production, release, and uptake of neurotrophins (NT) are activity dependent. The connections with electrical activity (depicted as a sequence of action potentials above the fiber) which is higher, more patterned, and richer in transients receive a greater NT supply (*thick, gray arrow*) and stabilize or enlarge their synaptic contacts (*big, thick knob* at the end of the fiber) with the target neuron, while the connections with poor electrical activity get weak neurotrophic support (*thin, gray arrow*) and lose their synaptic contacts (*small, thin knob*). Anterograde action of NT is also possible (*white arrow*). (Adapted from Berardi et al., 2000.)

Box 1. *Classical Neurotrophic Hypothesis*

During development of the nervous system, neuronal populations undergo a process of naturally occurring cell death at the time their axons innervate target areas. It is believed that this process ensures a match between the size of the innervating population and the size of its target territory. The classical neurotrophic hypothesis states that production of trophic factors by target organs regulates this matching process. Limited amounts of neurotrophic factors are produced by target cells: neurotrophic factors bind specific receptors, are internalized by projecting neurons, and are transported retrogradely to the soma, where they promote survival.

This hypothesis was first formulated for PNS neurons by Hamburger, Levi-Montalcini, and coworkers (reviews in Levi-Montalcini, 1987; Purves, 1988) on the basis of their landmark experiments with nerve growth factor (NGF), the first neurotrophic factor discovered: they demonstrated *in vivo* that this factor is essential for survival of sympathetic and nociceptive sensory neurons. Subsequently, each of the major predictions of the classical neurotrophic hypothesis for NGF was confirmed:

NGF is produced by the nonneuronal targets of sympathetic and sensory neurons but not by the neurons themselves; target ablation or blockage of axonal transport results in the death of neonatal sympathetic and sensory neurons; administration of NGF prevents naturally occurring cell death; NGF binds to specific receptors (trkA) and is retrogradely transported. Now this hypothesis has been extended to the other neurotrophins: brain-derived neurotrophic factor (BDNF), neurotrophin 3 (NT3), and neurotrophin 4 (NT4). The specific receptor for BDNF and NT4 is trkB and for NT3 it is trkC; all neurotrophins, NGF included, also bind to p75. It is now clear from examination of mutant mice carrying deletions for the genes encoding neurotrophins and their receptors that specific neuronal populations require trophic support of specific neurotrophins from their final targets. A table of neuronal losses in neurotrophin and receptor deficient mice is presented below. For a review on neurotrophic factors and their receptors see Bothwell (1995), Lewin and Barde (1996), and Reichardt and Farinas (1997).

Neuronal Population	trkA Deletion	NGF Deletion	trkB Deletion	BDNF Deletion	NT4 Deletion	trkC Deletion	NT3 Deletion
<i>Sensory</i>							
Trigeminal	75%	75%	60%	30%	n.s.	ND	60%
Dorsal root ganglia	70%	70%	30%	35%	n.s.	20%	60%

Neuronal losses are expressed as the percentage of neurons lost in mutant compared to wild-type controls. n.s. = not significantly different. ND = not determined. Only some of the populations examined in the original papers are reported for the sake of brevity.

specific neuronal populations in the peripheral and autonomic nervous systems fail to develop or do not survive (see Box 1). For instance, in mice deficient in trkA or NGF, virtually all sympathetic neurons in the superior cervical ganglion die, while in mice deficient in trkC or NT3, proprioceptive neurons die.

At variance with what is found in the peripheral or autonomic nervous system, no central nervous system (CNS) population is solely dependent on one neurotrophin for its survival. Indeed, in neurotrophin knockout mice, there is no loss of any specific population of neurons in the CNS (Thoenen, 1995).¹

With hindsight, this observation already hinted at the possibility that the role of neurotrophins in the CNS was not neuronal survival. However, it took a completely dif-

ferent series of experiments to show clearly that neurotrophins have an important role in the plasticity of the CNS, leading to the formulation of a new neurotrophic hypothesis. These experiments were performed in the developing visual system.

¹Note: Several authors have employed neurotrophins to save neurons from lesion-induced death. Paradigmatic is the effect of NGF on the survival of cholinergic basal forebrain neurons after axotomy. Retinal ganglion cell survival is also increased by exogenous neurotrophins. This, however, does not mean that the exogenous neurotrophin can substitute for the loss of the target-derived endogenous one. Indeed, blockage of axonal transport does not cause appreciable death of retinal ganglion cells.

A new neurotrophic hypothesis

Functional properties of mammalian visual cortical neurons are immature at eye opening and develop gradually during the first months of postnatal life (Fagiolini et al., 1994). Development of the visual system is strongly influenced by depriving one eye of patterned vision during a short period of postnatal development called the *critical period for the effects of monocular deprivation* (which, from now on, will be referred to as simply the *critical period*). Modifications of cortical circuitry in response to an imbalance between the inputs from the two eyes are extremely rapid; for instance, a few hours of monocular deprivation during the critical period are sufficient to shift the ocular dominance distribution of visual cortical cells toward the nondeprived eye, and a few days are enough to produce a shift which is equal to that induced by a deprivation lasting for the entire critical period. What are the mechanisms leading to such dramatic modifications of cortical connections?

Wiesel and Hubel introduced in visual physiology the important concept of *binocular competition* (Wiesel and Hubel, 1963). The two eyes compete for functional possession of the binocular cortical neurons, and the competition takes the form of electrical activity. If electrical activity in the two sets of thalamic fibers, those driven by the contralateral eye and those driven by the ipsilateral eye, is temporally correlated, then both sets of fibers will be allowed to maintain connections with the same cortical neuron. If, however, the activity in the two sets of fibers is not temporally correlated, only one set of fibers will be allowed to keep its hold on the postsynaptic neuron, the one whose activity is more able to drive it. In normal development, where the activity in the two sets of fibers driven by either eye is equally strong and temporally patterned, this process of activity-dependent competition leads to the existence of binocular neurons and to a balanced ocular dominance distribution: neurons in the visual cortex have very similar probabilities of being dominated by either eye. During monocular deprivation the competition between the two eyes becomes uneven, because electrical activity in the afferent fibers driven by the deprived eye is both uncorrelated with that of the fibers driven by the undeprived eye and weaker; as a result, the closed eye loses the fight at cortical level, leaving the dominance of cortical neurons to the undeprived eye.

It is not clear what the two eyes compete for at a molecular level. A reasonable hypothesis is that they compete for a reward important for their function. A reward can be thought of as chemical messages that strengthen nervous connections; therefore, it can be said that the two eyes, during development, compete for eating. Our initial hypothesis (see Fig. 4.1*B*) was that the fibers driven by either eye compete for a neurotrophic factor available in only a limited amount at cortical level (Maffei et al., 1992).

This introduced the neurotrophic hypothesis in the CNS, transforming neurotrophins from survival factors for neurons, derived from nonneuronal targets, to survival factors for neural connections, exchanged from neuron to neuron as they establish functional connections. This new neurotrophic hypothesis envisaged two broad fields of action for neurotrophins in the CNS. The first stage could influence the probability of formation of synaptic contacts between incoming fibers and target neurons. The second stage could be the regulation of synaptic efficacy, maintenance of connections, and development of a function, as in binocular vision development. This hypothesis implies that the production and uptake of the neurotrophic factor are functions of the quantity and pattern of electrical activity at both presynaptic and postsynaptic levels, and that neurotrophic factors, in turn, can enhance synaptic transmission at both the functional and morphological levels, thus firmly linking together neurotrophins and electrical activity in the control of visual development. It should be noted that at the time this new hypothesis concerning the role of neurotrophins in activity-dependent synaptic plasticity was put forth, the reciprocal control between neurotrophins and electrical activity, now well characterized, was totally unknown. The first demonstrations that neurotrophin production was under the control of electrical activity occurred around 1990 (Ernfors et al., 1991; Zafra et al., 1990), showing that artificially increasing the electrical activity in the hippocampus or neocortex increased both the mRNA and protein of neurotrophins; later on, it was shown that this also promoted their release (Blochl and Thoenen, 1995). Also, protocols inducing long-term potentiation (LTP) in the hippocampus were then shown to increase neurotrophin mRNA (Castren et al., 1993). Complementary to this, a decrease of activity by tetrodotoxin (TTX) decreased neurotrophin mRNA (Castren et al., 1992).

In addition to the two main differences already pointed out between the classical neurotrophic hypothesis for the PNS and the new one for the CNS (formation and survival of connections and not of neurons, produced by neurons and not by nonneuronal targets), another difference is emerging from the literature, namely, the possibility of an anterograde action of neurotrophins as opposed to the classical target-derived action. This significantly changes the frame of thought: in addition to thinking that cortex-derived factors guide, in concert with electrical activity, stabilization of thalamic afferents on cortical neurons, we may have to consider that thalamic fibers themselves release factors which promote and guide the formation and maintenance of their synapses on cortical neurons and that corticothalamic afferents may contribute to the development of the pattern of thalamocortical connectivity. The evidence for anterograde actions is illustrated in Box 2.

Box 2. *Anterograde and Retrograde Actions of Neurotrophins*

Following the experiments in the PNS, the concept had been accepted that neurotrophins are transported retrogradely and that this is the basis of their action.

This idea has been passively extended to the interpretation of CNS data.

In some instances, particularly for NGF and the cholinergic projection from the basal forebrain to the hippocampus, this assumption seems to hold. In other cases, it is supported only by the observation that exogenous neurotrophins injected into specific brain regions are retrogradely transported. However, recent experiments studying the transport of BDNF/NGF in the optic nerve of the rat have shown that the situation is somewhat more complicated. If one ligates the optic nerve and observes the accumulation of neurotrophins at both sides of the ligature, only accumulation of BDNF on the retinal side is seen; by contrast, if NGF and BDNF are injected in the superior colliculus and lateral geniculate nucleus, both promptly accumulate at the distal side of the ligature. This suggests that transport of exogenous neurotrophins is not proof of the transport of endogenous ones and that anterograde actions are more important than was previously thought (Caleo et al., 2000). Evidence for anterograde actions has also been obtained in the visual cortex (Kohara et al., 2001) and in the chick visual system (von Bartheld et al., 1996).

NGF and monocular deprivation

The rationale for most of the experiments performed to assess the role of neurotrophins in the changes induced at

the visual cortical level in monocularly deprived and strabismic animals is the following: if one provides exogenously the neurotrophic factor to the neural competitors, they should not have any reason to fight and even the geniculocortical axons driven by the eye unstimulated or not properly stimulated by vision might achieve enough neurotrophic factor at the level of its cortical projections to ensure its physiological development.

In short, the working hypothesis is that the effects of monocular deprivation or strabismus should be prevented by an exogenous supply of NGF.

This hypothesis may now appear somewhat simple-minded, but it turned out to be very appropriate operationally. Indeed, an intraventricular exogenous supply of NGF in the rat prevents all the tested effects of monocular deprivation and (convergent) strabismus (Domenici et al., 1991, 1992; Maffei et al., 1992). Interestingly, these results have been recently confirmed in another rodent, the mouse, by Fagiolini and Stryker (1996). In cats, an intraventricular supply of NGF was effective in attenuating monocular deprivation effects up to the behavioral level; visual acuity of the deprived eye developed normally in kittens treated with NGF (Fiorentini et al., 1995). A synopsis of the main results concerning NGF and monocular deprivation is presented in Figure 4.2.

More recently, NGF was directly provided to cortical neurons by intracortical infusion; this also prevented monocular deprivation effects on ocular dominance (Lodovichi et al., 2000), suggesting that the receptors for NGF should be

FIGURE 4.2. Intraventricular NGF administration counteracts the effects of monocular deprivation on ocular dominance and visual acuity. *Top:* Ocular dominance distributions for normal rats, rats monocularly deprived during the critical period and rats monocularly deprived and treated with NGF throughout the deprivation period (postnatal days 15–45, P15–P45). Cells were classified according to the Hubel and Wiesel criteria, with cells in classes 1 and 7 being monocular and driven exclusively by the contralateral and ipsilateral eye, respectively; cells in ocular dominance classes 2/3 and 5/6 being binocular and driven preferentially by the contralateral and ipsilateral eye, respectively; and cells in class 4 being binocular and driven equally by the two eyes. It is evident that the shift in ocular dominance distribution in monocularly deprived rats is absent in NGF-treated rats. (Data replotted from Maffei et al., 1992.) *Middle: A,* Visual evoked potentials (VEP) recorded in the visual cortex contralateral to the deprived eye in response to sinusoidal gratings of increasing spatial frequencies (examples of sinusoidal gratings with spatial frequency in the ratio 1:2:4 are reported on the left of the graphs). Mean relative VEP amplitude (normalized to the amplitude of the signal recorded for 0.2 cycle/deg) is reported as a function of stimulus spatial frequency for monocularly deprived control animals and monocularly deprived NGF-treated animals. Vertical bars represent standard deviations. The noise level is indicated by the dotted line. As the spatial frequency of the stimulus increases, the signal amplitude decreases until it falls

to the noise level. The highest spatial frequency still evoking a reliable signal with a maximal stimulus contrast is taken as the visual acuity. The symbols just above the noise level correspond to estimated mean visual acuity for the deprived and nondeprived eyes, which is 0.4 ± 0.7 vs. 1 ± 0.04 cycles/deg in monocularly deprived control animals and 0.97 ± 0.1 vs. 1 ± 0.08 cycles/deg in monocularly deprived NGF-treated animals. The difference between visual acuity in the deprived and undeprived eyes is significant for monocularly deprived animals but not for monocularly deprived animals treated with NGF (replotted from Domenici et al., 1991). To visualize the difference in acuity brought about by NGF in deprived animals, the ratio between the spatial frequency of the gratings below the abscissa is 1:2.5, which is the ratio between visual acuity for the deprived eye in control animals and for the deprived eye in NGF-treated animals. *Bottom: B,* Percentage of correct responses in a behavioral forced choice discrimination of a grating versus a uniform gray ($N = 85$ trials per point) plotted as a function of the spatial frequency of the grating for a kitten monocularly deprived from P30 to P45 and for a littermate deprived for the same period but treated with NGF. The estimated visual acuities (corresponding to 70% correct) for the deprived and nondeprived eyes are indicated by the arrows on the abscissa (adapted from Fiorentini et al., 1995). It is clear that the beneficial effects of NGF in preventing deprivation amblyopia (loss of visual acuity in the deprived eye) are present at the level of visual behavior.

present at the cortical level. Indeed, *trkA* and *p75* are present in the visual cortex during the critical period, and activation of cortical *trkA* receptors is sufficient to allow normal development of ocular dominance in monocularly deprived rats, mimicking the effects of NGF (Pizzorusso et al., 1999).

Thus, even in the presence of an abnormal visual experience, an increase in NGF availability to cortical neurons or activation of NGF cortical receptors allows normal development of visual cortical connectivity and, ultimately, of vision.

Administration of neurotrophins during dark rearing can replace the lack of visual experience

Without visual experience the visual cortex does not develop normally, and it remains largely immature even after the end of the critical period (Fagiolini et al., 1994; Timney et al., 1978). The classical signs of dark-rearing effects on cortical development are reported in Figure 4.3 and include abnormal habituation of cortical responses and decreased visual acuity.

Following the experiments on the effects of NGF in monocularly deprived animals, the hypothesis was advanced that visual experience during development promotes normal maturation of the visual cortex by regulating the availability of neurotrophins to visual cortical circuits or to structures projecting to them (Fagiolini et al., 1997; Pizzorusso et al., 1997). The physiological alterations induced by lack of visual experience in dark-reared animals could be due simply to an alteration in the level of expression of neurotrophins in the visual cortex. If so, increasing the availability of neurotrophins could replace, at least partly, the lack of visual experience during dark rearing. This hypothesis has been tested for NGF and BDNF.

Supplying animals with suitable doses of neurotrophins during the whole period of dark rearing poses technically difficult problems. It is known that neurotrophins do not cross the blood-brain barrier and therefore must be administered directly to the brain. Daily administration of neurotrophins, for instance, into the ventricles, is practically impossible or troublesome during dark rearing. To overcome this problem, three different methods have been used. All of them have been successful and could have a bearing on clinical applications of neurotrophins in humans. Conceptually the first two methods are very similar, in that they aim at implanting in the lateral ventricles biological minipumps delivering sufficient doses of neurotrophins (in this case NGF) throughout the whole period of dark rearing. As biological minipumps, either Schwann cells or polymer-encapsulated cells genetically engineered to release NGF have been employed (for details of the methods and results, see Fagiolini et al., 1997; Pizzorusso et al., 1997).

The results, summarized in Figure 4.3, show that NGF allows a normal or nearly normal development in dark-reared animals with respect to the tested parameters. In particular, Figure 4.3 shows that development of visual acuity is normal in dark-reared rats treated with NGF.

More recently, the problem of supplying neurotrophins to the CNS has been solved by taking advantage of BDNF overexpression in the postnatal forebrain of mice (Huang et al., 1999; see Fig. 4.7). Also in these animals, all tested parameters were normal despite dark rearing (Fig. 4.3).

In addition, in dark-reared BDNF-overexpressing mice we have observed that the critical period, which is normally prolonged by dark rearing, ends at the same time as in normally reared wild-type mice (P45). Thus, development of visual function can proceed almost normally even in the absence of visual experience, provided that neurotrophins are supplied.

A possible interpretation of these results is that visual experience controls development of visual function by controlling the expression of neurotrophins. Indeed, expression and function of neurotrophins are altered in dark-reared animals (Castren et al., 1992; Pollock et al., 2001; Vieg-

et al., 2002), suggesting that the effects of dark rearing could, at least in part, be attributed to the lack of appropriate neurotrophin action.

This allows us to speculate that neurotrophins engage in an innate program of visual development which is normally triggered by visual experience. This program is dependent on activity in the visual pathways, in particular on spontaneous activity. Blockage of spontaneous activity of retinal ganglion cells, at least in the case of monocular deprivation, caused a failure of NGF action (Caleo et al., 1999).

Blockage of endogenous NGF affects development of the visual system

If neurotrophic factors are a crucial link between activity and development of appropriate connectivity in the visual system, either by acting as retrograde messages from neurons or dendrites to nerve terminations, to selectively reinforce active inputs, as Donald Hebb envisaged, or by acting anterogradely, then the blockage of endogenous neurotrophins during the critical period should interfere with development of the visual system: connections should remain immature and the system plastic—for instance, sensitive to monocular deprivation—beyond the critical period. These predictions were tested by the intraventricular transplant of cells secreting antibodies against NGF during development (Berardi et al., 1994; Domenici et al., 1994), and it was shown that they were fulfilled (Fig. 4.4). Visual acuity was reduced, receptive fields remained large, and the critical period for monocular deprivation was abnormally prolonged, effects very similar to those produced by dark rearing.

Very similar results have been obtained in cats blocking endogenous trkB ligands; infusion of BDNF and NT4 scavengers (trkB-IgG fusion proteins) into the visual cortex (Cabelli et al., 1997) disrupts ocular dominance column formation (Fig. 4.5), an effect reminiscent of that produced by binocular deprivation (Crair et al., 1998).

Thus, not only can the deleterious effects of an abnormal or absent visual experience on development be counteracted by increasing neurotrophin availability to visual neurons, but a normal visual experience is unable to normally drive development and closure of the critical period if the action of endogenous neurotrophins is blocked. This last result strongly suggests that neurotrophins may be the crucial link in the chain of events linking visual experience with development of vision.

Do BDNF, NGF, NT4, and NT3 play similar or different roles in cortical plasticity and development?

The question now arose, what were the roles played by the different neurotrophins in developmental visual cortical plasticity? This question occurred because, over the years,

Effects of neurotrophins in dark rearing

DR	DR+NGF	DR+BDNF
•Decreased visual acuity	Normal visual acuity	Normal visual acuity
•Increased receptive field size	Normal receptive fields	Normal receptive fields
•Decreased orientation selectivity	Slightly decreased orientation selectivity	Slightly decreased orientation selectivity
•Increased binocularity	Normal binocularity	Normal binocularity
•Habituating responses to visual stimulation	Normal responses	Normal responses

FIGURE 4.3. *Top left:* summary of the functional properties affected by dark rearing (DR). Habituation is the progressive attenuation of cell responses to repetitive visual stimulation: typically, cell responses disappears after three or four passages of a drifting bar over the receptive field in DR animals (DR from birth to P60). Habituation is absent in normally reared animals. *Middle and right:* the deficits induced by DR are absent (no significant differences with respect to normal) or strongly attenuated (orientation selectivity, small difference with respect to normal) in rats subjected to intraventricular implant of NGF-producing cells (DR + NGF) or

in mice overexpressing BDNF in the telencephalon (DR + BDNF). *Bottom:* Summary of the results obtained for visual acuity in DR rats. The shaded area represents the range (mean \pm one standard deviation) of visual acuities for normal rats during development from P20 to adulthood. At each age and for each animal visual acuity was estimated by VEP, as in Figure 4.2. DR up to P45 strongly decreases visual acuity (*filled triangle*); visual acuity of DR rats with intraventricular implant of NGF-producing cells is, however, normal (*filled circle*).

some differences in the actions of the neurotrophins became apparent and a debate developed about the nature of the active neurotrophin(s). As for the effects on cortical development, only BDNF and NT4 disrupt ocular dominance columns in kittens (Cabelli et al., 1995); however, all neurotrophins influence dendritic growth in developing ferret visual cortex (McAllister et al., 1995, 1997). As for the

effects on plasticity, injection into the visual cortex of microbeads conjugated with neurotrophins has shown that NT4, and only NT4, is effective in preventing the shrinkage of lateral geniculate nucleus (LGN) neurons induced by monocular deprivation in ferrets (Riddle et al., 1995). On the other hand, BDNF was found to be able to prevent the shift of the ocular dominance distribution of cortical

Effects of Blocking Endogenous NGF During Development of Rat Visual System

- Shrinkage of LGN neurons
- Reduction of visual acuity
- Decrease in binocularity
- Larger receptive fields

FIGURE 4.4. *Top*: Summary of the main effects of the blockage of endogenous NGF action by implantation in the lateral ventricle of hybridoma cells secreting antibodies to NGF. The implant was done at the beginning of the critical period (P15). Rats implanted with parental myeloma cells were used as controls. Animals were left to develop normally, with both eyes open. LGN soma size, visual acuity, cell ocular dominance, and receptive field size were measured at P45. *Bottom*: The effects of NGF blockage on the critical period. Animals were left to develop normally, with both eyes open, up to P45, which is past the end of the rat critical period, and then were monocularly deprived; the effects of monocular deprivation were assessed electrophysiologically 1 month later. It is evident that monocular deprivation is still able to shift the ocular dominance distribution toward the nondeprived eye in rats with blockage of NGF (MD P45, blockage of NGF) but not in control rats (MD P45). (Adapted from Domenici et al., 1994).

neurons induced by monocular deprivation in cats (Galuske et al., 1996). It became necessary, therefore, to assess whether the differences observed were simply due to different experimental conditions, like the use of different animals, different methods of drug administration, and different ages of the animal, or whether different neurotrophins played different roles.

Another important question concerned the effects of neurotrophins on visual cortical cell electrical activity. Many studies had shown that neurotrophins, in particular BDNF, strongly modulate synaptic transmission and electrical activity of cortical neurons in vitro (see McAllister et al., 1999,

FIGURE 4.5. An example of the effects of trkB-IgG infusion on ocular dominance columns. trkB-IgG was infused into cat visual cortex from P21 to P42 at a rate of 2.5 mg/ml. To label ocular dominance patches in layer IV, geniculocortical afferents were labeled with the transneuronal tracer $[^3\text{H}]$ -proline injected into the vitreous chamber of one eye. *Top*: darkfield image from an infused brain; *bottom*: corresponding profile of silver grain density in layer 4. The position of the tip of the infusion cannula is marked with an X. Scale bar, 1 mm. It is evident that the regular alternation of labeled patches (axons of LGN neurons driven by the injected eye) and of gaps (axons of LGN neurons driven by the noninjected eye) is disrupted in the portion of visual cortex infused with trkB-IgG (zone above the cannula tip). (Adapted from Cabelli et al., 1997.)

for review). The most striking effect of BDNF was documented by Kafitz et al. (1999) in cultured hippocampal neurons: BDNF was as fast and potent as glutamate, a classical excitatory neurotransmitter, in exciting the neurons onto which it was puffed (Kafitz et al., 1999). Knowledge of neurotrophin effects on cortical cell activity in vivo is essential to understand more thoroughly their mechanisms of action in regulating visual cortical plasticity. Any strong direct effect on visual cortical cell electrical activity is bound to influence developmental cortical plasticity (Ramoia et al., 1988; Reiter and Stryker, 1988; Shaw and Cynader, 1984).

A recent study has compared in vivo the actions of all four neurotrophins—NGF, BDNF, NT3, and NT4—on cortical plasticity and on electrical activity in the same species, in animals of the same age, and in the same experimental conditions. This has been done in the rat, employing monocular deprivation as a plasticity test (Lodovichi et al., 2000). NGF and NT4 were found to be very effective in counteracting the shift in the ocular dominance distribution of rat visual cortical neurons induced by monocular deprivation. This protective effect was not accompanied by any detectable changes in cell responsiveness or in orientation selectivity. BDNF, even at much higher doses than NGF and NT4, was less effective in counteracting monocular deprivation effects and, in addition, was the only neurotrophin which altered visual cortical cell electrical activity, both spontaneous and evoked. These results suggest that the partial effect of BDNF on monocular deprivation could stem from its ability to dramatically alter the electrical activity of cor-

tical neurons. NT3 is ineffective in preventing ocular dominance shift, both at a dose comparable to that of NGF and NT4 and at a much higher dose. Thus, the differences found in the literature for neurotrophin action in visual cortical plasticity cannot be attributed solely to species differences: different neurotrophins play their roles in visual cortical plasticity through different mechanisms and, in particular, through a different interplay with electrical activity. This could be due to a difference in the cellular targets of neurotrophins (see below for the peculiar link between BDNF and intracortical inhibitory circuitry) and/or to differences in the intracellular signaling cascades activated. Diversity in the postreceptor transduction pathways is likely to be a necessary explanation for the differences between NT4 and BDNF actions, since they both bind trkB.

Neurotrophins and the modulation of synaptic transmission in the visual cortex

A possible mechanism of action of neurotrophins on neural plasticity is the modulation of synaptic efficacy (see McAllister et al., 1999, for review). To investigate whether neurotrophins can modulate synaptic transmission in the visual cortex, a very convenient *in vitro* preparation, visual cortex synaptosomes, has recently been used. Synaptosomes contain mainly the presynaptic component of synapses, with all the machinery for neurotransmitter release. The advantage of this preparation is that the effectiveness of one neurotrophin in modulating each neurotransmitter system can be investigated in isolation (Fig. 4.6). For instance, an effect of BDNF on acetylcholine release can be attributed to a direct action of BDNF on cholinergic terminals, and not secondary to release of another neurotransmitter acting on cholinergic terminals.

Both NGF and BDNF potentiate glutamate (Glu) and acetylcholine (ACh) release, while only BDNF does so for GABA release (Sala et al., 1998) (Fig. 4.6). trkA plays the major role in mediating NGF effects, with p75 playing a small facilitatory role. This suggests a direct trkA-mediated effect of NGF on synaptic terminals of glutamatergic neurons in the visual cortex. More recently, the effects of NT4 on synaptic release were investigated in the same preparation. Like BDNF, NT4 potentiated GABA and Glu release but was much less effective than BDNF in potentiating acetylcholine release.

Two conclusions can be drawn at this point. First, modulation of synaptic transmission is an important mechanism of action for neurotrophins in the developing visual cortex. Second, different neurotrophins have different targets: NGF modulates synaptic release of cholinergic and glutamatergic terminals but not of GABAergic interneurons; BDNF is active on all three neurotransmitter systems and NT4 on glutamatergic and GABAergic terminals. Putting this informa-

tion together with data on the expression of trk receptors in the visual cortex and with data on retrograde transport of cortically injected NGF (Domenici et al., 1994), it can be concluded that NGF is likely to act directly on cholinergic afferents from the basal forebrain and on a population of glutamatergic cortical neurons and, indirectly, by modulation of the cholinergic function, on cortical inhibitory interneurons (Xiang et al., 1998); BDNF targets are cortical pyramidal cells (glutamatergic), inhibitory interneurons, cholinergic afferents, and serotonergic afferents; NT4 acts on thalamic afferents (glutamatergic), probably pyramidal neurons, and certainly inhibitory interneurons. The likely action of NT4 on thalamic afferents could explain its effectiveness in preventing monocular deprivation effects without disturbing visual cortical neuron electrical activity. The same ability could be conferred on NGF by its combined action on a neuromodulatory system such as the cholinergic system (which also provides indirect control of some interneuronal populations) and on a selected population of glutamatergic cortical neurons. BDNF emerges as the neurotrophin with the largest spectrum of targets and the strongest effectiveness on cortical neurons, both pyramidal and interneurons.

BDNF overexpression accelerates the functional development of the visual cortex

The experiments on the role of neurotrophins in modulating synaptic release show that BDNF has a strong effect in potentiating GABA release which is not shared by NGF. These results show that neurotrophins (in particular BDNF and NT4) also act on the inhibitory circuitry. trkB is present on cortical interneurons, and BDNF regulates the development of at least one class of inhibitory interneurons.

The relationship between neurotrophins and the development of inhibitory processes has been investigated, using an elegant transgenic mouse with postnatal overexpression of BDNF in the forebrain (Huang et al., 1999), as shown in Figure 4.7*A,B*. In these animals, the levels of BDNF expression typical of adult age is reached in the second postnatal week (Fig. 4.7*B*). This precocious expression of BDNF is accompanied by a precocious development of inhibitory synapses (Fig. 4.7*C*, GAD staining) and of inhibitory currents (Fig. 4.7*C*, insert).

This accelerated development of inhibition is paralleled by changes in the functional development of the visual system: there is precocious development of visual acuity with respect to the wild type and precocious closure of the critical period, possibly accompanied by precocious opening. Figure 4.8 clearly illustrates that in BDNF mice there is a shift toward younger ages of the curve describing the developmental time course of visual acuity and of the curve describing the decline of monocular deprivation effective-

Neurotrophins potentiate neurotransmitter release in the visual cortex

FIGURE 4.6. *Top:* Sketch of the experiment. *Left:* A synaptosome containing synaptic vesicles filled with neurotransmitter and presenting receptors for neurotrophins is subjected to depolarizing stimuli (high K⁺ concentrations); this causes release of transmitter (molecules outside the synaptosome). *Right:* A synaptosome subjected to depolarization is also exposed to neurotrophins. Neurotrophins activate their receptors, and the ensuing transduction

signals cause an increased release of neurotransmitter. *Bottom:* NGF and BDNF effects on K⁺-induced release of neurotransmitter from synaptosomes isolated from P23 rat visual cortices. Each point represents the mean \pm SEM of five to seven experiments run in triplicate. The small increase in GABA release is not statistically significant. (Adapted from Sala et al., 1998.)

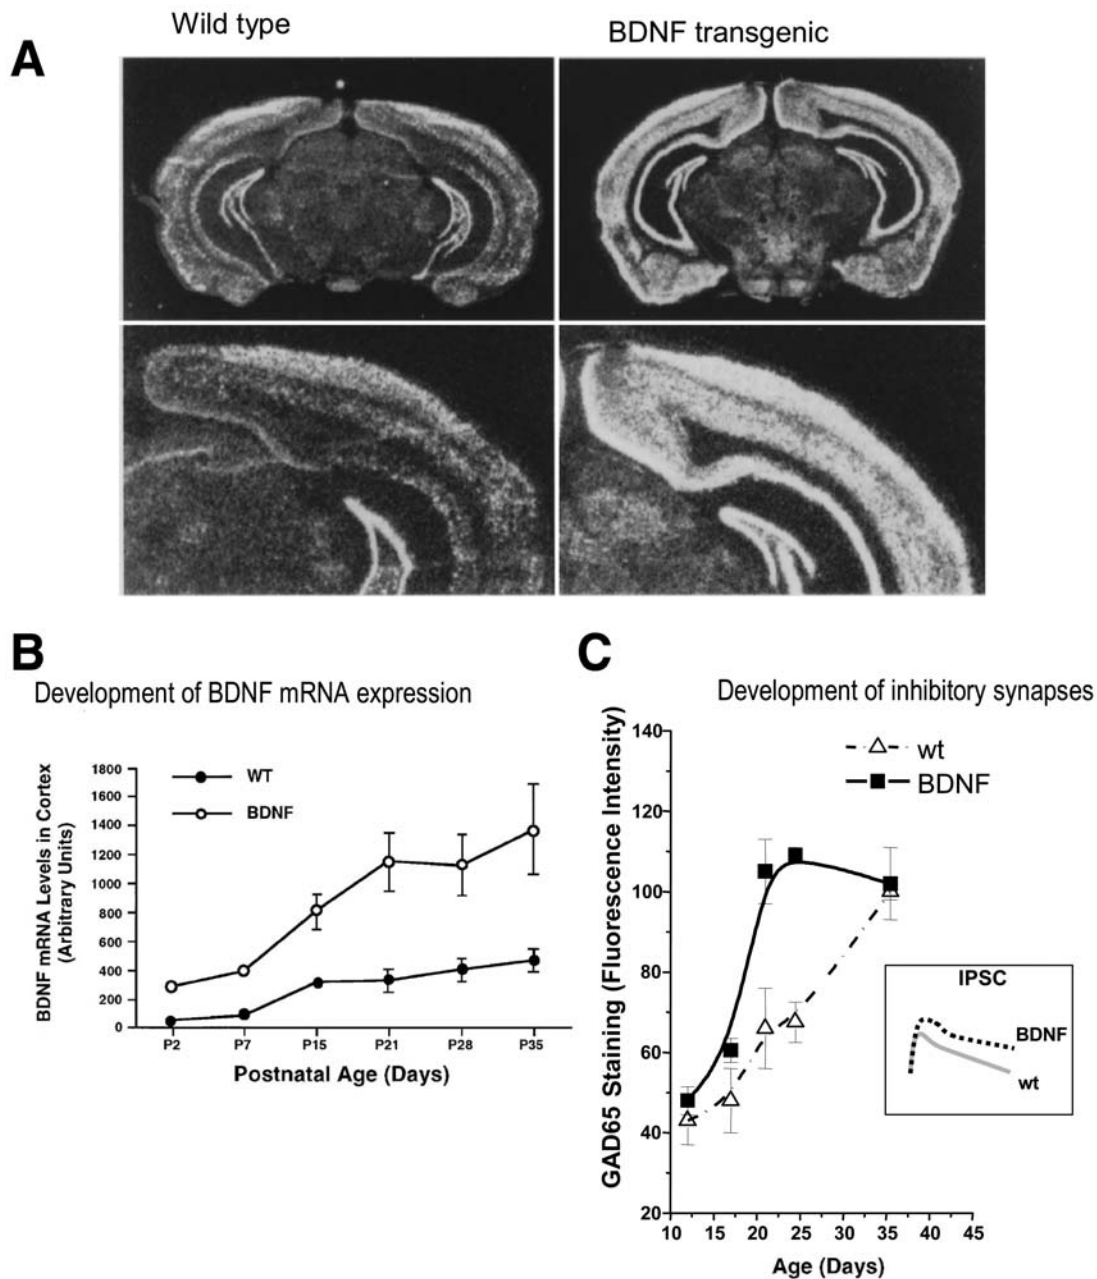

FIGURE 4.7. Precocious expression of BDNF in the telencephalon causes accelerated development of inhibition in the visual cortex. *A*, Spatial expression of the BDNF transgene revealed by in situ hybridization. Coronal brain sections from 4-week-old transgenic (*right*) and wild-type mice (*left*) hybridized with a BDNF oligonucleotide probe that detects both the endogenous and transgenic BDNF mRNA. Expression is restricted to the telencephalon. *B*, Quantification of total BDNF mRNA levels in the cerebral cortex at different developmental ages (data from Northern blotting experiments) for wild-type and transgenic mice. It is evident that the levels of expression normally reached after the third postnatal week

in wild-type mice are reached at P7 in BDNF mice. *C*, Development of GAD65, the synthetic enzyme for the inhibitory neurotransmitter GABA, in the visual cortex of wild-type and transgenic mice. Quantification of GAD65 expression in the presynaptic boutons of GABAergic interneurons was done around the soma of the target neurons. In BDNF mice there is accelerated maturation of GABAergic synapses. In the insert, examples of maximal inhibitory postsynaptic currents (IPSCs) recorded at P23–P26 from visual cortical slices of wild-type and transgenic mice. IPSCs are larger in transgenic mice. (Adapted from Huang et al., 1999.)

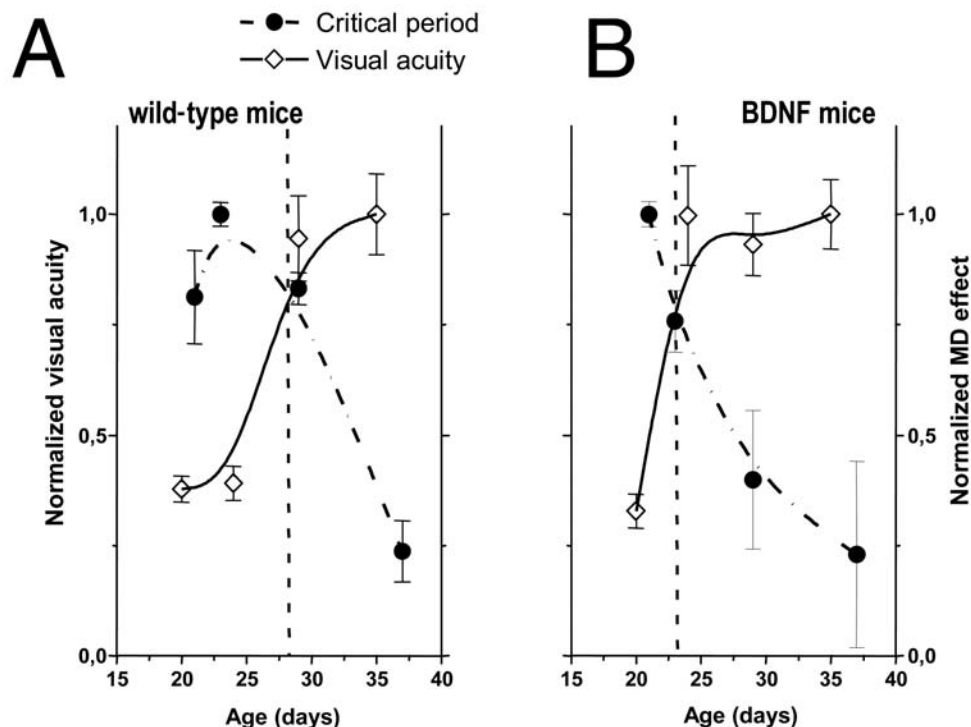

FIGURE 4.8. Critical periods for monocular deprivation and development of visual acuity are reported for wild-type mice, *A* and transgenic mice with precocious expression of BDNF, *B*. For BDNF mice, both the critical period (*dotted line*) and the visual acuity (*solid*

line) curves are shifted to the left (see crossing points, *dashed lines*). This indicates that precocious expression of BDNF induces both accelerated development of visual function and an early closure of critical period.

ness during the critical period. This reinforces the close link between the time course for visual acuity development and the time course of the critical period discussed in the Introduction.

The data presented in Figures 4.7 and 4.8 suggest the following considerations, which are relevant for the studies on development of neocortex:

1. Transgenic animals can be extremely useful in studies on development of visual function.
2. Modulation of a single molecule, in this case BDNF, can have dramatic consequences for the development of visual processes and the duration of the critical period. The observation that in the presence of normal visual experience overexpression of BDNF causes precocious development of vision can be considered the mirror finding to that obtained with blockage of endogenous neurotrophins: in that case, normal visual experience was unable to drive development, suggesting that neurotrophins are crucial effectors through which visual experience drives development of visual function. In BDNF-overexpressing mice, as in dark-reared animals with an increased supply of neurotrophins, neurotrophins seem to “substitute” for experience in driving development.

3. There is a new player on the stage of visual development, namely, inhibition. That inhibition is important for plasticity was previously suggested by experiments showing

that monocular deprivation is less effective in mice with reduced inhibitory transmission (GAD65 knockout mice) (Hensch et al., 1998). The data on the BDNF mouse, with precocious closure of the critical period and normal monocular deprivation effectiveness, clearly indicate that development of inhibition is important for the time course of the critical period. This point is further strengthened by the elegant experiment of Fagiolini and Hensch (2000) showing that precocious enhancement of inhibitory tone accelerates the opening of the critical period.

4. It seems that both NGF and BDNF are important in determining the timing of the critical period and of visual cortical development, pointing toward a more complex role for neurotrophins: they do not seem to be only retrograde, activity-dependent rewards for active thalamic afferents, but also important determinants of development for populations of cortical neurons.

Experience and neurotrophins: intracellular mechanisms

Several intracellular mechanisms are likely to be important in mediating the action of electrical activity and neurotrophins on structural and functional plasticity. Amongst these we have chosen to illustrate the involvement of a particular cascade, the ERK 1,2, also called p42/p44 MAPK.

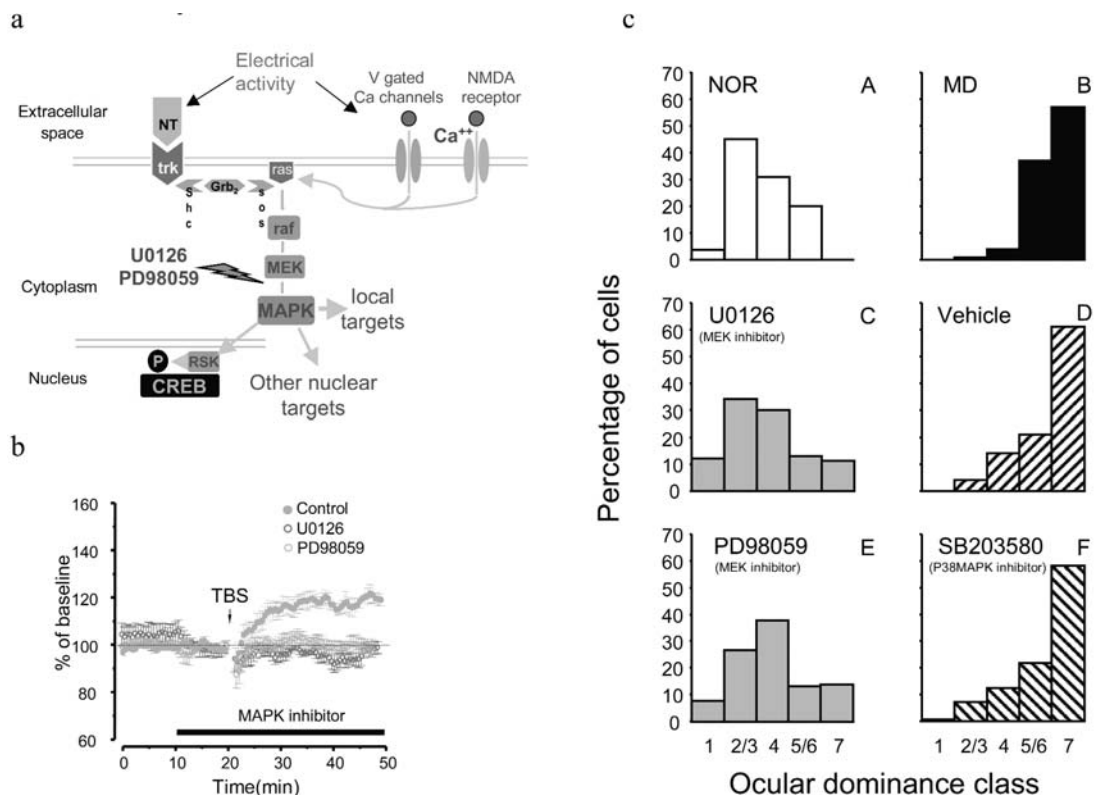

FIGURE 4.9. MAPK activation is required for visual cortical plasticity. *A*, Pathways of MAPK activation. MAPK is activated both by neurotrophins (NT) binding to their trk receptors via the transduction cascade of *ras* and by the influx of calcium through voltage-gated (V-gated) calcium channels and through glutamate NMDA receptors, also acting on *ras*. Electrical activity can therefore activate MAPK via two different converging pathways, and MAPK is a crucial converging point for the integrated action of electrical activity and neurotrophins. Activated MAPK can both act on local targets (synaptic proteins, adhesion molecules) and translocate to the nucleus, where, via kinases such as RSK, it can activate CREB, a transcription factor crucial for many plasticity phenomena. Other pathways impinging on MAPK are omitted for simplicity. The site of action of the two MAPK blockers employed in the experiment is indicated by the arrow. *B*, MAPK inhibitors

U0126 and PD98059 block LTP induction visual cortical slices. Average time course of layer III field potential amplitude before and after TBS of the white matter in the presence of U0126, PD98059, or vehicle. Field potentials recorded in layer III can be potentiated by TBS in control slices but not in U0126- and PD98059-treated slices. *C*, Blockage of MAPK activation prevents experience-dependent plasticity in the visual cortex. Ocular dominance distributions for normal P28 animals (NOR) and for animals monocularly deprived from P21 to P28, either untreated (MD) or treated with U0126, vehicle, PD98059, or SB203580 (an inhibitor of a kinases of the same family as MAPK). It is evident that blockage of MAPK activation by U0126 or PD98059 prevents the ocular dominance shift produced by monocular deprivation; the effect is specific for MAPK blockage, since inhibition of the related p38 kinase is ineffective. (Adapted from Di Cristo et al., 2001.)

The MAPK cascade has been involved in phenomena of synaptic plasticity and learning and memory from *Aplysia* to mammals (see Grewal et al., 1999, for review), but the characteristic which attracted our attention is that this biochemical cascade is sensitive to both electrical activity and neurotrophins, thus being a crucial converging point for the integrated action of the two. In the visual cortex, evidence that neurotrophins activate MAPK has been obtained only recently (Pizzorusso et al., 2000). The authors also show that MAPK activation is crucial for BDNF-induced cAMP response element binding protein (CREB) phosphorylation, which is likely to be an important step in BDNF action on synaptic plasticity.

In Figure 4.9A the principal pathways of MAPK activation are shown. It is clear from the figure that MAPK is a

hub linking neurotrophins and electrical activity with both cytoplasmatic and nuclear targets, an ideal position for a candidate player in visual cortical plasticity.

Recently, it has been shown that MAPK is important for experience-dependent plasticity in the visual cortex (Di Cristo et al., 2001). MAPK activation has been blocked with two specific inhibitors. The arrow in Figure 4.9A indicates the exact point of the transduction cascade where the block is performed (the molecule immediately upstream of MAPK, MEK).

Two approaches have been used, one in vivo, employing the paradigm of monocular deprivation, to investigate experience-dependent plasticity and one in vitro, using the paradigm of long-term potentiation (LTP) to investigate synaptic plasticity.

Patterned electrical stimulation (theta burst stimulation, TBS) of the white matter, which readily triggers LTP of field potentials recorded in layers II–III, rapidly triggers MAPK activation. Blockage of MAPK activation abolishes induction of LTP in the visual cortex (Fig. 4.9*B*). The link between MAPK activation and synaptic plasticity in the visual cortex is further confirmed by the observation that abolishing the ability of TBS to trigger LTP with an *N*-methyl-D-aspartate (NMDA) receptor antagonist also inhibits the ability of TBS to activate MAPK (Di Cristo et al., 2001).

In vivo, it has been found that visual experience rapidly triggers MAPK activation. In turn, MAPK activation is crucial for experience-dependent plasticity: the ocular dominance shift induced by monocular deprivation is prevented by both MAPK blockers employed U0126 and PD98050 (Fig. 4.9*C*). It is important to note that blockage of MAPK activation prevents experience-dependent plasticity without affecting the development of the visual cortex. Visual acuity, receptive fields, and orientation selectivity were normal in PD98050- and U0126-treated animals (Di Cristo et al., 2001).

The conclusion is that MAPK, acting on both local and nuclear targets, promotes strengthening of synaptic transmission under the control of electrical activity and neurotrophins. Thus, the effects of neurotrophins in preventing the ocular dominance shift induced by monocular deprivation could be attributed to activation of MAPK, which promotes stabilization of synaptic contacts even for the fibers driven by the deprived eye possessing only spontaneous electrical activity.

Conclusions

The results reported in this chapter show that visual experience and neurotrophins cooperate in guiding the development of vision. The actions of neurotrophins and electrical activity are linked in a functional chain which is often reciprocal: activity affects neurotrophin production and uptake, neurotrophins regulate synaptic transmission and may affect electrical activity in visual cortical neurons; visual experience is not sufficient to drive visual cortical development if endogenous neurotrophin action is antagonized, and exogenous neurotrophins become ineffective if electrical activity is blocked. At the other end, neurotrophins seem to be able to promote visual development even in the absence of visual experience, as suggested by the experiments with dark-reared animals.

The neurotrophins active in visual cortical development and plasticity—BDNF, NT4, and NGF—seem to play their roles by acting on different targets: each neurotrophin has its particular subset of targets among the intracortical neurons and the cortical afferents. Some targets are direct, as with the inhibitory circuitry and the neurotrophins BDNF and NT4; some are indirect, in that the action of the neurotrophin is mediated by a neuromodulatory system, such as the cholinergic system. The possible sites of action of neurotrophins in visual cortical plasticity are sketched in Figure 4.10. It is evident that neurotrophin action is not limited to thalamic afferents but involves both cortical circuitry and subcortical afferents.

FIGURE 4.10. Possible sites of action of neurotrophins on visual cortical plasticity. Synergistic and antagonistic effects of neurotrophins, however clearly possible, are not included in the model. Even so, it is clear that several neural circuits are involved. Some targets of neurotrophin action could be common, such as the basal

forebrain cholinergic neurons or the intracortical excitatory circuitry. Some could be specific targets for specific neurotrophins; for instance, NT4 seems to be most effective on thalamic afferents, and BDNF/NT4 seem to be specifically active on inhibitory intracortical circuitry.

Up to 10 years ago, neurotrophins were known for their involvement in survival, differentiation, and maintenance of specific classes of neurons in the PNS. Now the scenario has completely changed, and their involvement is at least equally prominent in the CNS. In the CNS, however, neurotrophins are not survival factors for neurons, but rather survival factors for neural connections. In the developing CNS, neurotrophins are essential for the formation, maintenance, and plasticity of synaptic contacts and are crucial for the development of sensory functions. In adult life, they are likely to be still at work in the control of cortical plasticity, and modifications of their activity could be responsible for the slow decline of cognitive functions with age.

5 Developmental and Genetic Control of Cell Number in the Retina

ROBERT W. WILLIAMS AND SALLY A. MOODY

Now, nearly a century after Weismann, it is self-evident that the missing chapters of the Modern Synthesis—the merging of genetics with development and the merging of development with evolution—remain the major tasks before us. Buss (1987)

Introduction

The retina is one of the most highly conserved parts of the central nervous system (CNS), with unambiguous homology of major cell types among most chordates. These cells and their progenitors therefore share common patterns of gene activity. This widespread commonality is illustrated most dramatically by the *Pax6* genes—a small family of transcription factors that trigger the formation of retinas, ommatidia, and photoreceptors in animals as diverse as fruit flies, squid, ascidians, fish, frogs, mice, and humans (Gehring and Ikeo, 1999; Onuma et al., 2002).

Retinas differ strikingly, however, in terms of the number and distribution of cells. Structural diversity of the vertebrate retina is generated using a relatively constant palette of cell types (Walls, 1942). Downstream effects mediated by transcription factors such as *Pax6*, and a rapidly expanding list of trophins, hormones, cytokines, and other signaling molecules, can produce significant changes in the number and ratio of cells and their interconnections. Evolution of the retina has therefore involved the episodic modulation of developmental processes that often adjust quantities, not quality.

The contrast between universal mechanisms and structural diversity highlights the need to study development using complementary approaches. The first approach focuses on fundamental qualitative features that are common denominators; the second approach focuses on quantitative adaptations of genetic networks that underlie functional and evolutionary transformations, as well as individual differences. This review is divided into sections that consider developmental, genetic, and functional factors that modulate the types and numbers of cells in the vertebrate retina from these two complementary viewpoints.

There are approximately 65 to 70 distinct cell types in the retina (Marc and Jones, 2002; Chapter 20, Retinal Neurotransmitters), each with its own idiosyncratic developmental history, and we only consider key themes and a few exem-

plar cell types. In Part 1, we cover the initial stages of visual system development, in which cell proliferation and differentiation produce the cellular substrates common to all vertebrate retinas. Most of our examples are drawn from studies of the South African clawed frog, *Xenopus laevis*, a long-favored experimental subject for developmental analyses. In Part 2, we consider the relation between cell number and visual system performance, addressing the question of how much variation is tolerated within species and why. Finally, we describe a novel approach called *complex trait analysis* that is being used to uncover the genetic basis of individual differences in retinal development. Combined developmental and genetic approaches should eventually provide a much better understanding of how evolutionary modifications have produced such amazing arrays of almost perfectly adapted eyes and retinas, a subject that gave Darwin serious pause (and a cold chill) a century and a half ago (Darwin, 1899; Dawkins, 1996).

PART 1: THE GENERATION OF A MENAGERIE OF RETINAL CELLS

A wide variety of retinal cell types are generated in appropriate numbers by sequential and cooperative changes in patterns of gene expression that are coupled with cell division, cell differentiation, and cell death. These changes start at very early stages, even before gastrulation and the establishment of the neural plate, and changes continue through to late stages of fetal development. Differentiation and cell division are directed by factors that act at different spatial scales and stages, but both ultimately affect the activity of enhancer and promoter response elements in single cells. Broadly speaking, these factors include (1) inherited maternal determinants, (2) regional molecular gradients, (3) cell autonomous lineage factors, and (4) local intercellular signals. In this section we consider some of the key mechanisms involved in selecting the embryonic progenitors of the retina, partitioning part of the forebrain neuroectoderm into a field of specified retinal stem cells, and the progressive differentiation of the many cell types common to all vertebrate retinas that are eventually derived from these stem cells.

Molecular complexity of the retina

The adult retina expresses at least 25,000 transcripts from over 20,000 genes (Sharon et al., 2002). Even more genes are likely to be expressed throughout development. The majority of these genes undoubtedly have common roles in cellular differentiation and metabolism, but a significant fraction—including many so-called housekeeping genes—are likely to contribute to unique features of retinal development and function. This is demonstrated clearly by the fact that over 10% of 12,422 transcripts quantified in triplicate using microarrays (Affymetrics U74Av2) differ more than twofold in abundance between retina and other brain regions such as cerebellum, brainstem, and forebrain (see the databases at www.nervenet.org/array). Even with modest numbers of samples, the expression levels of well over 20% of retinal transcripts differ significantly from forebrain transcripts using standard statistical criteria at the $p < 0.05$ level.

Given the imposing molecular complexity of development of the eye and retina, the reliability of the process is astonishing. The robust molecular systems that ensure the production of a functional retina clearly are built on a principle of genetic redundancy and feedback interactions. While a few genes are essential for eye development (e.g., *Pax6*), most genetic processes are sensitive to context and can adapt to significant perturbations. The inactivation of important genes is often associated with only mild ocular and retinal effects. For example, the loss of the retinoic acid alpha receptor early in retinal development has essentially no effect on the inner retina despite early and intense expression among the pool of progenitors (Mori et al., 2001; Zhou et al., 2001). A process that is controlled by a complex developmental network involving genetic and epigenetic interactions is likely to produce greater variance and flexibility, and is also likely to be more resistant to environmental perturbations (Waddington and Robertson, 1966). As presented below, flexibility is built into the retinal developmental program from beginning (progenitor competence) to end (cell type specification).

The first step: selecting competent retinal progenitors

Retinal development can be divided into several steps, some of which occur even before overt morphogenesis of the eye cup (Fig. 5.1). First, a subset of the pluripotent embryonic cells acquires the competence to contribute to the retina. From this competent pool, a smaller subset is biased to become the retina-forming cells. Later, a specified retinal stem cell population emerges from the descendants of the biased embryonic cells to form the eye field in the anterior neural plate. Further interactions during neural tube morphogenesis segregate this population into three major com-

FIGURE 5.1. Early steps of retinogenesis. Retinal development begins with several steps that set aside embryonic precursors. First, a subset of embryonic cells (green) becomes competent to contribute to the retina. The blue-hatched cell is inhibited from forming retina. Next, a smaller subset (yellow) is biased to become the retina-forming cells. Then a specified retinal stem cell population (red) emerges from the descendants of the biased embryonic cells (yellow) to form the eye field in the anterior neural plate (green). Finally, during neural tube morphogenesis, this specified population is segregated into three major compartments: neural retina (red), pigmented retina (black), and optic stalk (blue). (See color plate 1.)

partments: neural retina, pigmented retina, and optic stalk. Each of these compartments goes on to produce different subsets of specialized cells with distinct functions in the mature eye.

An initial question is, how and when during development do pluripotent embryonic cells acquire the differential competence to contribute to the retina? Is this a partly stochastic process, or do early factors bias or restrict the selection of retina-forming embryonic progenitors? *Xenopus* embryos have been crucial for studying the roles of maternal determinants, lineage effects, and cell-cell inductions at this early stage (even before gastrulation) because eggs and blastomeres are large and easily manipulated (Moody, 1999). Each retina in *Xenopus* descends from a stereotypic subset of 9 animal blastomeres at the 32-cell stage (Fig. 5.2), and each of these blastomeres produces characteristic proportions of the cells that make up the mature retina (Huang and Moody, 1993). Are these nine cells the only cells that are competent to form the retina, and just how fixed is their commitment to a retinal fate?

These questions have been largely answered by transplanting single cells to novel positions at a very early stage when only maternally inherited transcripts are expressed. The first key finding is that even at this stage, not all blastomeres are equally competent to contribute to the retina. For example, vegetal blastomeres transplanted to the most retinogenic coordinates never contribute progeny to the retina (Huang and Moody, 1993). This developmental restriction could not be overcome by providing components of the known maternal signaling pathways involved in neural and dorsal fate specification (see below), even in situations in which ectopic heads and eyes were induced successfully (Moore and Moody, 1999).

FIGURE 5.2. Retina competent and biased blastomeres in *Xenopus laevis* embryos. *Left*: animal pole view of a 32-cell embryo showing the major (orange) and minor (yellow) blastomeres that contribute to the retina. The numbers within each cell indicate the percentage of retinal cells that derive on average from each blastomere. *Right*: side view of a 32-cell embryo showing the retina-forming blastomeres (yellow), the blastomeres that do not make retina but are competent to do so (green), and the vegetal blastomeres that are inhibited by maternal factors from making retina (blue). Data are from Huang and Moody (1993). An, animal pole; D, dorsal; V, ventral; Veg, vegetal pole. (See color plate 2.)

These results indicate that vegetal blastomeres contain one or more maternal molecules that repress the transcription of genes that are critical in the initial steps of retinal differentiation.

Other blastomeres are not so refractive. Both ventral animal blastomeres and equatorial blastomeres that normally do not contribute progeny to the retina can reprogram when transplanted to the center of the retinogenic zone (Huang and Moody, 1993). Furthermore, if the most retinogenic blastomere is deleted, a ventral implant will be respecified in response to interactions with neighboring cells to help produce a normal-sized retina (Huang and Moody, 1993).

Complementing these findings, the retina-forming blastomeres are biased but not completely committed. When transplanted to a ventral vegetal site that normally produces gut and tail, they retain their neural fate but fail to make retina (Gallagher et al., 1991). Collectively, these embryonic manipulations demonstrate that the correct cellular coordinates within the animal hemisphere are necessary from the earliest stage for a blastomere to produce its normal cohort of mature retinal cells.

The position-specific selection of retina-forming blastomeres from the competent pool appears to be mediated by the local signaling environment within the blastula. The ectopic expression of components of several growth factor pathways involved in embryo patterning, such as activin, fibroblast growth factor (FGF), and bone morphogenetic protein (BMP), demonstrates that competent blastomeres acquire the ability to express a retinal fate by being located in an environment in which BMP signaling is repressed (Moore and Moody, 1999). Expression of BMP4 in a

blastomere that normally is a major contributor to the retina inhibits its retinal fate, whereas repressing BMP signaling in a blastomere that normally gives rise to epidermis induces retinal cells within that lineage. Consistent with this model in frog, *Bmp7* null mice are anophthalmic (Dudley et al., 1995) and rat embryos cultured in anti-BMP7 antibodies have reduced or absent eyes (Solorsh et al., 1996). The inhibition of BMP signaling in the dorsal part of the embryo defines the domain of presumptive retina, just as it defines the domain of presumptive neural plate (Harland, 2000).

Although fate maps show that there are nine retina-forming blastomeres in *Xenopus* (Fig. 5.2), not every one of these cells contributes to retina in every embryo. In the initial map (Moody, 1987), the major progenitors contributed to retina 85–100% of the time, whereas the minor progenitors contributed only 20–50% of the time. Thus, there is surprising individual variation in the number of embryonic cells that produce the retinal lineage. There also is individual variation in the number of retinal cells descended from each retina-forming blastomere (Huang and Moody, 1993). For the major progenitor, there is a 2-fold range in descendants between embryos, but for the others there is as much as a 10-fold range. These data have been verified in many subsequent studies using similar techniques. They demonstrate that the ultimate numbers of progeny produced by each lineage are not predetermined and that individual variation is well tolerated within consistent limits. This is apparently just as true in mammals as in *Xenopus* (Goldowitz et al., 1996; Williams and Goldowitz, 1992a).

The second step: specifying stem cells

The next step in retinogenesis is to select from the competent pool those cells that will become specified as retinal stem cells (Fig. 5.1). After the neural plate is established, it is subdivided into fields that give rise to different CNS domains. Both retinas arise from a common anterior midline group of cells called the *eye field*, which is specified as the sole source of retinal cells when the neural plate is established (Perron and Harris, 1999; Saha and Grainger, 1992).

A number of transcription factors regulate pattern formation in the anterior neural plate and eye field, and they are crucial in determining whether neuroepithelial cells express a retinal fate as opposed to another anterior neural fate. *Otx2*, a vertebrate homolog of the *Drosophila orthodenticle* gene, has at least two potential functions in the formation of the eye field. Early *Otx2* expression in the anterior endoderm appears necessary for the induction of the anterior neural plate (Acampora et al., 1995; Ang et al., 1996; Rhinn et al., 1998), and its continued expression is required to initiate or maintain the expression of several other key neurogenic factors (Rhinn et al., 1998), leading to the

regionalization of the neural plate that allows the eye field to form. *Bf1*, a fork head/winged helix transcription factor, is expressed in the forebrain and in the future nasal retina (Hatini et al., 1994; Tao and Lai, 1992). The *Xenopus* homolog *Fkh4* is expressed in the anterior margin of the neural plate and then in the eye field (Dirksen and Jamrich, 1995). *Pax6*, the potent paired box and homeodomain transcription factor mentioned in the Introduction, is highly expressed in the eye field, and its ectopic expression causes the formation of ectopic eye structures in fly and frog (Altmann et al., 1997; Chow et al., 1999; Halder et al., 1995; Kenyon et al., 2001). *Rx1*, a novel homeobox gene, is expressed exclusively in the eye field, retina, and pineal gland (Casarosa et al., 1997; Furukawa et al., 1997; Mathers et al., 1997). Its overexpression in *Xenopus* causes enlargement of native eye tissue and ectopic patches of pigmented retina (Kenyon et al., 2001; Mathers et al., 1997). *Six3*, related to the *Drosophila sine oculis* gene, is expressed in the eye field and optic vesicle (Oliver et al., 1995). Overexpression of mouse *Six3* in fish or mouse causes ectopic retinal tissues to form (Lagutin et al., 2001; Loosli et al., 1999). Another *six* family gene, *Otx2*, is also expressed in the eye field and optic vesicle (Toy et al., 1998), and when *Otx2* is overexpressed, it transforms more caudal neural plate into eye field (Bernier et al., 2000). Loss-of-function mutations of *Bf1*, *Otx2*, *Pax6*, and *Rx1* each lead to loss of retinal tissue, indicating that all are likely to have important roles during establishment of the eye field.

The segregation of the anterior neural plate into eye field versus non-eye field domains is likely to result from the localized expression of several transcription factors, including those described above, which then initiate eye-specific transcriptional programs. In addition, some of these genes are involved in even earlier retinal fate decisions. *Otx2*, *Pax6*, and *Rx1* are expressed more widely and diffusely at stages just before the formation of the eye field, and they can cause ventral epidermal-forming blastomeres to contribute to retina by altering gastrulation movements that allow their descendants access to the eye field (Kenyon et al., 2001). Thus, these genes appear to regulate the selection of retinal stem cells at multiple levels: transcriptional modulation, signaling, and cell movements.

This complex program of selecting retina-specific stem cells provides several opportunities for adjustments in cell number. From the pregastrula competent pool of cells, only a subset forms the eye field. Expressing the correct genetic program increases the probability of competent cells being selected to become retinal stem cells. For example, in the experiments of Kenyon et al. (2001), not every cell that ectopically expressed the exogenously supplied retinal gene expressed a retinal fate. Some cells migrated into the eye field and others did not. Some of the ventrally derived retinal clones were composed of hundreds of cells, and some were composed of fewer than ten cells. These data indicate that

there are local cues that also influence these fate decisions. Subtle epigenetic variations in these cues have significant effects on final retinal cell numbers by altering the size of the initial stem cell pool.

The third step: specification of different cell types

After the compartmental domains of the future eye are defined during neural plate and neural tube stages, cells within the optic cup begin to differentiate into the many different cell types that characterize the functional vertebrate retina. They exit the cell cycle in a defined spatiotemporal pattern, migrate to appropriate layers, turn on the correct neurotransmitters or visual pigments, and develop the correct pre- and postsynaptic connections. The ganglion cells project long axons to very distinct targets, whereas intrinsic cells make highly specialized connections locally. Intricate choreography! A large number of factors and interactions affect the diversity and number of distinct retinal cell types that are generated during this period of retinogenesis (reviewed in Cepko, 1999; Harris, 1997; Livesey and Cepko, 2001; Vetter and Brown, 2001; Vetter and Moore, 2001).

ROLES OF ENVIRONMENTAL AND LINEAGE IN CELL FATE The optic cup was one of the first vertebrate tissues in which the issue of lineage regulation of cell phenotype specification was addressed. Vertebrate embryos, with their enormous numbers of cells, are difficult subjects for complete lineage studies because it is not technically feasible to map every mitotic division. Nonetheless, parts of retinal lineages have been defined by intracellular injection of tracers into proliferating cells of the optic vesicle/cup (Holt et al., 1988; Wetts and Fraser, 1988) or by injecting a recombinant retrovirus that infects proliferating cells and marks their clones (Turner and Cepko, 1987; Turner et al., 1990). Both techniques showed that dividing cells of the optic vesicle/cup are multipotent; labeled clones spanned the entire thickness of the retina and were composed of various combinations of cells. They also retain striking pluripotency right up to their last division, often producing daughters consisting of two very different cell types—for example, Müller glial cells and bipolar cells (Turner and Cepko, 1987). The great majority of retinal stem cells are not committed to produce only a single phenotype, nor do they appear to be restricted to an identifiable invariant combination of cell types.

With the exception of retinal astrocytes, which originate from separate progenitors in the optic stalk (Chang-Ling and Stone, 1991), it was initially thought that lineage restriction plays little if any role in determining types or numbers of retinal cells. However, the amazing diversity in the cellular composition and size of clones labeled at very early stages (Williams and Goldowitz, 1992a) suggested the presence of

matched heterogeneity among retinal progenitors, which implies some form of differential commitment of the progenitors (Goldowitz et al., 1996; Williams and Goldowitz, 1992b). The original lineage tracing techniques could not label single identified progenitors across different animals—a criterion by which lineage mechanisms are usually identified—and this left the original data open to alternative interpretations.

MULTIPLE RETINAL STEM CELL TYPES We now know that the eye field stem cells are a heterogeneous population (Dyer and Cepko, 2001; Moody et al., 2000). There are at least two kinds of cells, those that produce radial clones and those that produce layer-restricted clones. In *Xenopus* these two progenitors differ in the layer distribution of their constituents, their cellular complexity, and the number of cell divisions remaining in their respective lineages. These two different eye field stem cell types may represent either two different determinative states or separate lineages for the early-formed primary (layered) versus later-formed secondary (radial) retina, similar to what has been described for neural plate progenitors of primary and secondary spinal neurons (Hartenstein, 1989). Two kinds of clones (single cells and radial columns) also have been described in the early chick and mouse retina (Fekete et al., 1994; Reese et al., 1999). Cellular diversity in type and number could easily be generated by changes in the processes that separate the original stem cell pool into different subsets of progenitors that have different ultimate fates. This could result in correlated shifts in populations that participate in common visual function—a primary example being scotopic and photopic subsystems.

Although lineage studies show that progenitor cells in the optic vesicle and cup are multipotent, recent *in vitro* studies also suggest that this pool contains differentially biased precursors (Alexiades and Cepko, 1997; Bellevue and Cepko, 1999; Jensen and Raff, 1997; Marrow et al., 1998). In fact, the concept that retinal lineages are not homogeneously multipotent but are differentially biased was elegantly demonstrated by a statistical analysis (Williams and Goldowitz, 1992b) of published data (Turner et al., 1990); the frequency of clones containing only two cell types was much higher than expected, and the frequency of clones extending across all layers was much lower than expected. Furthermore, *in vitro* studies showed that some rat optic cup progenitors are biased to produce amacrine and horizontal cells (Alexiades and Cepko, 1997). Other progenitors appear biased to produce either rod or bipolar cells (Marrow et al., 1999).

One model put forward to reconcile the strong evidence of extrinsic control of retinal cell differentiation and the strong evidence of fate-biased determination acting via committed progenitors is simply that retinal progenitors pass

through a series of determinative states, each of which is intrinsically specified to respond to particular environmental cues that influence the cell types produced (Cepko, 1999). For example, embryonic retinal progenitor cells differ in many characteristics from neonatal ones (Alexiades and Cepko, 1997; Lillien and Cepko, 1992; Marrow et al., 1998; Waid and McLoon, 1995; Watanabe and Raff, 1990), and these states can be influenced by the presence of other cell populations (Austin et al., 1995; Bellevue and Cepko, 1999; Reh, 1992; Reh and Tully, 1986; Waid and McLoon, 1998) and cytokines (Harris, 1997). An important aspect of this process is a cell-autonomous “clock” that regulates the competence of progenitors (Rapaport et al., 2001). Subtle changes in the timing of the determinative states and/or progenitor competence could be significant contributors to individual variation in cell numbers and types.

LINEAGE BIAS OF SOME AMACRINE SUBTYPES One approach used to eliminate the problem of labeling progenitors at random was to map the origins of specific cell types from the “identified” retina-forming blastomeres of the 32-cell frog embryo (Fig. 5.2). When specific progeny within retinal clones were identified by neurotransmitter expression, certain subtypes of amacrine cells—dopamine (DA), neuropeptide Y (NPY), and serotonin (5-hydroxytryptamine, 5-HT) were observed to arise from different subsets of blastomeres, whereas others (GABA, glycine) did not (Huang and Moody, 1995, 1997). This novel information likely was revealed because blastomeres can be consistently identified, unlike single progenitors in the optic cup, and each subtype of cell may follow its own subprogram of developmental instructions that would not be obvious from studying the broad population. This proposed lineage bias of DA, NPY, and 5-HT amacrine cell specification could result from the asymmetric distribution of intrinsic (i.e., maternal) factors that autonomously influence the different amacrine fates, or from inductive signaling related to the position in which the blastomere descendants differentiate. To test whether amacrine fate is intrinsically biased, blastomeres with distinct amacrine fates were transplanted to a position that normally expresses a different amacrine fate (Moody et al., 2000). A lateral animal blastomere expressed its normal, large number of DA amacrine cells after it was transplanted into a position that normally produces few of these cells, suggesting an intrinsic bias in amacrine fate within this lineage. However, another blastomere changed amacrine fate in accord with its new position. These experiments illustrate that the retina-producing blastomeres are already a mosaic of intrinsically biased and positionally specified progenitors.

At later stages of development, there also is evidence for lineage bias in the specification of amacrine cell subtypes.

When DA, NPY, and 5-HT amacrine cell subtypes first differentiate, they are arranged as single cells scattered across the inner nuclear layer (Huang and Moody, 1995, 1997). As more cells differentiate, the first cells are joined by like-expressing cells to form small clusters (Huang and Moody, 1995, 1997). If amacrine cell clusters are induced to express the same neurotransmitter by local interactions with their peers, then clusters should form even in the absence of cell division and after the emergence of the first amacrine cell. This is true of 5-HT clusters (Moody et al., 2000). In sharp contrast, DA and NPY clusters are virtually eliminated by blocking mitosis, indicating that cells in these clusters are generated by continued asymmetrical divisions of a strongly biased lineage. An important point is that even within a single cell class, specification of subtypes can be modulated by surprisingly different processes and at different stages of development.

LOCAL INTERCELLULAR SIGNALS Local signaling in the developing retina is critical in the progressive changes in retinal progenitors and in the subsequent differentiation of many cell types (Adler and Hatlee, 1989; Gan et al., 1996, 1999; Harris, 1997; Reh, 1992; Repka and Adler, 1992). A growing number of secreted factors have effects on cellular differentiation, usually as assayed in tissue culture and explants. Ciliary neurotrophic factor (CNTF) (Ezzeddine et al., 1997; Fuhrmann et al., 1995; Kirsch et al., 1996), brain-derived neurotrophic factor (BDNF) (Rickman and Rickman, 1996), (GDNF) (Politi et al., 2001), (TGF α) (Lillien, 1995), retinoic acid and thyroid hormone (Kelley et al., 1994, 1995), *sonic hedgehog* (Shh) (Levine et al., 1997), FGFs (Hyer et al., 1998; McFarlane et al., 1998; Opas and Dziak, 1994; Pittack et al., 1991, 1997), and BMPs (Belecky-Adams and Adler, 2001) all appear to have important roles in discriminating among different retinal class fates, in some cases also shifting relative numbers of early- and late-generated cell types. Activin signaling, for example, decreases the number of photoreceptors and increases the number of nonphotoreceptor cells present in low-density retinal cultures in a dose-dependent manner (Davis et al., 2000). Retinoic acid can do the opposite (Kelley et al., 1994). Chick ganglion cells express BMP receptors, and retinal explants exposed to BMPs contain enhanced numbers of ganglion cells (Carri et al., 1998). FGF2 has been reported to either stimulate (Hicks and Courtois, 1992) or suppress (Perron and Harris, 1999) photoreceptor numbers. There is convincing evidence that in the intact embryo, FGF2 may not alter photoreceptor number per se but may affect the ratio of rods to cones (Patel and McFarlane, 2000). Increased FGF2 signaling also reduces the number of Müller glial cells and increases the number of retinal ganglion cells (Patel and McFarlane, 2000). These examples highlight the fact that signaling factors have diverse effects on cell fate specifica-

tion. Local signaling can profoundly influence the cell types generated in culture.

RETINAL TRANSCRIPTIONAL CASCADES A large number of transcriptional regulators are involved in retinal cell fate decisions. Several of the same genes that establish the eye field also are expressed in distinct patterns in the developing retina (Perron and Harris, 1999). *Otx2*, *Pax6*, *Rx1*, and *Six3* are expressed by the stem cells at the margins of the retina, and it has been proposed that their collective expression maintains a retinal identity in these cells (Perron et al., 1998). *Otx2* has been implicated in transforming pigmented retina into neural retina (Toy et al., 1998). Many of these genes also are implicated in regulating the proliferation of the optic vesicle and cup progenitor cells (Loosli et al., 2001; Martinez-Morales et al., 2001). For example, retinoblasts transfected with *Otx2* produce clones that are twofold larger than control clones, and its overexpression early in embryogenesis results in giant eyes (Zuber et al., 1999).

Furthermore, eye field genes are expressed differentially as retinal cells differentiate (Perron and Harris, 1999). Ganglion and amacrine cells express *Pax6* and *Six3*; cells in the outer zone of the inner nuclear layer express *Six3*, *Rx1*, and *Otx2*; and photoreceptor cells express *Rx1*. Added to this complexity is the differential expression of a large number of basic helix-loop-helix (bHLH) differentiation factors (Perron and Harris, 1999; Vetter and Brown, 2001). Different combinations of these latter genes are expressed as cells transit from the purely stem cell zone at the margin, through more restricted progenitor zones, and finally into their retinal layers. Photoreceptors require *NeuroD* and *Ngn2*; bipolar cells require *Ash1*, *Ash3*, and *Ngn2*; amacrine cells require *NeuroD* and *Ath3*; and ganglion cells require *Ath5*. There is compelling evidence that *Pax6* directly regulates several of the bHLH genes (Marquardt et al., 2001) and that *Pax6*, *Six3*, and *Rx1* modulate a cell's responsiveness to the bHLH genes (Inoue et al., 2002).

Many of these genes also cross-regulate each other: when a gene manipulation eliminates one cell class, other classes are significantly enlarged. This indicates that the transcriptional program that specifies one cell type is interrelated with programs that specify other cell types, forming transcriptional webs. This suggests that individual and evolutionary changes in the expression of single genes, the main topic of the next section, will frequently have pleiotropic effects that lead to coordinate changes in several cell types.

PART 2: FUNCTIONAL AND GENETIC ANALYSIS OF INDIVIDUAL DIFFERENCES

The types and numbers of cells that are generated and distributed across the retina represent an explicit, although still incompletely deciphered, summary of a species' relationship

with its visual world (Hayes and Brooke, 1990; Østerberg, 1935; Walls, 1942). These cellular parameters can be modified relatively rapidly in response to changes in selective pressure (Jeffery and Martasian, 1998; Jeffery et al., 2000; Williams et al., 1993). Variation is by no means limited to retina, and there are even more striking quantitative differences in the size and structure of the complex quilt of visual areas that extend from occipital pole into temporal and parietal neocortex of mammals (Chapter 32, Organization of Visual Areas in Macaque and Human Cerebral Cortex; Chapter 105, the Evolution of the Visual System in Primates).

In this part, we first consider the functional relevance of variation in numbers of neurons and photoreceptors and review what we are beginning to learn about the genetic basis of individual differences within species. As illustrated by a few specific examples as the end of this part, variation in retinal structure traces back to specific allelic differences that affect developmental processes.

Functional perspective on cell population size

NEED FOR LARGE NUMBERS An enormous number of cells and synapses are needed to generate and interpret multiple neural representations of the visual world. The advantage of having large numbers of cells is most obvious in the vertebrate fovea (e.g., Collin and Collin, 1999; Wikler et al., 1990). Cones are often packed together in a tight triangular mosaic with peak densities that reach up to 300,000/mm² in humans (Curcio et al., 1987, 1990). Trios of photoreceptors, midretinal bipolar cells, and retinal ganglion cells are organized with nearly pixel-like precision to recapture and transmit the high spatial frequencies into the central visual system. Several remarkable developmental events help to generate large numbers of these cells in central retina (Hendrickson, 1994; LaVail et al., 1991; Lia et al., 1987; Provis et al., 1998; Springer, 1999), the most surprising being a shift of cones toward fovea from surrounding retina late in retinal development (Packer et al., 1990).

The need for large numbers cascades through the dorsal lateral geniculate nucleus (LGN) to the primary visual cortex. Ratios of retinal ganglion cells and projection neurons in the LGN are close to 1:1 in both rhesus monkeys and humans (Spear et al., 1996; Williams and Rakic, 1988). Cell densities are about 25% higher in the posterior region that represents fovea (Ahmad and Spear, 1993). The numbers increase 300- to 400-fold in visual cortex. An average of 350 million neurons are packed into area 17 of both macaques and humans (Suner and Rakic, 1996; Tolhurst and Ling, 1988). Cell densities may be twice as high as those in other neocortical areas (Powell and Hendrickson, 1981; Rockel et al., 1980). A staggering 2–3 trillion synapses are involved in the first stage cortical analysis of the visual world (Colonnier and O’Kusky, 1981; O’Kusky and Colonnier,

1982). Further amplifying these numbers, area 17 devotes disproportionate computational resources to the foveal representation. The central 1 mm² of both retinas contains a total of about 150,000 cones that view the central 12 square degrees of visual space. These receptors feed signals bilaterally to 400–500 mm² of visual cortex that contains approximately 50 million neurons and 150 billion synapses (estimate computed for both hemispheres by combining data in O’Kusky and Colonnier, 1982; Tolhurst and Ling, 1988; and van Essen et al., 1984).

FUNCTIONAL CORRELATE A behavioral corollary of high numbers in fovea and the visual cortex is extremely high acuity, that is, an ability to resolve spatial frequencies of 60–100 cycles per degree (Banks et al., 1991). Even more remarkable, humans can detect misalignments of short line segments finer than the grain of the photoreceptor mosaic. Detection thresholds can be as low as 10 arc-seconds. This computational feat, referred to as *vernier hyperacuity* (Kumar and Glaser, 1993; Westheimer, 1981), depends in part on maintaining high spatiotemporal precision across large numbers of coactivated neurons (Kandil and Fahle, 2001).

NUMBERS AND NEURAL NOISE Impressive visual capabilities of this type depend on minimizing noise at all levels of the retinogeniculocortical system. Noise is suppressed roughly as a function of the square root of n , where n is numbers of active neurons, synapses, and synaptic vesicle fusion events (Sterling, 1998). Small gains in signal-to-noise ratios may appreciably improve fitness due to increased acuity, and this in turn may have fueled steep evolutionary increases in numbers of cells in several vertebrate lineages. For example, the prominent expansion of the peristriate visual cortex in hominids may have been driven both by the complexity of simultaneously processing multiple streams of visual information (Dacey, 2000) and by selective pressure to improve the signal-to-noise ratios of cortical circuits.

EVEN LOW-LIGHT VISION REQUIRES LARGE NUMBERS OF CELLS Vision in low light also demands high numbers of cells, but for reasons other than visual acuity. A wide belt of the retina that usually surrounds the fovea at 10–15 degrees of eccentricity has rod densities that can rise to 500,000–850,000 cells/mm² in primates (Dkhissi-Benyahya et al., 2001; Wikler and Rakic, 1990), cats (Williams et al., 1993), and mice (Jeon et al., 1998). Even in the far periphery of humans, rod density is still typically above 40,000 cells/mm² (Williams, 1991).

An explanation for the high density and small size of rods is that they must be able to convert the absorption of a single photon into a distinct reduction in the transmitter release (Rodieck, 1998). This requires an exceedingly slender rod

outer segment in which a single photon will generate a sufficient reduction in cGMP concentration to shut cation channels. The high impedance of rods converts small fluctuations in outer segment currents into corresponding voltage fluctuations at the synaptic terminal. The great majority of the outer surface of the retina is tiled by rod outer segments to ensure efficient capture of the few photons available under low light. Their signals are averaged and integrated by AII amacrine cells, and these cells appear to define the acuity limit under low-light conditions (Mills and Massey, 1999), much as ganglion cell densities define the acuity limit in daylight.

Because of the inherent noise of the sporadic arrival of photons and receptor noise generated by spontaneous isomerization of rhodopsin and Poisson variance in vesicle release, detecting and interpreting objects in the dark is a challenging computational task. The consequence of these particular environmental and photochemical characteristics is that the population of rods in the human retina is incredibly high—typically ranging from 100 to 150 million (Curcio et al., 1990). Even a mouse retina has approximately 6 million rods. Having very large photoreceptor populations ensures high acuity (cones) in daylight or higher sensitivity and lowered noise levels (rods) in the dark.

CELL FUNCTION AND CELL NUMBERS The functional relationship between cell number and visual system performance is not always as clear-cut as suggested by these examples. There are approximately 60 cell types in the retina and certainly just as many or more in the central part of the visual system, each of which, by definition, makes somewhat different contributions to vision. Some cells, such as horizontal cells and the population of photosensitive retinal ganglion cells that project to hypothalamic circadian pacemaker cells, have computational roles that can best be summarized as averaging mean illuminance (Hattar et al., 2002). In the case of horizontal cells, this averaged signal provides a negative feedback to photoreceptors. Losing all horizontal cells has severe consequences, reducing retinal transduction efficiency and increasing the latency of visual evoked potentials in the cortex (Peachey et al., 1997). However, the crucial biometric parameter in this case is not numbers of channels but uniform field coverage. Small numbers of cells with extensive dendritic and axonal arbors may provide equivalent or even superior feedback compared to larger numbers of cells with smaller fields. Cells with this sort of role will have a number:performance function that is relatively flat or even negative when their numbers exceed the optimum.

EVOLUTIONARY FLEXIBILITY OF NUMBERS Given these considerations, populations of neurons in evolving species will ratchet up or down in numbers at somewhat idiosyncratic

rates that depend on their functional contributions to visual performance. For example, populations of rods are higher in domestic cats than in ancestral wildcats (Williams et al., 1993), and populations of retinal ganglion cells are lower in domestic cats and dogs than in wildcats and wolves (Peichl, 1992; Williams et al., 1993); in addition, both domestic species are likely to have lower acuity than their wild peers. Numbers of neurons will reach asymptotes at which further changes are blunted by countervailing selective pressure, such as the metabolic load associated with increased population size (Franco et al., 2000).

The final cell number is a compromise between the marginal utility of adding yet more cells and the metabolic costs that these extra neurons inevitably incur. An interesting consequence of reaching a functional asymptote is that cell populations within a species will typically be maintained at levels around which significant numerical deviation is surprisingly well tolerated by individual animals (see the list below). Near the asymptote, the relation between number and function is nearly flat, and visual system performance will be robust even in the face of surprisingly large deviations in numbers and ratios of cells that may be introduced by rare alleles and mutations, population admixture, developmental noise, environmental perturbation, or disease.

VARIATION WITHIN SPECIES AND GENOTYPE Ranges of normal variation in absolute numbers of cells and in ratios of cells within a species are often large. There is usually no obvious functional effect. The estimates of variation that are listed below come from small samples, and these examples therefore are likely to underestimate the actual range of variation. In most cases, the examples illustrate variation among individuals.

1. Foveal cone densities vary at least threefold among humans without retinal disease (Curcio et al., 1990; $n = 8$).
2. Ratios of L and M cones (red and green) in human central retina can range from 1:1 to 3.8:1 without evident (or with only subtle) differences in the categorization of colors (Roorda and Williams, 1999; $n = 2$).
3. Even within a single retina, the ratio of rods and cones can vary twofold. In one case, adjacent large fields in the periphery of a normal human retina had rod:cone ratios of 1:2 and 2:1 (Williams, 1991).
4. Twofold differences in horizontal cell number and density are common among normal inbred strains of mice (Williams et al., 1998a). A single strain of inbred mouse does not provide a good index of a typical ratio of cell types (see Williams et al., 1998b). For example, the ratio of ganglion cells to horizontal cells in mice varies from 3.2:1 to 6.7:1.
5. The population of retinal ganglion cells—the information bottleneck of the entire visual system—varies from 1,000,000 to 1,600,000 in humans and macaques (Provis et

al., 1985; Rakic and Riley, 1983; Spear et al., 1996). This population varies from 45,000 to 75,000 among strains of mice (Williams et al., 1996).

6. The population of projection neurons in the dorso-lateral geniculate varies as much as twofold within cat, mouse, and macaque (Ahmad and Spear, 1993; Williams and Rakic, 1988; $n < 10$ in cat and macaque; $n = 100$ in mouse). For example, in mouse, the population of projection neurons varies from 12,000 in CE/J to 22,000 in AKR/J (Kulkarni et al., 2000).

7. The surface area and cell population of primary visual cortex in both humans and macaques vary two- or even threefold (Gillisen and Zilles, 1996; Leuba and Kraftsik, 1994; Suner and Rakic, 1996; van Essen et al., 1984; $n \leq 20$).

8. Ocular dominance column numbers along the vertical meridian range from 101 to 154 in macaques. The width of columns ranges from 400 to nearly 700 μm (Horton and Hocking, 1996; $n = 12$ hemispheres).

THE PARADOX OF HIGH VARIATION The magnitude of this variation may be puzzling, particularly in species that are highly dependent on vision. Stabilizing selection, a process that normally trims away the tails of a distribution of phenotypes, would normally limit the range of variation that is tolerated in an interbreeding population. But the examples above provide ample demonstration that wide variation is well tolerated even in species, such as macaques and humans, that are utterly dependent on vision. The apparent paradox is resolved if we come back to the point that the visual system is overengineered and that there is much functional and developmental redundancy built into the retinas of most individuals. This also means that directional selection has plenty of variation with which to work on an evolutionary scale. Selection is highly effective in changing the cellular demographics of the retina and other parts of the visual system. Rapid changes in cell number have occurred in at least two carnivore lineages—wolves and wildcats—over an interval of less than 20,000 years (Peichl, 1992; Williams et al., 1993). In cats, the population of retinal ganglion cells has eroded from about 240,000 in wildcats to 160,000 in domestic cats. Even more extreme changes have been uncovered in response to rapid changes in habitat—for example, isolation in lightless cave systems in which the eyes regress due to the accumulation of deleterious mutations in genes critical at several stages of eye development (Jeffery and Martasian, 1998).

Genetic basis of individual difference in retinal structure

GENETIC POLYMORPHISM WITHIN SPECIES The striking differences in the retinal architecture of the mouse and the

human arose from natural genetic variation generated and selected within single species. Roughly one-fifth of the genes in most species have functional polymorphisms that produce changes in the electrophoretic mobility of the corresponding proteins. This reservoir of genetic variation often translates into correspondingly high heritability estimates for quantitative retinal traits (Williams, 2000; Zhou and Williams, 1999). For example, variation in retinal ganglion cell number in mice has a heritability above 80% (Williams et al., 1996), demonstrating strong genetic modulation of this population under typical laboratory conditions. The goal of a new field of genetics called *complex trait analysis* is to convert these bland estimates of heritability into the much more interesting and informative gene variants. These gene variants or polymorphisms can, in turn, be used to explore the genetic control of retinal development.

MENDELIAN AND QUANTITATIVE GENETICS Mendelian methods of gene analysis, with which most readers will be familiar, assume that single gene variants—usually rare alleles or mutations—generate essentially all interesting differences. For example, mutation of the tyrosinase gene (albinism) causes a 35% reduction in the fraction of retinal ganglion cells with ipsilateral projections in mice, regardless of genetic background (Rice et al., 1995).

In contrast to Mendelian genetics, complex trait analysis begins with the assumption that differences in cell populations are generated by the combined effects of a large number of polymorphic genes scattered across the genome. The goal is to map this set of genes to precisely delimited chromosomal locations and then proceed to identify these genes and the molecular pathways of which they are part. The types of genes that are part of these multigenic systems are known as *quantitative trait loci* (QTLs). Overwhelming technical difficulties prevented QTLs from being mapped in vertebrates even a decade ago. However, with the introduction of efficient polymerase chain reaction (PCR)-based methods to genotype animals and sophisticated statistical programs to discover associations between gene variants and phenotypes, the prospects for QTL mapping are now greatly improved. It is possible to target virtually any heritable quantitative trait for what is called *genetic dissection*. This is particularly the case if one can exploit strains of inbred mice.

USE OF ISOGENIC LINES An inbred strain is essentially an isogenic clone of fully homozygous animals that are able to reproduce sexually. They are a remarkable tool with which it is possible to resample the same genetic individual at different stages and after different treatments. They can also be used to obtain reliable quantitative estimates of traits that have high noise caused either by technical error or by stochastic developmental variation. If two or more inbred lines

differ substantially in a set of retinal traits under a common environment, then the difference traces back to genetic differences between those lines. These characteristics have been exploited to map and characterize novel gene loci that modulate cell populations in the retina.

The population of retinal ganglion cells has been counted in over 1000 mice belonging to 60 isogenic lines. Numbers range from 45,000 in strain CAST/Ei to 75,000 in BXD32 (Williams et al., 1996). While individual values have a normal distribution, when cases are pooled by strain the histogram has a characteristic multimodal structure in which the different modes represent different combinations of genotypes at several QTLs. The most prominent pair of modes is present in neonatal mice before ganglion cells have been eliminated by apoptosis (Strom and Williams, 1998). This indicates that the QTL responsible for these modes, the *Nnc1* locus, has a modulatory effect on the proliferation or differentiation of retinal ganglion cells.

MAPPING NEUROGENIC GENES Crosses between strains with high and low ganglion cell numbers have been used to map *Nnc1* and three other QTLs responsible for much of the variation in ganglion cell number (Strom, 1999; Williams et al., 1998b). The gene mapping method can be distilled to statistical tests of association between differences in cell number and differences in genotype (genotypes are often scored in a numerical format: AA = 1, Aa = 0, aa = -1). For example, the correlation between ganglion cell number and genotypes at *Nnc1* reaches a peak of 0.72 on chromosome (Chr) 11. The other three QTLs that modulate ganglion cell number map to Chr 7 at 65 cM (*Nnc2*, likelihood adds ratio [LOD] score of 5.9), Chr 1 at 82 cM (*Nnc3*, LOD of 9.3), and Chr 16 at 42 cM (*Nnc4*, LOD of 6.0).

Nnc1 has the largest effect, and this QTL maps to a 6 million base pair stretch of DNA on Chr 11 between *Hoxb* and *Krt1*. This region contains two obvious candidate genes—the retinoic acid alpha receptor and the thyroid hormone alpha receptor. The addition of exogenous retinoic acid to tissue cultures increases rod production at the expense of amacrine cells (Kelley et al., 1994). However, knockouts of the retinoic acid receptor have no detectible effect on retinal ganglion number, a surprising result given the high expression of this gene in ganglion cells from very early stages (Zhou et al., 2001). In contrast, inactivation of the thyroid hormone alpha receptor neatly reproduces a 15% predicted difference in cell number. This result suggests that the QTL on Chr 11 corresponds to a polymorphism of the thyroid hormone receptor gene (Strom, 1999), but this idea has not yet been confirmed by sequence comparison. However, the hypothesis is attractive because thyroid hormone has long been known to control retinal ganglion cell proliferation during *Xenopus* metamorphosis—the stage in this species' development when a population of ipsilater-

ally projecting ganglion cells is first generated (Hoskins, 1985). The thyroid receptor is a transcription factor that often pairs with a retinoid X receptor to control gene expression. It may not be coincidental that the QTL on Chr 1 that modulates ganglion cell number overlaps the position of the *Rxrg* gene (Strom, 1999).

Conclusion

It is already apparent that many developmental processes are intertwined in such a way as to maintain general conformity in retinal structure and cellular content while still permitting substantial latitude for individual variation. A growing number of molecules and processes are now known to affect the diversity and number of retinal cell types generated in multiple steps during retinogenesis (Cepko, 1999; Harris, 1997; Livesey and Cepko, 2001; Vetter and Brown, 2001; Vetter and Moore, 2001). Experimental tests to sort out their relative contributions also demonstrate that there are numerous stages at which the final numbers and relative proportions of the different retinal phenotypes can be changed. Understanding this process of differentiation at a quantitative level will require an analysis of the transcriptome and proteome of the lineages of the major cell types, and an understanding of the processes that occur during the very early embryonic stages to bias and then select the retinal stem cells. Although we are still far from being able to navigate through the molecular labyrinths that generate different retinal cell types in appropriate numbers, the pace of research is now so rapid that it is hard not to be optimistic.

6 Development of the Vertebrate Retina

RACHEL O. L. WONG AND LEANNE GODINHO

Introduction

The neural retina, the light-sensitive part of the eye, converts light into electrical signals that are relayed to visual centers in the brain. The retina is part of the central nervous system (CNS), originating from the neural ectoderm during development. In vertebrates, the retina begins as an apparently homogeneous collection of cells in a single-layered neuroepithelium. With maturation, however, it develops into a laminated tissue with seven major cell classes, each of which occupies characteristic positions within the retina. The structural and functional development of the retina has long been studied because of its importance in vision, and because its highly organized structure is ideally suited for studying cell fate, differentiation, and patterning of synaptic networks in the nervous system.

Generation of cellular components

CELL GENESIS Like other regions of the CNS, the retina is derived from the neural tube (Pei and Rhodin, 1970). Each eye begins as an outgrowth on either side of the neural tube. These outgrowths, called *optic vesicles*, invaginate to form a double-layered, cup-shaped structure. The thin outer wall becomes the pigment epithelium, while the inner wall develops into the neural retina. At this stage, the neural retina is a single-layered, pseudostratified epithelium. An extended period of cell proliferation begins to furnish the structure that will become multilayered.

Cell proliferation in the retinal neuroepithelium occurs in a manner peculiar to the CNS. With their cytoplasmic processes extending from the pigment epithelial end to the internal limiting membrane, the nuclei of individual progenitor cells engage in a back-and-forth movement, undergoing different phases of the cell cycle at specific depths within the retinal neuroepithelium (Sidman, 1961; Young, 1985a). This nuclear movement, termed *interkinetic migration*, was first observed in the developing chick neural tube (Sauer, 1935). In the retina, mitosis (M-phase) occurs at the outermost surface, near the pigment epithelium. Each daughter cell resulting from a mitotic division extends a process toward the opposing vitreal surface while maintaining contact with the ventricular side. The daughter nuclei then enter G₁, a resting phase, while migrating within their cytoplasmic pro-

jections toward the vitreal surface. At their destination, nuclei replicate their DNA (S-phase) and subsequently enter the G₂ resting phase on their inward journey to the ventricular surface. Upon arriving, cells retract their cytoplasmic processes from the opposing end and remain poised for the next mitotic division (Robinson, 1991; Sidman, 1961; Young, 1985a). The resulting daughter cells then either reenter the cell cycle or leave it to become postmitotic neuroblasts.

Cohorts of progenitors leave the cell cycle throughout the period of retinal development to differentiate into one of seven cell classes (Carter-Dawson and LaVail, 1979; Sidman, 1961; Young, 1985a, 1985b). The developmental time point at which this occurs for a particular cell type can be referred to as its *birth date*. The “birth dates” of each of the seven retinal cell classes have been deduced by exposing retinal cells to ³H-thymidine at known time points during development and examining the identity of the most heavily labeled nuclei in the mature retina (Carter-Dawson and LaVail, 1979; Sidman, 1961; Young, 1985a, 1985b). Each retinal cell type has a characteristic period during which its entire population is generated. However, there is considerable temporal overlap between the generation periods of most cell classes. Across species, retinal neuroblasts destined to become ganglion cells are the first to become postmitotic. Amacrine, horizontal, and cone photoreceptor cells are generated next; bipolar and Müller glial cells then follow. There is still some debate as to whether an early and transient population of Müller glial cells is generated during the period when ganglion and amacrine cells are born (Robinson, 1991). Rod photoreceptors are generated almost throughout the entire period of cytogenesis in the retina (Carter-Dawson and LaVail, 1979; Sidman, 1961; Young, 1985a, 1985b). Figure 6.1 summarizes the temporal order of appearance and placement of the cell types in the retina.

In addition to the sequential addition of cells across the depth of the retina, cytogenesis also proceeds in a strict centropерipheral sequence. The first postmitotic retinal cells are found in a region (see the section “Cell Distribution”) close to the optic nerve head. Cell genesis occurs last, near the ora serrata (Carter-Dawson and LaVail, 1979; Sidman, 1961; Young, 1985a, 1985b). In many species, the centropерipheral sequence of cell genesis holds true for every retinal cell type.

FIGURE 6.1. Basic structure and temporal order of cell differentiation of the vertebrate retina. *A*, The neural retina begins as a sheet of neuroepithelial cells (NBL, neuroblastic layer) with processes that contact the internal (ILM) and external (ELM) limiting membranes. *B*, Ganglion cells are the first cell type to differentiate and migrate toward the ILM to form the ganglion cell layer (GCL). *C*, Amacrine cells and horizontal cells differentiate next. Cone photoreceptors are born at this stage but do not differentiate until later. The first network of connections, between amacrine cells and ganglion cells, is established as a continuous inner plexiform layer (IPL)

forms across the retina. *D*, In the inner nuclear layer (INL), bipolar cells and Müller glial cells are generated and differentiate. At this stage, both cone and rod photoreceptors comprising the outer nuclear layer (ONL) begin to mature, bearing few outer segments or discs. The outer plexiform layer (OPL) emerges, and connections between photoreceptors, horizontal cells, and bipolar cells are formed. Cell genesis (mainly rods) continues at this stage but to a greatly reduced degree. *E*, At maturity, all cell types are present, connections in both plexiform layers are established, and photoreceptor outer segments are well developed.

CELL FATE Cell fate determination in the vertebrate retina is complex. Separate progenitors, each exclusively dedicated to the production of a single retinal cell type, do not exist. Instead, progenitor cells in the retina are regarded as multipotent (Holt et al., 1988; Turner and Cepko, 1987; Turner et al., 1990; Wetts and Fraser, 1988), that is, they are capable of producing more than one retinal cell class. How they adopt distinct fates during development has therefore been an area of intense research. The findings of numerous studies have resulted in a proposed model of retinal development in which cues both intrinsic and extrinsic to progenitors contribute to the determination of the cell fate (Cepko et al., 1996; Livesey and Cepko, 2001; Marquardt and Gruss, 2002).

In this model, progenitor cells are believed to move sequentially through a series of stages, during which they are capable of producing only a limited repertoire of cell types (Cepko et al., 1996). For example, progenitor cells taken from chick retina at an early age when ganglion cells are exclusively produced continue to produce this cell type alone even when transplanted into a later retinal environment when signals conducive to a rod cell fate are present (Austin

et al., 1995). This limited competence of progenitor cells to produce only a small number of cell types at any given stage is thought to result from their genetic makeup. Progenitor cells destined for ganglion cell fates have been shown to express transcription factors such as Brain-3 (Brn-3) and retina-derived POU-domain factor-1 (RPF-1) (reviewed in Harris, 1997). Subsets of progenitors in the rat retina that express markers of mature amacrine and horizontal cells (syntaxin 1a and VC1.1) are biased toward producing these cell types (Alexiades and Cepko, 1997). Thus, the progenitor cell population is a heterogeneous one that is biased toward producing different cell fates. It is on this heterogeneous population of progenitors that extrinsic signals exert their influence.

Extrinsic signals that have been implied in cell fate determination include neurotrophic factors such as nerve growth factor (NGF) and ciliary neurotrophic factor (CNTF), as well as other factors such as transforming growth factor α and β (TGF- α and - β), insulin-like growth factor (IGF), retinoic acid, thyroid hormone, and the amino acid taurine (reviewed in Harris, 1997). A direct role in cell fate determination is more evident for some factors such as CNTF (promotes

bipolar cell fates) and retinoic acid and taurine [rod photoreceptor cell fate (Altshuler et al., 1993)], while for others it remains unclear whether they are also involved in neurogenesis, differentiation, and cell survival. Of course, extrinsic signals that promote a particular cell fate are only positively received by cells competent to respond to them.

Environmental signals could also act to suppress cell fates. Postmitotic neurons might be the source of such factors providing feedback to progenitors to cease the production of a particular cell type. This has been shown for ganglion cells; a still unidentified diffusible factor produced by ganglion cells limits the further production of this cell type (Waid and McLoon, 1998). While diffusible factors are a means of signaling between retinal cells during cell fate determination, communication also occurs by contact-mediated lateral inhibition. The receptor Notch and its ligand Delta have been shown to play a role in controlling cell fate. All cells start off with equal amounts of Notch and Delta. Activation of Notch blocks differentiation of the cell, at the same time leading to a reduction in its Delta levels. Expression of an activated form of Notch in progenitor cells from *Xenopus* and rat essentially inhibited cell differentiation and caused cells to remain in a progenitor-like state (Bao and Cepko, 1997; Dorsky et al., 1995). Conversely, when antisense oligonucleotides were used to reduce Notch activity in the retina, the number of ganglion cells produced was greatly increased (Austin et al., 1995). By misexpressing Delta in the *Xenopus* retina, Dorsky et al. (1997) demonstrated how the Notch-Delta pathway regulates cellular differentiation in the retina. At early stages of development, cells with high levels of Delta adopt a ganglion cell or cone photoreceptor fate when surrounded by wild-type cells because their neighbors failed to suppress their differentiation. Misexpression at older stages leads to a high proportion of photoreceptor fate. Delta overexpressors, however, failed to differentiate when they were surrounded by cells with similarly high Delta levels. In contrast, reduction of Delta levels by expression of a dominant negative form of Delta resulted in an increase in the percentage of cells with an earlier fate. Thus the Notch-Delta pathway is important for regulating the competence of progenitors to differentiate and respond to signals biasing their choice of fate at each stage of development.

CELL MIGRATION All cells are effectively “born” at the outer surface of the retina, apposed to the pigment epithelium (Sidman, 1961). Postmitotic cells must therefore migrate some distance to occupy positions characteristic of their phenotype within the retina. Unlike the cerebral cortex, another highly laminated structure, cell positioning in the vertical dimension of the retina is not strictly related to cell genesis. Cells born at similar times, for example, horizontal cells and amacrine cells, can end up in different layers.

In the cerebral cortex, postmitotic neuroblasts migrate radially along radial glial fibers from the ventricular zone toward the pia to take up their final positions (Rakic, 1971, 1990). Retinal neuroblasts are also believed to disperse radially from their point of origin. However, whether such radially migrating neuroblasts use glial guides, like their counterparts in the cortex, remains contentious. The presence of a radial glial scaffold in the immature retina was suggested by studies based on electron microscopy and immunohistochemistry with glial-specific antibodies (Meller and Tetzlaff, 1976; Wolburg et al., 1991). However, the positive identification of such glial structures by electron microscopy remains unclear, and glial markers such as vimentin may not be specific to such cells during development (Bennett and DiLullo, 1985; Lemmon and Rieser, 1983).

Perikaryal translocation has been proposed as an alternative mechanism to account for radial migration within the retina (Book and Morest, 1990; Morest, 1970; Snow and Robson, 1994, 1995). This theory suggests that a newly postmitotic cell, located at the scleral surface of the neuroepithelium, extends a process toward the vitreal surface, its nucleus moving to its final destination within this process. The cell maintains an attachment with the scleral side of the neuroepithelium as its nucleus translocates, losing this attachment and that from the vitreal surface only when migration is complete. Evidence in support of perikaryal translocation in the retina originally came from studies of the morphology of retinal neuroblasts by Golgi impregnations (Morest, 1970; Prada et al., 1981). Observations from the retrograde labeling of ganglion cells (Dunlop, 1990; Snow and Robson, 1994, 1995) and immunohistochemical studies using ganglion cell-specific antibodies (McLoon and Barnes, 1989) support this hypothesis. All these studies reported postmitotic cells with a bipolar morphology, attached by processes to both surfaces of the retinal epithelium, and somata located at various depths within the neuroepithelium.

Whatever mechanism is employed, it is now well accepted that newborn retinal cells migrate to their final positions in a radial fashion. When single or small numbers of progenitor cells were marked early in development by the injection of retroviral constructs or fluorescent dyes (Fekete et al., 1994; Turner and Cepko, 1987; Turner et al., 1990), and the distribution of their progeny was examined in the mature retina, they were seen to be distributed radially across the entire depth of the retina in tightly organized columns. Such a cell dispersion pattern was suggestive of the way in which retinal neuroblasts move from their point of origin in the germinal zone. Not all cells move strictly in the radial axis, however. When larger numbers of progenitors were labeled using transgenic (Fig. 6.2; Reese et al., 1995, 1999) or chimeric mice (Williams and Goldowitz, 1992), a small

X-Gal stained section of adult retina

FIGURE 6.2. Schematic depicting the creation of X-inactivation transgenic mosaic retinas. A transgenic mouse line was created in which the *lacZ* transgene was inserted into one of the X-chromosomes (depicted as a blue-colored X). Early in development, all progenitor cells express β -galactosidase, the protein product of the *lacZ* transgene, as both chromosomes are active. In female transgenic mice, through the natural phenomenon of X-inactivation, one of the two X-chromosomes is randomly inactivated. This results in roughly equal numbers of transgene-expressing and -nonexpressing cells. In the adult, only the progeny of transgene-active cells express β -galactosidase. When histochemically detected, these cells appear blue. Alternating radial columns of blue and white can be seen in a section of retina from such a transgenic mouse, indicative of their mode of dispersion. Occasionally however, individual blue cells can be seen tangentially removed from blue radial columns (arrow). ONL, outer plexiform layer; INL, inner nuclear layer; GCL, ganglion cell layer. (L. Godinho and S. S. Tan, unpublished.) (See color plate 3.)

percentage of clonally related cells were found to stray outside the boundaries of the radial columns. Such cells are regarded to have dispersed tangentially from their point of origin in the germinal zone. Importantly, whether a cell dispersed radially or tangentially from its birthplace appears to be linked to its ultimate phenotype. Cells destined for rod photoreceptor, bipolar, and Müller glial cell fates were always found to disperse radially; radial columns are always composed of these cell types. Cells that disperse tangentially include cone photoreceptors and horizontal, amacrine, and ganglion cells (Reese et al., 1995).

CELL DISTRIBUTION At maturity, retinal neurons are often densely packed in a small region, typically referred to as *central retina*, which is actually located temporal to the optic nerve head. In primates this corresponds to the fovea, the center of which is a deep pit-like structure where cone photoreceptor density is at its highest (Chapter 26). Not all animals have a fovea, however; in some species, cell densities peak at a small patch called the *area centralis*. Spatial resolution of the retina is limited by the densities of cone photoreceptors and ganglion cells at the fovea and the area centralis (Rodieck, 1998). As the retina grows, cell density in the peripheral retina declines steeply, but it is reduced by a relatively smaller amount in the central retina (reviewed by Robinson, 1991). In primates, a further step takes place in fovea development, in which ganglion cell bodies become displaced from the center of the fovea with maturation, giving rise to the foveal pit. This lateral movement occurs after synapses have formed on the ganglion cells and may involve active migration of the cell bodies while their connections are “anchored” in place (reviewed by Kirby and Steineke, 1996).

How do retinal cells become differentially distributed? Selective neurogenesis and naturally occurring cell death could contribute to the sharpening of the centropertipheral gradients in cell density. While there is little evidence for selective cell addition across the retina, cell death, particularly in the ganglion cell layer, is common and widespread (Robinson, 1991). In fact, about half the population of ganglion cells dies by maturity. But there is no well-defined spatiotemporal pattern of cell death across the retina, although this process, like other maturation events, follows a centropertipheral gradient. Differential expansion of the retina in which the peripheral region becomes stretched, like the surface of a balloon, has been suggested to be an important mechanism which shapes the density gradients of retinal neurons (Lia et al., 1987; Mastronarde et al., 1984; Robinson, 1991). This is because cell gradients continue to sharpen even after the period of neurogenesis and cell death. No one mechanism, however, appears to account for the final centropertipheral density gradients of each cell type (Robinson, 1991; Wikler and Rakic, 1996). Understanding how each gradient of cell density is determined,

and whether there is coordination in setting up these neuronal gradients, will reflect on how the convergence or divergence of information is established in the retina during development.

Cell differentiation and formation of the plexiform layers

Cell differentiation in the developing retina is clearly reflected by the emergence of the inner and outer plexiform layers. These laminar synaptic regions appear before functional synaptic inputs are formed, as retinal neurons extend neurites toward each other in an apparently coordinated fashion. Here we will discuss what is known about process outgrowth in retinal neurons and what mechanisms might direct and coordinate their morphological differentiation, as well as produce laminar organizations of their connections.

CELL POLARITY AND PROCESS OUTGROWTH The patterns of early neurite outgrowth in the retina have largely been investigated for retinal ganglion cells, mainly because of interest in the organization of their axonal projections to visual targets in the brain. Upon becoming postmitotic, retinal ganglion cells become polarized, generating an axon which is directed toward the vitreal surface and dendrites which project toward the neuroblastic layer (Fig. 6.3). Comparing the morphology of dye-labeled cells at different stages in development suggests that the axon may arise *de novo* from the cell body or is derived from the vitreally directed ventricular process (Hinds and Hinds, 1974; Maslim et al., 1986; Thanos and Mey, 2001). Axon outgrowth begins even prior to the arrival of the cell body to take a position in the forming ganglion cell layer. From static images of cells at different ages, it appears that dendritic outgrowth begins only when the cell body reaches the vitreal surface and when the

process attached to the ventricular surface retracts (Fig. 6.3). Axonal growth cones reach the optic fissure to form the optic nerve, and in some species they arrive at their central targets even before dendrites elaborate within the retina (Thanos and Mey, 2001).

Coculture studies demonstrate that ganglion cell axonal and dendritic growth is directed or promoted by the microenvironment of the inner and outer retina, respectively (Bauch et al., 1998; Stier and Schlosshauer, 1998). Radial glial cells, thought to be Müller glia, influence the outgrowth of axons or dendrites in a highly selective way; their vitreal endfeet provide cues that encourage axon outgrowth, whereas cues from the region of the glial cell body direct dendritic, rather than axonal, outgrowth. The molecular interactions that polarize retinal ganglion cells are not yet fully understood, but some key players have been identified. For example, in the absence of Brn-3b, a POU-domain transcription factor, most retinal ganglion cells fail to extend axons, and instead prefer to generate dendrites (Wang et al., 2000).

Compared to retinal ganglion cells, there is relatively little information concerning differentiation and process outgrowth of other inner retinal neurons. The majority of amacrine interneurons do not have polarized axons and dendrites; this makes these cells interesting candidates for studying how a single neurite can achieve this dual function. Neurite outgrowth from amacrine cells has been studied by serially reconstructing these cells by electron microscopy (Hinds and Hinds, 1983). These studies suggest that amacrine cells may be derived from retinal ganglion cells that have lost their axons, or that they may originate directly from ventricular neuroblasts. However, direct evidence demonstrating how amacrine cells differentiate and extend neurites to form the inner plexiform layer is still lacking. The observations of Hinds and Hinds do suggest that neurite outgrowth from amacrine cells is unlikely to be directed exclusively toward the ganglion cell–amacrine

FIGURE 6.3. Presumed sequence of retinal ganglion cell differentiation. *P*, postmitotic ganglion cell; *ELM* and *ILM*, external and internal limiting membranes, respectively. Ganglion cells are first recognized when their axons appear.

cell border. Instead, it is possible that neurite outgrowth in amacrine cells is initially random or multidirectional, but that in time only processes growing laterally are maintained and elaborate to form the inner plexiform layer (Hinds and Hinds, 1983).

How bipolar cells become polarized has not been investigated, but it is possible that the cues that direct ganglion cell polarization may be involved. The difficulty in following bipolar cell development has been the lack of bipolar cell-specific markers that are needed to identify these cells early in development. The earliest available marker is recoverin, which labels a subset of bipolar cells (Milam et al., 1993). However, recoverin also labels photoreceptors before they differentiate. Markers that distinguish different bipolar cell classes in the mature retina, such as protein kinase C or calbindin, appear relatively late, that is, when bipolar axonal terminals are already stratified in the inner plexiform layer (Miller et al., 1999). In the future, the use of molecular approaches to drive fluorescent protein expression in subsets of bipolar cells will be invaluable once suitable promoters are identified.

In the outer retina, process outgrowth begins even before an outer plexiform layer is apparent (Robinson, 1991). Interestingly, photoreceptor terminals which in the mature retina stratify only within this outer lamina may do so only after retracting processes from the inner plexiform layer. In the ferret, recoverin-immunoreactive rods and cones transiently project an axon to the inner plexiform layer before bipolar cells differentiate and the outer plexiform layer forms (Johnson et al., 1999). The function of this early projection is not known, but if connections are made with inner retinal neurons, these early projections would suggest the presence of a novel circuit in the developing retina. The first indica-

tion of a forming outer plexiform layer is when horizontal cells elaborate processes laterally, demarcating a border between the inner and outer retina. Initially, these cells put out processes in multiple directions, some even reaching the inner plexiform layer (Schnitzer and Rusoff, 1984). Eventually, horizontal cells maintain only processes that elaborate laterally. What signals direct the lateral growth of horizontal cell processes at the relevant position and time remain a mystery.

CELL TYPE-SPECIFIC ARBORIZATIONS Shortly after retinal neurons extend neurites, they undergo a period of extensive process outgrowth. In some cells, a great deal of structural remodeling takes place before the final morphologies are attained. Factors, intrinsic and extrinsic to the cells, that may influence the final patterning of neurites in retinal neurons have largely been studied for the inner retinal neurons, particularly for ganglion cells.

Dendritic development of retinal ganglion cells is complex, requiring each cell to achieve a specific pattern of branching, arbor size, and stratification within the inner plexiform layer. As dendrites emanate from the cell body, a rudimentary tree is formed, which elaborates by branching and process extension (Dunlop, 1990; Maslim et al., 1986). However, dendrites also retract, suggesting that the final spatial arrangement results from selective elaboration and elimination of processes (Fig. 6.4).

A combination of genetic factors, environmental cues, and cell-cell interactions is likely to govern dendritic elaboration and retraction in retinal ganglion cells. Evidence for intrinsic control of dendritic patterning in ganglion cells comes from studies in which neonatal cat ganglion cells, dissociated and cultured without contacting neighboring cells,

FIGURE 6.4. The dendritic arbor of retinal ganglion cells is sculpted by the addition and elimination of processes over time. Shown here is a ganglion cell from an embryonic chick retina labeled after transfection with plasmid encoding green fluorescent

protein. Images obtained 3 hours apart indicate that whereas some processes are stable (*arrowhead*), others are eliminated (*el*), have extended (*ex*), or have retracted (*r*). New processes are also added (*a*). (W. T. Wong and R. O. L. Wong, unpublished.)

regrow dendritic arbors that are diverse in morphology but resemble that of mature cells (Montague and Friedlander, 1989). Whether the neonatal cells reexecute an earlier plan to elaborate specific patterns of dendritic arborizations is unknown, but the observations suggest that patterning of the arbor can emerge in the absence of direct cell-cell contact. Also, cells with distinctive patterns such as large-field alpha-like cells can be found across several species (Peichl, 1991), implying that the basic “dendritic plan” of ganglion cell classes may be specified intrinsically. Of course, whether there is a complement of genes issuing branching instructions to generate “alpha-like” patterns remains unknown, but it is tempting to speculate about such a possibility. Finally, the dendritic terminals of alpha-like cells in the ferret form dendro-dendritic contacts or fascicles early in development only if they are destined to be of the same ON or OFF subtype (Lohmann and Wong, 2001). Together, these observations encourage investigation into the genetic makeup of retinal ganglion cell classes.

There is also substantial support for a role for cell-cell interactions or environmental cues that regulate the final dendritic patterning of retinal ganglion cells. Neurotrophins such as BDNF and NT-4 affect the patterning of retinal ganglion cell dendrites (Lom and Cohen-Cory, 1999); the source of these neurotrophins may be outside or inside the retina. In addition, neighbor relationships influence the size and symmetry of the ganglion cell dendritic arbor. In all species examined, dendritic field size varies inversely with cell density across the retina. This relationship is present before the retina matures (Sernagor et al., 2001). Experimental manipulations to increase or decrease eye size, and thus affect cell density distributions, result in adjustments in dendritic field area (Troilo et al., 1996). A direct relationship between cell density and the patterning of the dendritic arbor is evident from studies in which ganglion cells have been ablated in some regions of the retina (Deplano et al., 1994; Perry and Linden, 1982). Ganglion cells reorient their dendrites toward the lesion zone apparently in an attempt to cover the cell-depleted area. It is still unclear whether such rearrangements are due to a loss of neighboring ganglion cells of the same class or subclass (Ault et al., 1993; Weber et al., 1998). This knowledge will provide more insight into whether cell-cell interactions between specific cell types are needed to maintain, for example, coverage of the retina by a single cell class (see Chapter 29) or whether it is the overall availability of presynaptic terminals that is key to regulating dendritic patterns. What is apparent, however, is that neurotransmission is involved in regulating the dendritic patterning of retinal ganglion cells (Sernagor and Grzywacz, 1996; Wong et al., 2000a, 2000b).

Much less is known about how the many classes of amacrine and bipolar cells achieve their characteristic arborizations. Cholinergic amacrine cells which differentiate

early in development (Galli-Resta et al., 1997) have radially arranged arbors that undergo some structural remodeling with maturation (Wong and Collin, 1989; Fig. 6.5). In contrast, process outgrowth in another amacrine cell with a radiating arbor, the so-called fireworks cell, may be more “deterministic.” The characteristic nonbranching, radiating processes of this type of amacrine cell are evident even during embryonic development (Fig. 6.5). However, studies in the rodent retina suggest that cell-cell interactions are also important for defining the arborization patterns of amacrine cells. Signaling involving neurotrophins (Rickman, 2000) and reelin (Rice et al., 2001) shape the projection patterns of AII amacrine cells.

LAMINATION From a developmental point of view, it is intriguing to find that the retinal layers are generated sequentially, and normally, without error in their order of appearance. For instance, in all species studied, the inner plexiform layer appears before the outer plexiform layer. As noted in the section on “Cell Genesis,” apart from ganglion cells, when a retinal cell type is generated does not necessarily predict where it will ultimately reside. Thus, environmental factors must come into play to organize the layering of the retina in terms of cell body location and where their processes eventually elaborate.

Another intriguing aspect of lamination concerns how the layers become contiguous across the retina. Not only do the major lamination patterns extend across the retina, but for each type of inner retinal neuron, such as amacrine cells, processes of the same kind ramify in one or a few distinct sublaminae, forming a contiguous plexus (or plexuses) across the retinal surface. How does this happen? Zebrafish mutants have provided some insights into how this might occur for both the inner and outer plexiform layers. In *lakritz* mutants, a continuous inner plexiform layer still develops, suggesting that the formation of this synaptic lamina does not require the presence of ganglion cells, which fail to differentiate in this mutant (Kay et al., 2001). In other zebrafish mutants, however, such as *young*, there are no obvious plexiform layers; this may be because of the perturbed final stages of morphological differentiation of retinal neurons (Link et al., 2000). The outer plexiform layer forms in the absence of transmission from photoreceptors, implying that elaboration of processes within this layer does not require this form of cell-cell communication (Allwardt et al., 2001). Although our knowledge of the mechanisms that regulate layering in the retina is still sketchy, it is likely that this situation will change when more lamination mutants and the genes responsible for these mutations are identified.

The actions of multiple well-coordinated mechanisms come to mind when we also realize that within the inner plexiform layer, up to 10 or more functionally distinct sublaminae are established by maturity (see Chapter 18). Of

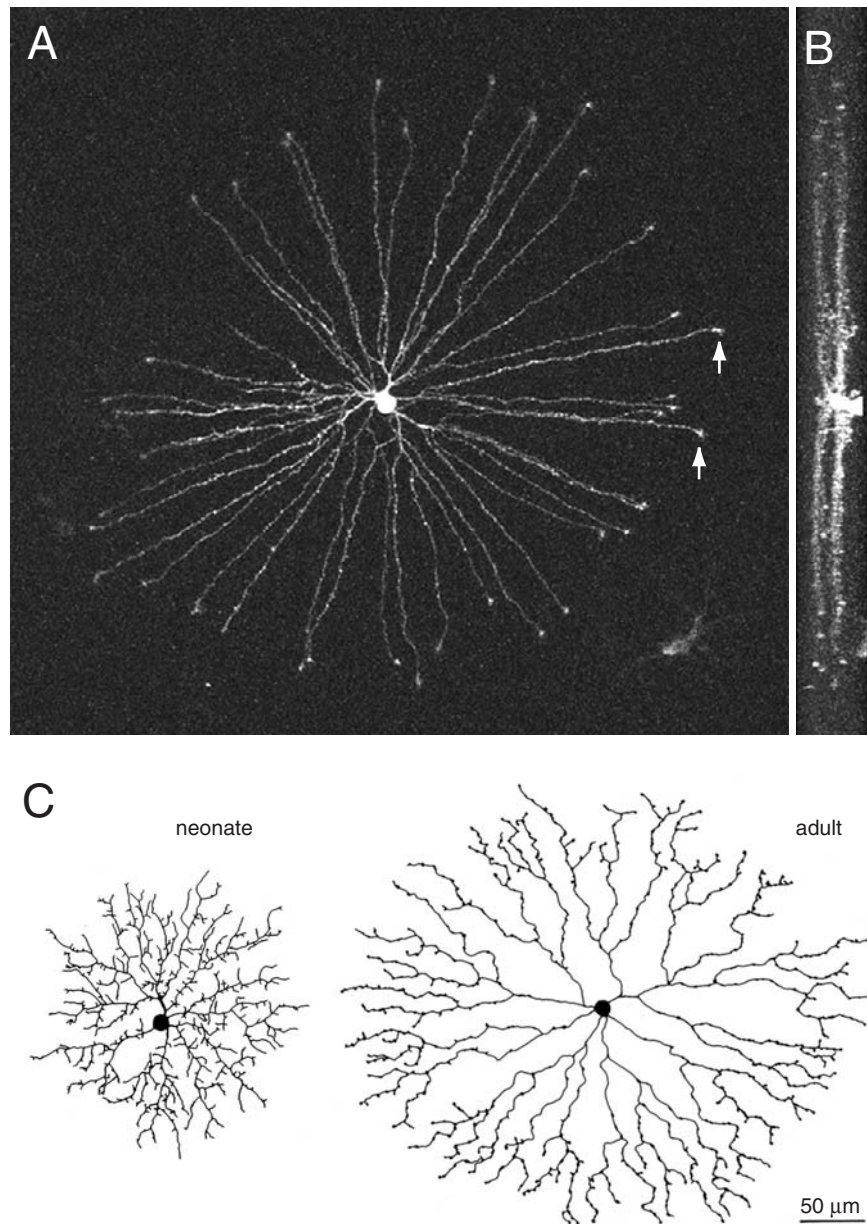

FIGURE 6.5. Development of amacrine cell processes. *A*, A “fireworks” type of amacrine cell in the embryonic chick retina sends out processes radially without much branching. Each process is tipped with a growth cone (examples, *arrows*). Even at this immature stage, the arbor morphology of this cell type is already patterned. Moreover, the processes are already confined to two distinct

strata in the inner plexiform layer (*B*, side view of the cell). The cell was labeled after transfection with plasmid encoding green fluorescent protein. *C*, In contrast, the processes of cholinergic amacrine cells (from the rabbit retina) undergo remodeling with maturation. Many small branches are eliminated with age (Wong and Collin, 1989). Cells labeled by intracellular dye filling.

most interest is how ON and OFF sublamination takes place, an event that commences well before eye opening and requires the sorting out of three sets of neuronal processes—the dendrites of ganglion cells, processes of amacrine cells, and axons of bipolar cells. Morphological studies show that much structural reorganization takes place before the dendrites of ganglion cells become confined to the ON or OFF sublamina (Fig. 6.6; Bodnarenko and Chalupa, 1993;

Bodnarenko et al., 1999; Kirby and Steineke, 1996; Lohmann and Wong, 2001; Maslim and Stone, 1988). Retinal ganglion cells which at maturity have either ON- or OFF-center responses receive converging inputs from ON and OFF bipolar cells when their arbors have not yet stratified (Wang et al., 2001). Thus, importantly, developmental rearrangements in the dendritic structure of the ganglion cells underlie their functional maturation.

How ganglion cell dendritic stratification is achieved is not yet known, but it is a subject of intense investigation. The first indication that transmission from presynaptic interneurons is involved in dendritic stratification of retinal ganglion cells came from studies in which 2-amino-4-phosphonobutyric acid (APB), an agonist of mGluR6 receptors, was injected intraocularly during the period in which dendritic arbors of ganglion cells became stratified (Bodnarenko et al., 1995, 1999). Retinal ganglion cells failed to stratify in the APB-treated eyes. Although APB treatment disrupts the stratification of ganglion cell dendrites, it is unlikely that glutamatergic transmission initiates this process. This is because the process of stratification begins before bipolar cells have differentiated. Amacrine cells, which differentiate earlier than bipolar cells and around the same time as ganglion cells, may mediate the early stratification process. Knockout mice in which populations of amacrine cells are ablated or their function perturbed will be useful for assessing the role of these interneurons. Examination of mice lacking the beta2 subunit of the cholinergic receptor indicated that ganglion cell stratification still occurs, although there may be some abnormalities (Bansal et al., 2000). However, it may be that not all ganglion cell dendritic arbors are affected in beta2 knockout mice because not all ganglion cells may be major postsynaptic targets of cholinergic amacrine cells. Because there are many other popula-

tions of amacrine cells, determining whether ganglion cell dendritic stratification is affected by amacrine transmission will require detailed consideration of subcircuits within the inner retina. This will involve determining which amacrine cells form the major input onto each type of ganglion cell, a task that is extremely challenging. Finally, bipolar cell interactions are likely to be important for the maintenance of stratification in the ganglion cells. Selective perturbation of transmission from ON or OFF bipolar cells should help determine whether bipolar cell inputs affect structural reorganization of the ganglion cell dendritic arbor. Ganglion cell dendritic stratification in mGluR6 knockout mice appears normal, but this may be because activity is enhanced in the ON bipolar cells rather than suppressed (Tagawa et al., 1999).

How could neurotransmission help determine the stratification of ganglion cell arbors? One possibility is that initially, synaptic inputs are not equally distributed across the dendritic arbor. Through competitive interactions that favor the retention of more “active” or collectively “stronger” inputs, dendrites in one sublamina may be selectively maintained or eliminated. To date, however, the initial distributions and synaptic strengths of inputs onto the dendritic arbor of retinal ganglion cells are unknown, but their measurement would be very helpful in understanding how the inner retinal circuitry is established.

FIGURE 6.6. The dendritic arbors of retinal ganglion cells undergo structural reorganization during the period of synapse formation and maturation. *A*, Reconstructions from confocal images of alpha-like ganglion cells in the newborn (*left*) and 3-week-old (*right*) ferret retina. Below, orthogonal view of the cells. Scale bars,

20 μ m. The distribution of dendrites within the inner plexiform layer (IPL) becomes gradually restricted to either the ON or OFF sublamina with age. *B*, Schematic representation of the stratification process. *GCL*, ganglion cell layer. (*A* adapted from Lohmann and Wong, 2001.)

Even though interactions between amacrine cells and bipolar cells may influence the segregation of ON and OFF pathways within the retina, other nonactivity-dependent mechanisms must be considered. This is because there are other aspects of dendritic development in ganglion cells that may not depend on neurotransmission alone. Notably, mechanisms which regulate the arbor size of retinal ganglion cells during mosaic formation are likely to include molecular cues (Sernagor et al., 2001). Thus, the remodeling of dendritic arbors during development of retinal ganglion cells possibly requires several mechanisms that act together to shape their lateral and vertical distributions in a coordinated way. While contact between retinal interneurons and ganglion cells might direct their stratification according to depth within the inner plexiform layer, contact between retinal ganglion cells themselves may organize the lateral extent of their dendritic territory (see also Chapter 9).

If amacrine and bipolar cell interactions effect the dendritic stratification of ganglion cells, what controls the stratification of these interneurons? Although an answer is still far off, deletion of one of the three major inner retinal cell classes during development should provide important insights. What is known so far is that in rodents, ganglion cells are not needed for amacrine or bipolar cell processes to stratify in the inner plexiform layer (Gunhan-Agar et al., 2000).

Wiring up the retina

NEUROTRANSMITTERS AND RECEPTORS The functional maturation of retinal circuits depends on the expression of neu-

rotransmitters and their receptors, as well as the formation of synaptic contacts. We will discuss briefly the timing and patterns of expression of the major excitatory and inhibitory transmitters in the retina and summarize when receptors for these transmitters appear (see Fig. 6.7).

Glutamate is the major excitatory transmitter in the adult retina, present in photoreceptors, bipolar cells, and retinal ganglion cells. Immunolabeling for glutamate in the developing retina demonstrates that expression of this amino acid is first detected in undifferentiated cells in the ventricular zone of the retina before the plexiform layers appear. Surprisingly, cell bodies in the ganglion cell layer are immunonegative for glutamate until bipolar cells and Müller glial cells have differentiated. This may be because ganglion cells synthesize glutamate from glutamine that is normally provided by the Müller glia. In the outer retina, photoreceptors express glutamate long before they differentiate and form connections. Functional receptors for glutamate are expressed by retinal ganglion cells and amacrine cells before they receive synaptic inputs (Liets and Chalupa, 2001; Wong, 1999). The distribution of the various ionotropic glutamate receptor subunits has been assessed by immunocytochemistry: both Alpha-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) and N-methyl-D-aspartate (NMDA) receptor subunit staining becomes restricted to distinct bands within the inner plexiform layer by the time of eye opening (Grunder et al., 2000a, 2000b). These banding patterns appear in retinas immunolabeled for AMPA receptor subunits before those of NMDA receptor subunits.

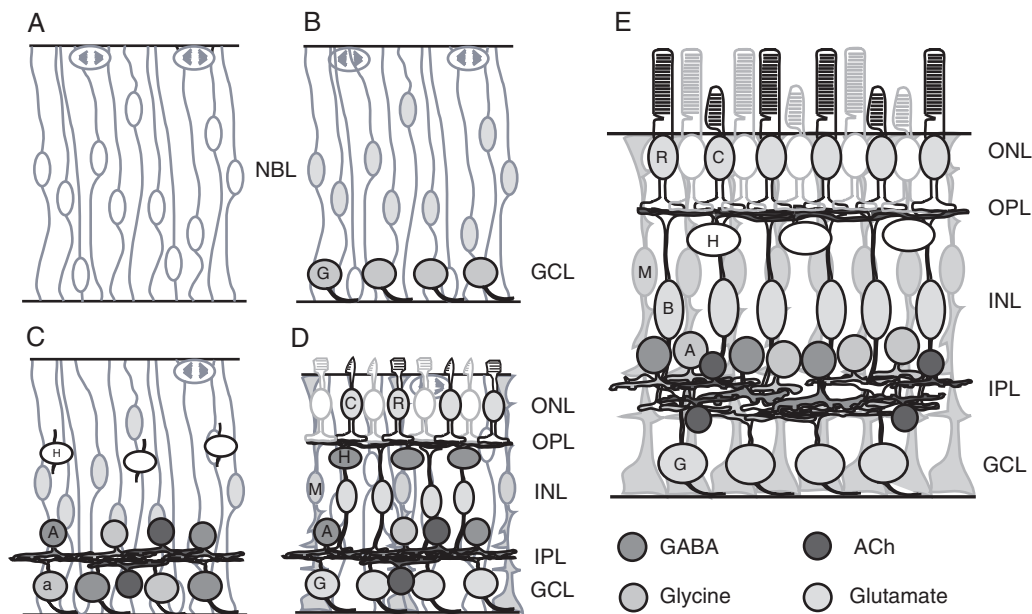

FIGURE 6.7. Expression patterns of major excitatory and inhibitory neurotransmitters in the developing and adult retina. Labeling of cell types and retinal layers are provided in Figure 6.1. *GABA*, gamma-aminobutyric acid; *ACh*, acetylcholine. (See color plate 4.)

The other major excitatory fast neurotransmitter in the retina is acetylcholine. Immunolabeling for choline acetyltransferase (ChAT) has been carried out in a large range of species. ChAT expression is present early in development, often prenatally, and cholinergic transmission takes place before glutamatergic transmission is apparent (see the section "Spontaneous Activity"). In mammal and chick, retinal neuroblasts in the ventricular cell layer demonstrate an increase in intracellular calcium upon stimulation with muscarinic receptor agonists (Sakaki et al., 1996; Wong, 1995a). Whether the expression of these receptors has a major functional role in the differentiation of these cells remains to be determined. Amacrine and ganglion cells, prior to the formation of synapses, are also able to respond to applied nicotine (Wong, 1995b). Thus, like ionotropic glutamate receptors, retinal neurons express functional cholinergic receptors prior to the emergence of synaptic networks.

There has been much interest in the development of the inhibitory systems of the retina, primarily because GABA and glycine have been linked to cell survival and differentiation in many neuronal systems (Cherubini et al., 1991). GABA immunoreactivity is first detected in amacrine cells and in some ganglion cells just before birth in the rabbit and in rodents. Ganglion cell expression disappears at maturity. In mammals, horizontal cells are transiently immunoreactive for GABA at the time when cone photoreceptors can respond to this amino acid (Huang and Redburn, 1996). Glycine immunoreactivity is dominant in the ganglion cell layer and the fiber layer in the immature retina. With maturation, glycine immunoreactivity disappears from the ganglion cells and becomes restricted to amacrine cells and a few bipolar cells (Pow et al., 1994). In contrast to cells at maturity, retinal neurons, including ganglion cells, are depolarized by GABA and glycine early in development (Wong et al., 2000b; Yamashita and Fukuda, 1993). This is because, like other neurons in the developing CNS, immature retinal ganglion cells have a relatively high intracellular chloride concentration. This is probably because the K-Cl cotransporter (KCC2) that extrudes chloride from cells increases in expression only after birth (Vu et al., 2000). Interestingly, KCC2 expression in the inner retina precedes that in the outer retina, suggesting that prior to eye opening, GABA action in the outer plexiform layer may differ from that in the inner retina.

A common feature, then, of the developing neurotransmitter system in the retina is that expression of the transmitters and their receptors occurs before visual processing, and even before electrical activity can be detected. It is possible that communication between retinal neurons still occurs, perhaps through release of transmitter from growth cones (Gordon-Weeks et al., 1984). Such communication could be important for maturation events in the retina,

although direct evidence for a developmental role for transmitter-mediated interactions in cell differentiation is still lacking. During the period of synaptogenesis, however, neurotransmission appears to be important for the maintenance of dendritic structure, as discussed earlier (Wong et al., 2000a). Furthermore, early transmission, before vision, is also necessary for establishing the correct patterns of connections between the retina and visual centers in the brain (see the section "Spontaneous Activity"). The availability of knockout mice lacking synthetic enzymes for various neurotransmitters and the ability to generate conditional knockouts of these mice will no doubt be useful in the future for assessing the importance of the early expression of neurotransmitter systems in the retina and in other parts of the nervous system.

SYNAPSE FORMATION Synapse formation in the retina has largely been assessed by electron microscopy (see Robinson, 1991, for a review). In many species, synaptogenesis in both plexiform layers begins before eye opening, occurring first in the inner plexiform layer about two-thirds of the way through gestation. In particular, amacrine cells form synapses with ganglion cells, and between themselves, shortly after these populations of neurons extend neurites into the inner plexiform layer (Maslim and Stone, 1986; Nishimura and Rakic, 1985, 1987).

Membrane thickenings are observed in the inner plexiform layer before synaptic vesicles can be recognized. Studies of primate retina suggest that these thickenings or specializations occur first in postsynaptic processes, the dendrites of ganglion cells, before they are apposed by amacrine cell processes (Nishimura and Rakic, 1985, 1987). Maturation of conventional synapses involves the acquisition of an increasing number of synaptic vesicles. Bipolar synapses, which are characterized by the presence of a ribbon-like structure, appear after conventional synapses are formed in the retinal periphery of primates. Initially, serial electron microscopy indicates that putative bipolar terminals are observed without ribbons. Then ribbon-containing terminals form dyads, making contact with a single postsynaptic process. With maturation, the typical triad arrangement is seen when each bipolar terminal contacts two processes, which could belong to amacrine or ganglion cells. In contrast to the retinal periphery, in the fovea bipolar synapses appear before conventional synapses are observed (Crooks et al., 1995). It may be that in cone-dominated regions of the retina, bipolar synapses develop before amacrine synapses (see Hendrickson, 1996).

Synapses in the outer plexiform layer are first formed between photoreceptors and horizontal cells (McArdle et al., 1977). The last cellular element to enter into the circuitry is the bipolar cell that appears to be contacted first by cones. Rod bipolar cell differentiation may occur later, and

synapses from rods are therefore established after those of cones, although there is substantial overlap in timing. Synaptogenesis in the outer plexiform layer continues after eye opening, raising the possibility that the properties of this outer synaptic layer may be more susceptible to sculpting by visual stimulation compared to synapses in the inner plexiform layer (Robinson, 1991).

The ultrastructural observations provide a broad view of the order of appearance of synapses within the retina, as well as provide clues as to how various connections may arise. To gain an understanding of the nature of the initial interactions that result in the contact and maturation of synapses between retinal neurons, it will be necessary to watch how pre- and postsynaptic processes behave in living tissue. Although this has not yet been achieved, recent imaging experiments of dendritic motility in the isolated developing retina suggest that contact between inner retinal neurons may involve transient filopodia-like structures that are highly dynamic in nature (Wässle, 1988; Wong and Wong, 2000; Wong et al., 2000b). These filopodia-like structures, which extend and retract over the course of seconds to minutes, are most abundant during the period of synaptogenesis in the inner retina. Because of their high density and motility, dendritic filopodia effectively increase the volume of dendrite that can be contacted by incoming amacrine or bipolar afferents. Although this potential role for dendritic filopodia has yet to be demonstrated, their regulation by neurotransmission supports the notion that afferent signaling encourages contact with dendrites by promoting their motility (Wong and Wong, 2001).

Many questions, of course, remain. How do the many classes and subclasses of retinal neurons find their appropriate synaptic partners? How much remodeling of the initial connectivity occurs in retinal circuits? What determines the lamination and sublamination of the plexiform layers? How is synapse formation coordinated across the plexiform layers and within each lateral and vertical network? Is the mature mammalian retina capable of regenerating connections?

Physiology of the developing retina

SPONTANEOUS ACTIVITY Neurotransmission occurs in the developing retina even before photoreceptors mature, and begins around the time that amacrine inputs to ganglion cells are formed. This early transmission between amacrine and ganglion cells sustains a unique pattern of retinal activity that has important developmental roles. Retinal ganglion cells fire action potentials during the period when their connections with central targets undergo reorganization. Recordings from rat fetuses in vivo demonstrated that immature ganglion cells fire spikes in bursts that occur periodically, about once every minute (Galli and Maffei, 1988;

Maffei and Galli-Resta, 1990). Simultaneous recordings from neighboring ganglion cells using multielectrode arrays (Fig. 6.8) later showed that bursts of spikes from the ganglion cells are temporally synchronized (Meister et al., 1991). This is because activity propagates across the retinal surface as waves, which are clearly seen using optical imaging techniques (Fig. 6.8).

All major classes of retinal ganglion cells and subpopulations of amacrine cells participate in the wave activity. The waves are generated by mechanisms requiring synaptic input from amacrine cells, and later with maturation, transmission from bipolar cells (reviewed in Wong, 1999). Exactly how this inner retinal circuitry generates the wave pattern of activity is not fully known, but transmission from cholinergic amacrine cells is important early on (Feller et al., 1996; Sernagor et al., 2001). Waves are abolished in the presence of neuronal nicotinic receptor antagonists and are absent in mice which lack specific subunits of these receptors (Bansal et al., 2000).

The spontaneous activity patterns of the immature ganglion cells contain several spatiotemporal cues that could be important for the refinement of their connectivity with their central targets. First, spiking in bursts appears necessary for long-term potentiation of synapses between retinal ganglion cells and the lateral geniculate nucleus (Mooney et al., 1996). Second, the propagating waves ensure that activity of neighboring cells is better correlated compared to cells that are more distant. This feature provides a means for geniculate neurons to gauge intercellular distance within the retina based on the timing of their spikes. Such information could be important in helping refine the retinotopic map, which becomes sharpened in many species with maturation. Third, because waves occur randomly and are relatively infrequent, waves from the two eyes are unlikely to be synchronized. Such asynchronous activity from the two eyes is thought to drive the segregation of connections from the two eyes which initially converge onto single geniculate neurons. Indeed, the projections from the left and right eyes are abnormal in nicotinic receptor knockout mice and in ferrets that have been injected intraocularly with epibatidine, a nicotinic receptor antagonist, during the period of axonal segregation (Penn et al., 1998; Bansal et al., 2000). Although activity from the retinas prior to visual stimulation is important for establishing the projection patterns of the ganglion cells during development, direct evidence for patterned activity underlying these events has yet to be obtained. This would require maintaining spontaneous activity but altering the spatiotemporal relationship between spiking of neighboring ganglion cells.

Prior to eye opening in the ferret, the spontaneous spiking patterns of retinal ganglion cells are altered in their temporal characteristics in a cell-type-specific manner. Although waves are still present and each wave synchronizes the spiking of neighboring ON and OFF cells, OFF cells spike

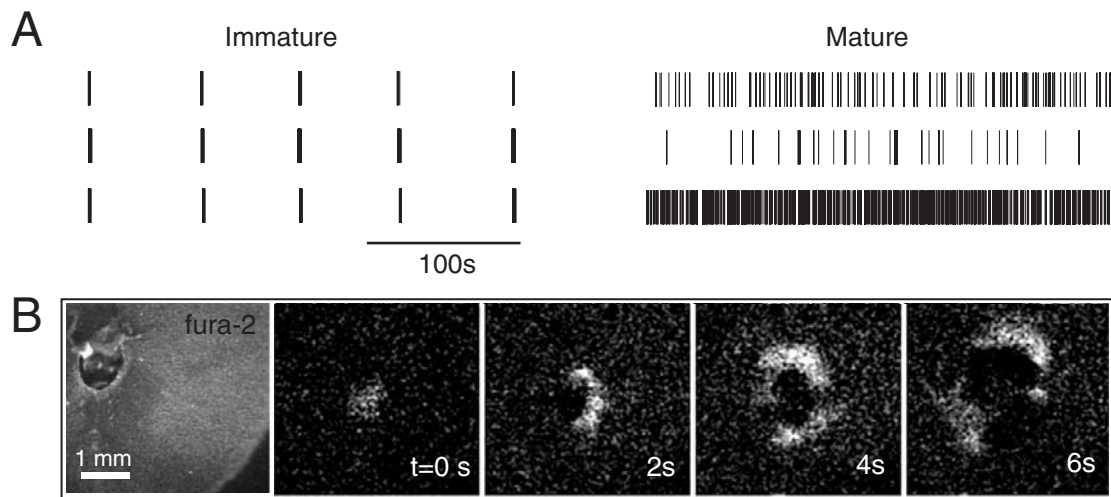

FIGURE 6.8. Patterns of spontaneous activity in the developing retina. *A*, Spike recordings from the mouse retinal ganglion cell layer using a multielectrode array before (immature) and after (mature) eye opening. *B*, Calcium imaging of the immature mouse

retina showing labeling of the retina with the calcium indicator, fura-2, and the spread of activity, indicated by the white pixels, across the retinal surface over time. (*A*, J. Demas and R. O. L. Wong, unpublished; *B*, R. O. L. Wong, unpublished.)

more frequently between waves than ON cells (Wong and Oakley, 1996). This change in the activity patterns of the ON and OFF ganglion cells occurs during the period when the axonal projections of these ganglion cells to the geniculate nucleus becomes refined. Theoretical studies suggest that the decrease in correlated activity between ON and OFF ganglion cells is sufficient to cause their inputs onto geniculate neurons to segregate over time (Lee et al., 2002). By the time of eye opening, waves disappear and the spontaneous spike activity of retinal ganglion cells is no longer patterned, instead appearing randomly (Fig. 6.8). However, different rates of spontaneous firing occur even in the adult retina, although their correlation with retinal ganglion cell type has yet to be established.

The mechanisms that underlie the progressive change in spontaneous activity patterns of the ganglion cells are not yet fully uncovered. It is likely that the developmental maturation of the spike patterns is shaped by both intrinsic properties of the ON and OFF ganglion cells and by their circuitry (Myhr et al., 2001). It is also possible that maturation of the outer retina, particularly the emergence of light sensitivity in photoreceptors, affects the patterns of spontaneous spiking of ganglion cells.

LIGHT RESPONSES Light responses emerge as the photoreceptor-bipolar pathway begins to mature shortly before eye opening (Dacheux and Miller, 1981a, 1981b; Masland, 1977; Tootle, 1993). Electrophysiological recordings from retinal ganglion cells show several major trends in the maturation of their responses to light. The early response of retinal ganglion cells to light stimulation is weak and the cells adapt rapidly (Masland, 1977; Tootle, 1993). But when robust responses to light become detectable a few

days later, the concentric center-surround organization of the receptive fields, as well as ON and OFF center responses, are already present (Bowe-Anders et al., 1975; Masland, 1977; Tootle, 1993). Whether the connectivity that underlies these physiological properties is established before photoreceptors are present is unknown. Determining how surround inhibition appears in the retinal ganglion cells has not been straightforward. Some immature rabbit retinal ganglion cells have silent surrounds that, when stimulated, can suppress the response to center stimulation, but direct stimulation of the surround does not evoke a response (Masland, 1977). In the cat, however, the strength of the antagonistic surround relative to that of the center does not seem to change with postnatal maturation (Tootle, 1993).

Recordings from ferrets, however, clearly demonstrate that connectivity in the inner retina is remodeled with maturation. In the postnatal ferret, alpha- and beta-like retinal ganglion cells have convergent ON and OFF inputs prior to maturity (Wang et al., 2001). In these cells, maturation of the receptive field center responses thus involves the loss of one type of input. Specialized receptive field properties such as direction selectivity also develop before eye opening (Masland, 1977; Sernagor and Grzywacz, 1995), although the synaptic basis for this property remains to be determined.

How then is the ganglion cell receptive field established during development? Visual experience after eye opening does not appear to alter the receptive field properties of mammals that were raised in an environment with unidirectionally moving stimuli (Daw and Wyatt, 1974). But this may be because, in rabbits, ganglion cell receptive fields are fairly mature by the time of eye opening (Masland, 1977). In contrast, the peak firing rate of retinal ganglion cells

in response to light stimulation is decreased in dark-reared mice (Tian and Copenhagen, 2001). Cells also respond more sluggishly in dark-reared animals. The spatial organizations of the receptive fields have not yet been assessed after dark rearing of mice. In turtles, which become light responsive prior to hatching, dark rearing causes an increase in receptive field size (Sernagor and Grzywacz, 1996). However, this study also suggested that it is spontaneous activity rather than visual stimulation that regulates the receptive field size.

Clearly, much remains to be done to fill our knowledge gaps concerning how the light responses of retinal neurons are established in ways that are characteristic of each cell type. While in the past such properties were largely studied using electrophysiological methods, it is likely that the combination of physiology with molecular and live-imaging techniques will now aid investigations in this important area of retinal development.

7 The Development of Retinal Decussations

CAROL MASON AND LYNDA ERSKINE

Introduction

In the vertebrate visual system, retinal ganglion cell (RGC) axons from each eye grow toward the brain and meet at the midline of the ventral diencephalon. Here they establish an X-shaped pathway, the optic chiasm. This major brain decussation, or crossing, carries fibers from the retina to targets in the thalamus (the lateral geniculate nuclei, LGN) and the midbrain (superior colliculus, or optic tectum in lower vertebrates). The projection through the chiasm establishes connections in central targets for an orderly topographic map of the retina. During development of the optic chiasm, RGC axons from each eye diverge from one another to grow to the optic tract on the same and opposite sides of the brain, a projection pattern that subserves binocular vision in higher animals.

Here we will review optic chiasm development, including the axon paths and behaviors of RGCs during their growth as they form the chiasm, and the relationships of RGC growth cones to specialized cells positioned in and around the optic chiasm. Where relevant, we will highlight differences across species in terms of degree of binocularity and the developmental principles underlying the plan of retinal projection. We will then discuss the recent progress on uncovering the cellular and molecular mechanisms directing chiasm formation. Finally, we will discuss aberrations in chiasm development, such as in albinos, in which reduced ocular pigment is linked to a decrease in uncrossed projections, and in a rarer condition in which complete failure of optic chiasm development occurs.

Principles of optic chiasm organization

THE BINOCULAR PLAN The patterns of RGC axon projection at the optic chiasm in different species range from complete crossing and segregation of fibers from each eye to partial decussation and formation of an ipsilateral projection with complex intermingling of the fibers from the two eyes. The presence and relative size of the ipsilateral projection depend on the degree of binocular overlap in the visual field. In lower vertebrates, such as fish, that lack binocular vision, the fibers from each eye are segregated and the mature visual system contains an entirely crossed projection (Fig. 7.1). Amphibian tadpoles also have an entirely crossed projection. However, in some species, for example, *Xenopus*

laevis, an ipsilateral projection develops at metamorphosis when the eyes change position and binocularity develops to subserve their now predatory lifestyle (Grant and Keating, 1986). In chickens, as in fish, there is nearly complete crossing but the fibers intercalate as they cross and, early in development, there is a transient ipsilateral projection (Drenhaus and Rager, 1992; O'Leary et al., 1983; Thanos et al., 1984). In mammals, partial decussation occurs, the extent of which varies widely among species. In humans and primates, all RGC axons originating from the nasal retina cross the midline to project into the contralateral optic tract and all RGC axons from the temporal retina project into the ipsilateral optic tract (Chalupa and Lia, 1991; Polyak, 1957; Stone et al., 1973). By contrast, in mouse, only a small proportion of RGCs (<5%) located in the peripheral temporal retina project ipsilaterally, and these cells are intermingled with RGCs whose axons project contralaterally (Godement et al., 1990) (Fig. 7.1).

CHANGES IN RGC AXON ORGANIZATION IN THE OPTIC NERVE, CHIASM, AND TRACT In all species, as RGC axons grow from the eye to their targets in the thalamus and midbrain, several changes in axon organization occur. In the optic nerve immediately behind the eye, RGC axons are organized by retinal quadrant of origin and display a faithful point-to-point retinotopic order. In nonprimates, the retinotopic but not the quadrantic organization is lost rapidly. In the chiasm, axons become ordered in an age-related manner, traversing along radial glial endfeet at the pial surface, but cross the midline in eye-specific bundles deep to the pia. In fish, the fibers from each optic nerve remain bundled and each bundle overlaps to form the chiasm, whereas in higher vertebrates, there are increasingly finer degrees of eye-specific bundle interleaving at the chiasmatic crossing. Chronotopic order is reestablished in the later chiasm and optic tracts and, subsequently, axons regroup according to retinal quadrant but in a different spatial arrangement distinct from that found in the optic nerve (see Chan and Chung, 1999; Colello and Guillery, 1992, 1998; Drenhaus and Rager, 1994; Guillery, 1995; Guillery et al., 1995; Horton et al., 1979; Jeffery, 2001; Mitrofanis et al., 1997; Reese, 1996; and Silver and Rutishauser, 1984, for more detailed descriptions). The functional significance and mechanisms underlying these patterns of rearrangement are not known.

FIGURE 7.1. Basic plan for binocular vision: wiring to the optic chiasm and targets. Line thickness reflects approximate proportions of fibers projecting to ipsilateral or contralateral targets.

Perhaps the most complex change in RGC axon arrangement that occurs along the optic pathway, and the focus of this review, is the divergence of crossed and uncrossed axons at the optic chiasm. An early view of RGC axon behavior during divergent growth was made by Ramón y Cajal. His drawing of the chiasm of the kitten revealed that some uncrossed axons grow directly into the ipsilateral optic tract, while others project toward the midline and then curve back to project ipsilaterally (Ramon y Cajal, 1911). Similarly, in mouse, the best-studied mammalian species, the axons that give rise to the permanent ipsilateral projection arise specifically in the ventrotemporal part of the retina and separate from axons destined to project contralaterally close to the midline (Colello and Guillery, 1992; Godement et al., 1990, 1994). There is no obvious segregation of fibers that will grow ipsilaterally from those projecting across the midline. By contrast, in the marsupial, the ipsilaterally projecting axons diverge laterally and never approach the midline (Jeffery and Harman, 1992; Taylor and Guillery, 1995). Direct growth of RGC axons into the ipsilateral optic tract also occurs during early stages of mouse chiasm development (Colello and Guillery, 1990; Marcus et al., 1995; Silver and Rutishauser, 1984), the formation of the transient ipsilateral projection in

the chick (Hoyt and Luis, 1963; Thanos et al., 1984), and possibly also at the primate chiasm (Hoyt and Luis, 1963; Meissirel and Chalupa, 1994). Although the routes taken by RGC axons through the chiasm may be fundamentally different, in all species the mechanisms that regulate RGC axon divergence at the chiasm must include distinct properties encoded by the ipsilaterally and contralaterally projecting RGCs such that their axons respond differentially to guidance cues arrayed at the midline (see below).

OTHER PROJECTION PATTERNS FOUND AT THE OPTIC CHIASM

In addition to the normal projection into the optic tract, a subset of RGC axons originating in the nasal part of the retina extend through the chiasm into the contralateral optic nerve. This retinoretinal projection has been described in developing rodents (Bunt and Lund, 1981; Plump et al., 2002), chicks (McLoon and Lund, 1982; Thanos, 1999), and the regenerating frog visual system (Bohn and Stelzner, 1981). The growth cones of these axons terminate superficially in the temporal part of the contralateral retina and fail to penetrate into deeper layers of the retina. In all species, this retinoretinal projection is eliminated later in development. Thus, it is not clear if the growth of fibers from one eye to the other has a developmental significance or simply represents an erroneous projection.

Axons also extend from the brain into the optic nerve (Reese and Geller, 1995; Thanos, 1999). These fibers originate early in development in the ventrolateral diencephalon prior to outgrowth of axons from the retina. In the ferret, these axons enter the optic nerve and grow toward but never invade the retina. By contrast, in the chick, they terminate on amacrine and displaced ganglion cells of the contralateral retina. Again, the function of this projection is not known, but it could potentially serve a guidance function for the later developing RGC axons.

Development of the optic chiasm: growth cone behaviors at the midline and the cellular environment

In the past 20 years, much has been learned, particularly in the mouse, about the birth dates and properties of ipsilateral and contralateral RGCs and the timing of axon growth through the optic chiasm (Colello and Guillery, 1990; Dräger, 1985; Sretavan, 1990). Static and dynamic analyses have revealed the behavior of crossed and uncrossed axons and have uncovered cell and molecular cues in the pathway that direct RGC axon outgrowth (see Dingwell et al., 2000; Mason and Erskine, 2000).

STATIC AND DYNAMIC CHRONICLES OF RGC AXON BEHAVIOR AT THE CHIASM Dye tracing of small groups of axons in fixed tissue has provided a picture of the sequential steps in chiasm development and demonstrated that, in the mouse,

formation of the chiasm occurs in two separate phases (Colello and Guillery, 1992; Godement et al., 1990; Marcus et al., 1995; Marcus and Mason, 1995) (Fig. 7.2). In the first phase, axons of early-generated RGCs located in dorsocentral retina enter the ventral diencephalon at E12–E12.5 (E, embryonic day) and grow across the midline to establish the position of the chiasm along the anterior-posterior axis of the brain. Subsequently, at E13–E14, axons from more peripheral parts of the retina enter the nascent chiasm and make specific pathfinding choices into either the ipsilateral or contralateral optic tract (Fig. 7.2*B*).

Analysis of dye-labeled axons and growth cones in fixed preparations has demonstrated that growth cones on axons from ventrotemporal retina are highly complex and spread when positioned near the midline, some appearing as though they are making a U turn (Godement et al., 1990). Dynamic chronicles using time-lapse video microscopy confirmed that at the midline growth cones pause frequently and become highly complex prior to making a turn (Fig. 7.2*A*). This is in contrast to the optic nerves and tracts, in which pausing is less common and the growth cones tend to adopt more streamlined shapes, or in targets during arbor formation when branches have smaller tips (Chan et al., 1998; Godement et al., 1994; Harris et al., 1987; Mason and Wang, 1997; Sretavan and Reichardt, 1993).

The static analyses initially led to the hypothesis that growth cone morphology is related to position along the pathway: complex and spread at the chiasm and streamlined in the optic nerve and tract (Bovolenta and Mason, 1987; Fig. 7.2*A*). The dynamic chronicles revealed that growth cone form is in fact behavior specific. In all regions of the pathway, pausing growth cones have complex forms and advancing growth cones have streamlined shapes (Fig. 7.2*A*). Moreover, while the rate of advance and the duration of each pause period during advance are similar throughout the pathway (about 60 $\mu\text{m/hr}$ and 30–40 minutes, respectively), the duration of the advance periods and the total number of pauses per unit distance vary widely along the trajectory from the retina. At the midline, growth cones pause frequently, interspersed with short periods of advance, but in the optic nerve and tracts, they can spend up to an hour or more in straight advance without pausing. Thus, complex growth cones are more common in the chiasm midline, and streamlined growth cones predominate in the optic nerve and tracts (Fig. 7.2*A*). Consequently, since distinct behaviors occur in different regions of the pathway, growth cone form appears to be position specific (Mason and Wang, 1997). The changes in growth cone dynamics that occur at the midline have been interpreted as reflecting interactions of the growth cones with guidance cues localized to this region. Similar conclusions have been drawn from other studies of growth cone behavior in both vertebrates and invertebrates (e.g., Caudy and Bentley,

1986; Holt, 1989; Mason and Erskine, 2000; Tosney and Landmesser, 1985).

CELLULAR SPECIALIZATIONS AT THE VENTRAL MIDLINE The region of the ventral diencephalon in which the optic chiasm develops contains a number of cellular specializations that have been implicated in regulating RGC axon guidance. Rostral to the developing chiasm in both the chick and mouse is the glial knot, a dense interwoven cluster of non-neuronal cells (Silver and Rutishauser, 1984; Silver et al., 1987). This cellular formation is located at the boundary between the diencephalon and telencephalon and has been postulated to serve as a barrier that prevents the RGC axons from extending anteriorly into the telencephalon.

At the site where the optic chiasm forms in the mouse, two additional groups of cells are located: a specialized group of midline radial glia that have molecular expression patterns distinct from those of surrounding radial glia cells and an early-born population of diencephalic neurons (Marcus and Mason, 1995; Marcus et al., 1995; Mason and Sretavan, 1997; Sretavan et al., 1994) (Fig. 7.2*B*). These cells mark the site where the RGC axons diverge and the posterior boundary of the chiasm. The cell bodies of the midline glia are positioned close to the floor of the third ventricle, and during the establishment of the permanent ipsilateral projection, their radial processes extend to about one-third of the width of the mediolateral extent of the chiasm (Marcus and Mason, 1995). All growth cones enter the glial palisade before either crossing or turning back from the midline. Ultrastructural analysis of neuronal-glial interactions in this region has demonstrated that the lamellae of the growth cones interdigitate with and wrap around the radial glial processes, suggesting that the interactions between these cells may play a critical role in directing RGC axon pathfinding (Marcus et al., 1995).

The early-born diencephalic neurons comprise a V-shaped template of cells with the tip of the V pointing anteriorly along the midline (Fig. 7.2*B*). These cells form the posterior boundary of the chiasm and express a panel of specific markers including carbohydrate epitopes (e.g., stage-specific embryonic antigen-1, SSEA-1) and the hyaluronan binding protein CD44 (Kaprielian et al., 2001; Marcus et al., 1995; Sretavan et al., 1994). It appears likely that these diencephalic neurons (CD44/SSEA neurons) are the mammalian homolog of the cells that generate the tract of the postoptic commissure (TPOC) in lower vertebrates such as fish and amphibians (Easter et al., 1993; Mason and Sretavan, 1997). In the first stage of RGC axon outgrowth in the mouse, crossed and uncrossed axons follow the contour of the early-born diencephalic neurons, thereby establishing the position of the chiasm within the ventral diencephalon. Later, when the permanent pattern is established, the axons diverge at the rostral tip of the neuronal array (Fig. 7.2*B*).

FIGURE 7.2. Trajectory of retinal ganglion cell axons during early and late phase of chiasm formation. Horizontal view of axon growth and cells of the ventral diencephalon during the early (E12–E13) and later (E15–E16) phases of axon growth. Specialized radial glia (*small dots*) form palisades on either side of the midline, and express RC2, as well as *slit2* (rostrally), EphA and EphB receptors, and NrCAM. The early-born neurons (*large dots*) express CD44 and SSEA-1, as well as ephrinA's, Slit1, Robo1, and Robo2, and sulfated proteoglycans. *Slit1* is expressed dorsal to and around the optic nerve as it enters the brain and, more weakly, by the CD44/SSEA neurons. *Slit2* is strongly expressed in the preoptic region directly dorsal and anterior to the chiasm. *A*, At E15–E16, during the major phase of retinal axon divergence, growth cones have different forms, depending on their locale and behavior. Crossing (*thick line*) and uncrossed (*thin line*) fibers have slender streamlined growth cones in the optic nerve and

optic tract. Near the midline, all axons pause and have more spread forms. Uncrossed growth cones extend along the midline in highly complex shapes before turning back to the ipsilateral optic tract. *B*, In the early phase of retinal axon growth, the first-born uncrossed retinal axons from the dorsocentral retina (DC) enter the ipsilateral optic tract directly, quite far from the midline, similar to marsupial RGCs. In contrast, in the later period, uncrossed axons travel toward the midline and diverge from crossing axons within the radial glial palisade. Crossed axons at both ages traverse the midline close to the rostral tip of the early-born neurons. All retinal axons at both ages grow around the contours of the early-born neurons. *C*, Maneuvers of retinal axons with respect to the resident cells of the optic chiasm. See key and text for details. DC, dorsocentral; D, dorsal; V, ventral; N, nasal; T, temporal.

Cell and molecular mechanisms underlying the patterning and formation of the optic chiasm

CELLULAR SPECIALIZATIONS AT THE MIDLINE REGULATE RGC AXON GROWTH AND DIVERGENCE A number of different approaches have provided direct evidence that the cellular

specializations of the ventral diencephalon (radial glia, CD44/SSEA neurons; see above and Fig. 7.2*B*) express cues that regulate RGC axon growth and guidance. In mouse embryos, ablation of the CD44/SSEA neurons early in development results in failure of the optic chiasm to develop and stalling of the RGC axons prior to crossing the midline

(Sretavan et al., 1995). This agenesis of the chiasm is not due to general damage of the neuroepithelium but is specific to the loss of the CD44/SSEA neurons. Puncturing the neuroepithelium at the junction of the optic stalks and ventral diencephalon prior to ingrowth of RGC axons does not prevent optic chiasm formation. By contrast, in amphibians, the presence of axon pathways within the ventral diencephalon is not essential for RGC axon pathfinding. When eyes are transplanted from older tadpoles into younger *Xenopus* embryos at a stage when the first axon tracts have not yet developed, the ectopic RGC axons pathfind normally (Cornel and Holt, 1992).

Additional support for a critical role of the resident cells of the ventral diencephalon in rodent chiasm development has come from tissue culture studies. Culturing retinal explants on membranes or cells derived from the ventral midline of the diencephalon inhibits RGC axon outgrowth (Wang et al., 1995; Wizenmann et al., 1993). Furthermore, axons from ventrotemporal retina, the main source of ipsilaterally projecting axons in the rodent retina, are more inhibited by these cells or membranes than are axons from the remainder of the retina. This strongly suggests that the cellular specializations of the ventral diencephalon express cues that direct RGC axon divergence at the optic chiasm. The ventral diencephalon also secretes a diffusible signal that dampens the growth of all retinal axons to a similar extent (Wang et al., 1996). Coculturing in collagen gels retinal explants from all four quadrants of the retina at a short distance from ventral diencephalon tissue results in a decrease in the number and length of the RGC axons extending from the explants into the collagen. The retinal axons are not repelled by the diencephalic tissue but instead continue to grow toward it, but at a greatly reduced rate. This inhibitory activity has therefore been termed *chemosuppression* and may underlie the slowed growth of RGC axons extending in situ as they approach the midline (Godement et al., 1994; Mason and Wang, 1997; see above).

INTERACTIONS BETWEEN FIBERS FROM EACH EYE When uncrossed axons turn back from the midline, they come into close association with axons from the opposite eye that have crossed the midline. In rodents and ferrets, removing one eye early in development results in failure of many ipsilaterally projecting axons to exit the chiasm and enter the optic tract (Chan and Guillery, 1993; Godement et al., 1987; Guillery, 1989; but see Sretavan and Reichardt, 1993). Because the cellular specializations at the midline are arrayed normally after eye removal (Chan et al., 1999), it has been proposed that binocular fiber interactions are essential for the formation of the ipsilateral projection in rodents. However, this is not true in all species. In marsupials, removal of one eye at any time during development does not affect development

of the uncrossed pathway (for a review see Guillery et al., 1995).

The in vitro demonstration that cues emanate from chiasm cells, coupled with static and dynamic views of dye-labeled axons, suggests the maneuvers of RGCs as they establish the optic chiasm. These maneuvers include maintenance of fasciculation as the axons enter the ventral diencephalon, crossing the midline at the proper anteroposterior point and avoiding the glial knot or preoptic area rostrally; uncrossed fiber divergence from crossed fibers; fasciculation of uncrossed fibers subsequent to turning with crossed fibers from the other eye; avoidance of growth into the zone of early-born CD44/SSEA neurons; and formation of the optic tract (Fig. 7.2C). The molecular factors mediating some of these aspects of RGC pathfinding are discussed below.

MOLECULAR FACTORS CRITICAL FOR OPTIC CHIASM DEVELOPMENT In recent years, a number of different molecular factors have been identified that play a critical role in regulating RGC axon guidance at the optic chiasm and in the path from eye to targets (for reviews see Dingwell et al., 2000; Jeffery, 2001; Thanos and Mey, 2001). Due to the current rapid rate of advance in this field of study, it is not our intention to provide an exhaustive list of all the factors implicated in regulating the development of the optic chiasm. Instead, we focus on the function of a few key molecules, many of them relevant to guidance in other midline structures (Kaprielian et al., 2001; Shu and Richards, 2001; Stoeckli and Landmesser, 1998).

NETRIN/DELETED IN COLORECTAL CANCER Netrins are a family of secreted guidance molecules that can both promote and inhibit outgrowth of different types of neurons. Deleted in Colorectal Cancer (DCC) is an immunoglobulin superfamily member that appears to act as a netrin receptor (Culotti and Merz, 1998). In the developing eye, DCC is expressed by RGCs and netrin-1 is strongly expressed around the optic disc and at the junction of the optic nerve and brain. However, in contrast to the spinal cord, no netrin-1 expression is found at the diencephalic midline (Deiner and Sretavan, 1999; Deiner et al., 1997; Höpker et al., 1999). In vitro, netrin-1, acting through DCC, can promote RGC axon outgrowth (de la Torre et al., 1997; Wang et al., 1996). In netrin-1- or DCC-deficient mice many RGC axons fail to exit the optic disc, resulting in optic nerve hypoplasia. Those axons that do exit the eye approach the chiasm at an abnormal angle but then decussate normally (Deiner and Sretavan, 1999; Deiner et al., 1997). This abnormal angular growth of the RGC axons as they approach the chiasm is not simply a consequence of the decreased number of axons found in the optic nerves; in *Pax6* heterozygous mice that also have optic nerve hypoplasia, the optic chiasm develops

normally (Deiner and Sretavan, 1999). The netrin-1- and DCC-deficient mice also exhibit defects in the formations of other hypothalamic axon pathways and in the location of specific subpopulations of neurons, raising the possibility that the abnormal trajectory of the RGC axons may occur secondarily to these patterning defects. Nevertheless, these results clearly show that unlike spinal commissural axons, guidance of RGC axons to the ventral midline of the diencephalon does not require midline expression of netrin-1.

EPHS/EPHRINS The Eph receptors constitute the largest subfamily of receptor tyrosine kinases and can be subdivided into two groups: the EphA receptors that bind preferentially to the glycosylphosphatidylinositol (GPI)-linked ephrinA ligands and the EphB receptors that bind preferentially to the transmembrane ephrinB ligands (Flanagan and Vanderhaeghen, 1998). Specific Ephs and ephrins are expressed in distinct regions of the developing retina and brain and are key regulators of many different aspects of nervous system development, including the establishment of the topographic map of visual projections within the tectum/superior colliculus (Holder and Klein, 1999). More recently, these molecules have been implicated as playing a pivotal role in regulating axon growth and divergence at the optic chiasm. Both the receptors and ligands are expressed in complex patterns in the developing retina and ventral diencephalon at the time when RGC axons are actively navigating through this region (Marcus et al., 1996a, 2000; Nakagawa et al., 2000). Eph/ephrins are expressed by the midline radial glia and in a region caudal to the site where the chiasm develops. Clusters of Eph/ephrin-expressing cells derived from the ventral diencephalon inhibit RGC axon outgrowth; this inhibition is reduced in the presence of soluble EphA5-Fc that blocks Eph/ephrinA subclass interactions (Marcus et al., 2000). Thus, Ephs/ephrins may play a role in generally dampening the growth of retinal axons within the chiasm region.

The divergence of RGC axons at the chiasm midline may also be critically regulated by Eph/ephrin interactions. In *Xenopus*, during the period when the permanent ipsilateral projection is actively being generated, but not at earlier stages, there is discrete expression of an ephrinB at the site where the RGC axons diverge. Ectopic expression ephrinB2 at the midline in early tadpoles induces a precocious ipsilateral projection that arises specifically from EphB-expressing RGCs in the ventral retina. Furthermore, comparative studies between species that have (postmetamorphic frogs, mice) and do not have (premetamorphic frogs, fish, chicks) a permanent ipsilateral projection at the optic chiasm have shown that there is a correlation between midline ephrinB expression and divergent RGC axon growth at the chiasm (Mann and Holt, 2001; Nakagawa et al., 2000). In mice, the ephrinB expressed at the chiasm

midline has been identified as ephrinB2. Similar to the situation in frogs, its expression in this region is under tight temporal regulation and can only be detected during the period when the ipsilateral projection is produced (Marcus et al., 2000; L. Erskine, S. E. Williams, and C. A. Mason, unpublished results). A critical challenge for the future will be to establish if this midline expression of ephrinB is both necessary and sufficient for the establishment of the ipsilateral pathway.

The expression of ephrins by the RGCs themselves may also play a critical role in regulating chiasm development. In the developing retina, both ephrinA and ephrinB ligands are expressed in complementary gradients to their respective receptors (Marcus et al., 1996a). Overexpressing ephrinA2 or ephrinA5 in the chick retina results in the establishment of a stable ipsilateral projection at the optic chiasm as well as topographic projection errors in the tectum (Dütting et al., 1999; Hornberger et al., 1999). The ipsilaterally projecting axons diverge from their normal path proximal to the midline and are maintained long after the transient ipsilateral projection in chick is eliminated normally. The mechanisms by which ephrin overexpression in the retina perturbs axon guidance at the chiasm remain unclear.

ROUNABOUT (ROBOS)/SLITS The Roundabout (Robos) and Slits are highly evolutionarily conserved families of axon guidance receptors and ligands, respectively. They were initially identified in *Drosophila*, where they play a critical role in regulating axon divergence at the midline of the developing nervous system (Kidd et al., 1999; Seeger et al., 1993). To date, three Robo (Robo1, 2, 3) and three Slit (Slit1, 2, 3) homologs have been identified in vertebrates and implicated as possible mediators of a number of axon guidance events within the developing spinal cord and brain (for reviews see Brose and Tessier-Lavigne, 2000; Nguyen-Ba-Charvet and Chedotal, 2002).

In the developing visual system of both mouse and fish, one of the three *robos* (*robo2*) is expressed by RGCs from the time that the first RGC axons begin to extend into the brain and, within the diencephalon, the Slits are expressed around the path of the RGC axons as they extend through the optic chiasm and toward their targets (Erskine et al., 2000; Fricke et al., 2001; Hutson and Chien, 2002; Niclou et al., 2000; Ringstedt et al., 2000). *Slit1* is expressed dorsal to and around the optic nerve as it enters the brain and, more weakly, by the CD44/SSEA neurons. *Slit2* is strongly expressed in the preoptic region directly dorsal and anterior to the chiasm. Interestingly, in all species examined to date, none of the *slits* are expressed in the region where the RGC axons actually cross the midline. Using in vitro assays, both Slit1 and Slit2 have been found to induce collapse and inhibit outgrowth of RGC axons (Erskine et al.,

2000; Niclou et al., 2000; Plump et al., 2002; Ringstedt et al., 2000).

Direct evidence that the Robos and Slits play an essential role in regulating optic chiasm development has come from analysis of mutants with disrupted expression of these genes. In *astray* zebrafish mutants the gene encoding *robo2* is defective, and RGC axons make severe axon pathfinding errors (Fricke et al., 2001; Karlstrom et al., 1996; Fig. 7.3). These include straying along the anterior and posterior midline, excessive midline crossing, and defasciculation of the retinal projection. Similarly, in mice with disrupted expression of two of the three *slit* genes (*slit1* and *slit2*), RGC axon pathfinding at the chiasm is grossly perturbed. An ectopic chiasm forms anterior to the normal optic chiasm, and RGC axons stray dorsally and posteriorly along the midline and within the lateral diencephalon (Plump et al., 2002; Fig. 7.3). There also is a significant increase in the number of fibers that extend ectopically into the contralateral optic nerve. These pathfinding defects are not due to alterations in the structure of the brain or in the arrangement of the resident cells of the ventral diencephalon which are positioned similar to those in wild-type mice. Moreover, although it appears that fewer axons may project ipsilaterally in the *slit*-deficient mice, it is likely that this is due to the large number of axons that fail to reach the chiasm midline as opposed to a disruption of the crossing/noncrossing decision per se. These data indicate that Robos and Slits play an essential role in restraining the RGC axons to their normal pathway, and that this function is conserved from fish to mammals.

PROTEOGLYCANS Proteoglycans are composed of a protein core to which various types of carbohydrate side chains (glycosaminoglycans) are attached. They are a structurally diverse group of molecules that can promote or inhibit and consequently direct nerve growth (reviewed by Letourneau et al., 1994). Chondroitin sulfate proteoglycans (CSPGs) are expressed in the developing visual system of several species (Chung et al., 2000a; McAdams and McLoon, 1995) and, in vitro, are potent inhibitors of RGC axon outgrowth (Snow et al., 1991). In mouse, CSPGs are highly expressed at the ventral midline of the diencephalon and posterior to the chiasm in a domain that corresponds to the position of the CD44/SSEA neurons (Chung et al., 2000a). Enzymatic removal of the CS chains from an in vitro semi-intact preparation of the retina, optic nerves, and brain results in severe RGC axon pathfinding defects. RGC axons stray anteriorly away from their normal decussation point, project aberrantly into the contralateral optic nerve, and fail to turn into the ipsilateral optic tract (Chung et al., 2000b). These experiments suggest that CSPGs are an important component of the guidance machinery regulating chiasm development. However, an important caveat to this conclusion is that it is

FIGURE 7.3. Mutations of genes expressed in the ventral diencephalon lead to perturbations of chiasm formation. Disruption of known regulatory genes encoding for transcription factors (*Brn3b*, *Brn3c*, *Vax1*), guidance and signaling molecules (*Robo*, *Slit*, *GAP-43*), or pigment (albino—*tyrosinase*) leads to a change in the proportion of ipsilateral to contralateral fibers, as well as aberrant axon projection in and around the chiasm.

not known if the expression patterns of other guidance molecules are disrupted following the enzymatic treatment.

GAP-43 GAP-43 is a major growth cone protein that is highly expressed in developing and regenerating axons and may form part of the signaling machinery linking extracellular signals to changes in growth cone behavior (Benowitz and Routtenberg, 1997). In mice lacking GAP-43 the optic chiasm fails to develop. RGC cross the midline but then stall

and fail to progress normally into the optic tracts (Strittmatter et al., 1995; Fig. 7.3). Later in development, some axons do manage to extend into the optic tracts. However, the routing of these axons is randomized, with axons of cells distributed throughout the retina projecting into either optic tract (Sretavan and Kruger, 1998). These pathfinding errors are due to cell autonomous loss of GAP-43 in the RGC axon growth cones (Kruger et al., 1998) and appear to occur because, in the absence of GAP-43 function, both ipsilaterally and contralaterally projecting RGC axons are inhibited from extending into the lateral diencephalon. In the absence of GAP-43, RGC axons exhibit reduced growth in the presence of lateral diencephalic cell membranes. Furthermore, culturing a semi-intact preparation of the retina, optic nerve, and chiasm such that, from the chiasm, RGC axons extend out of the brain onto a laminin or collagen substratum or into transplanted mid-brain tissue results in robust RGC axon outgrowth from the chiasm (Zhang et al., 2000).

Regulation of chiasm development by control of gene transcription in the retina and brain

During development, a number of different regulatory genes are expressed in specific domains in the region of the brain where the optic chiasm develops. In general, the expression patterns of these genes reflect the longitudinal subdivisions of the forebrain, and RGC axons tend to grow parallel to these subdivisions (Marcus et al., 1999). Analysis of animals with disrupted expression of regulatory genes has revealed a critical role of specific factors in directing the normal development of the optic chiasm.

PAX2 *Pax2*, a paired box transcription factor, is initially expressed in the ventral half of the optic vesicle but later becomes confined to regions destined to contribute to the optic nerve and chiasm. In *Pax2*-deficient mice, the morphology and patterning of the ventral diencephalon are abnormal and the optic chiasm fails to develop. Instead, all RGC axons project into the ipsilateral optic tracts and never approach the midline (Torres et al., 1996). Ectopic ipsilaterally projecting RGC axons are also found in zebrafish *Pax2* (*noi*) mutants in addition to other RGC pathfinding errors (Macdonald et al., 1997). In both species, there is ectopic expression of the patterning gene *sonic hedgehog* (*Shh*) at the ventral midline. In addition to its well-described role in regulating cell fate, recent work has demonstrated that *Shh* can act as an inhibitory guidance cue for RGC axons (Trousse et al., 2001). Thus, the failure of RGC axons to extend across the midline in *Pax2*-deficient animals may result from the inhibitory influence of the ectopic *Shh* expressed in this region.

VAX1 AND VAX2 The homeobox gene *Vax1* is normally expressed at the ventral midline of the developing forebrain and by the optic nerve. In mice lacking *Vax1*, the RGC axons fail to enter the brain in significant numbers and, consequently, do not form an optic chiasm (Fig. 7.3). Disruption of *Vax1* expression does not grossly affect the expression patterns of other regulatory genes in the ventral diencephalon. However, the expression of distinct axon guidance molecules is altered. The attractive guidance cue, netrin-1, is no longer expressed along the optic pathway whereas expression of the inhibitory signal Slit1, is maintained. Thus, it appears that *Vax1* regulates chiasm development by controlling the disposition of specific guidance cues within the ventral diencephalon (Bertuzzi et al., 1999; Hallonet et al., 1999).

The expression of the related factor, *Vax2*, is normally restricted to the ventral part of the retina. In two independently generated mouse lines with disrupted expression of *Vax2*, the patterning of the retina was found to be abnormal and RGC axons make targeting errors in the superior colliculus (Barbieri et al., 2002; Mui et al., 2002). However, these studies reported differential effects on RGC axon guidance at the optic chiasm. In the first study, no effect was found on the development of the ipsilateral pathway despite the fact that the projection from the ventral temporal retina was the most perturbed in the contralateral superior colliculus (Mui et al., 2002). By contrast, Barbieri et al. (2002) reported almost the complete absence of the ipsilateral projections. The reason for this discrepancy is not known. Thus, further study will be required to clarify the role of *Vax2* in optic chiasm development.

BRN3B/C The *Brn3* POU domain transcription factors are expressed early in retinal development and play an essential role in regulating the differentiation and survival of RGCs. They also have been implicated in forming part of the hierarchical program that regulates the response properties of RGC axons to guidance cues along their pathway. In mice with disrupted expression of *Brn3b*, fewer than normal RGCs are generated and the axons of those cells that are produced make pathfinding errors at numerous points along their pathway (Fig. 7.3). At the optic chiasm, some axons stall and fail to exit the chiasm, while others project aberrantly into the ipsilateral optic tract or contralateral optic nerve, or ventrally along the midline. The establishment of the topographic map in the superior colliculus is also perturbed (Erkman et al., 2000). Interestingly, in mice lacking both *Brn3b* and *Brn3c*, similar RGC axon guidance defects are observed, except that no axons project ipsilaterally (Wang et al., 2002). This raises the possibility that *Brn3c* may be a critical component of the signaling machinery specifying ipsilaterally projecting RGCs.

In summary, mutations of genes expressed in the ventral diencephalon lead to perturbations of chiasm formation and disruption of guidance molecule expression in this region. Mutation of these and other genes expressed in the retina also cause aberrant chiasm formation. Understanding of the role of regulatory genes in directing chiasm development will depend on discerning the contribution of these genes to patterning of the ventral diencephalon and to the specification of RGC response properties during growth toward targets.

Defects in chiasm development are associated with lack of ocular pigment

In albino animals, a point mutation in tyrosinase, the key enzyme in melanin synthesis, results in the absence of pigment in the retinal pigment epithelium (RPE) and severe visual deficits. These include underdevelopment of the central retina, a reduction in the number of rod-photoreceptor cells, and an abnormally small, uncrossed RGC projection at the optic chiasm (Dräger and Olsen, 1980; Guillery et al., 1995; Jeffery, 1997; Rice et al., 1995; Fig. 7.3). Insertion of a functional tyrosinase gene into albino mice restores normal pigmentation and normal RGC projections at the optic chiasm (Jeffery, 1997; Jeffery et al., 1994), demonstrating that the tyrosinase gene is involved in determining the projection phenotype of RGCs. However, it is unlikely that tyrosinase itself is the critical factor. A decrease in the number of ipsilaterally projecting RGC axons is found in other pigment-deficient mutants with normal tyrosinase activity (Balkema and Dräger, 1990). Mutations in genes responsible for melanin synthesis, packaging, and transport all cause albino-like visual defects (McGarry et al., 1999; Oetting and King, 1999; Orlow and Brilliant, 1999), as does a loss of function of the OA1 (ocular albinism 1) gene product, a G-protein couple receptor implicated in regulating melanosome biogenesis (Samaraweera et al., 2001; Schiaffino et al., 1999). It is not known which component of the pigment pathway—factors leading to melanin formation or melanin itself—affects the ratio of crossed to uncrossed RGC axons.

There are two possible sites of gene action that could lead to an imbalance in the number of cells that cross or do not cross the midline in hypopigmented mammals. The first is the retina, leading to a decrease in the induction of ipsilaterally projecting RGCs. The second is the optic chiasm, the site of retinal axon divergence. Pigment cells in the optic stalk are avoided by RGC axons and have been implicated in directing RGC axon guidance at the midline (Silver and Sapiro, 1981). Using anatomical techniques and a retinal-chiasm chimeric coculture approach, Marcus et al. (1996b) provided direct evidence that the albino mutation acts on

specification of RGC growth properties at the retinal level. They found that the morphology and cellular composition of the ventral diencephalon of albino animals are indistinguishable from those of normally pigmented animals. Furthermore, in vitro, axons from pigmented retinal explants behaved similarly when cultured on diencephalic cells derived from either pigmented or albino animals, whereas the percentage of axons from albino retinas strongly inhibited by these cells was markedly reduced. This strongly suggests that the albino mutation acts by respecifying the properties of the RGCs rather than by altering the signals for divergence associated with the diencephalic midline (Marcus et al., 1996b). In support of this, no correlation has been found between the size of the adult ipsilateral projection and the existence of optic stalk melanin during development (Colello and Jeffery, 1991).

The mechanism by which lack of pigment affects the size of the uncrossed pathway is enigmatic. Evidence that the effect is extracellular/non-cell autonomous comes from mosaic animals in which the size of the uncrossed projection correlates with the amount of pigment in the RPE and not with the genotype of the RGCs. During development, proliferating retinal progenitor cells are located in a ventricular zone adjacent to the RPE and are in contact with the RPE layer at the time of mitosis. Furthermore, the timing of pigment production and the onset of neurogenesis in the retina are tightly correlated. In retinæ of normally pigmented mice, tyrosinase expression is first detected at E10.5, and the first melanin and RGCs are produced approximately half a day later (Colello and Guillery, 1990; Dräger, 1985). Birthdating studies of pigmented mice (Dräger, 1985) have shown that RGCs that project either ipsilaterally or contralaterally are born concurrently but that the production of ipsilateral cells terminates at E16, while the birth of contralaterally projecting cells continues until birth. This, combined with comparisons of patterns of cell generation in albino and normally pigmented retinæ, has led to the suggestion that perturbations in the temporal features of neurogenesis (Ilia and Jeffery, 1996) and/or retinal maturation (Webster and Rowe, 1991) underlie the abnormal development of the albino retina. More recently, using cell type-specific markers and refined birthdating methods, it has been demonstrated that, relative to normally pigmented mice, more RGCs are born in early stages of neurogenesis in the albino retina and that the spatial organization of these cells is perturbed (Rachel et al., 2002). Thus, the evidence to date suggests that spatiotemporal defects in RGC production in the albino retina act to alter the proportion of cells with axons that project ipsilaterally and contralaterally at the optic chiasm.

How might a factor in the pigment pathway affect the cell cycle kinetics and projection phenotype of cells located on

the opposite side of the retina? It is possible that the RPE normally emits a diffusible signal that acts to regulate retinal neurogenesis. Alternatively, melanin may act as a sink for a factor or ion produced in the neural retina (Dräger, 1985) that, in excess, perturbs normal development. Further studies will be needed to distinguish between these possibilities and identify the factor in the pigment pathway essential for normal retinal development.

Failure of optic chiasm development in the absence of other brain abnormalities

In a breed of Belgian sheepdogs with an autosomal recessive mutation in an unknown gene, the optic chiasm fails to develop (Williams et al., 1994). Instead, all RGCs, irrespective of their site of origin within the retina, extend into the ipsilateral optic tract. Despite the fact that approximately 80% of RGCs in these animals project to targets on the wrong side of the brain, the RGCs terminate appropriately in their targets. Consequently, in the LGN, noncongruent mirror-image maps of visual space are formed in adjacent layers. Other than elimination of the optic chiasm, no other gross brain malformations have been identified in these dogs. The retinae and optic nerves are also relatively normal in size (Hogan and Williams, 1995).

Similar defects in optic chiasm development have been described in a small number of humans (Fig. 7.3). This condition, termed *nondecussating retinofugal fiber syndrome*, results in complete absence of the optic chiasm and projection of all RGC axons to ipsilateral visual targets (Apkarian et al., 1994). With the exception of abnormal eye movements, the affected individuals are otherwise mentally and physically normal and have no other gross brain abnormalities. Their vision is also remarkably normal, possibly as a result of transfer of visual information between the visual hemispheres via the corpus callosum (Victor et al., 2000).

The achiasmatic phenotype is opposite to that found in albinism, in which the size of the ipsilateral projection is increased (see above and Fig. 7.3). However, it is unlikely that this represents a true anti-albino. In a few of the Belgian sheepdogs a small, abnormal chiasm develops. However, in these animals there is no peripheral shift in the retinal line that separates the crossed and uncrossed RGCs, as found in albinism. Instead, the cells that give rise to the residual crossing axons are distributed throughout the retina (Hogan and Williams, 1995).

Summary and perspectives

The optic chiasm represents one of the simpler choice points for growing axons in the developing nervous system. At this

site, axons from each eye either cross or turn back from the ventral midline, thereby projecting to targets on both sides of the brain. In recent years, considerable progress has been made in deciphering the cellular and molecular mechanisms underlying the positioning of the X-shaped chiasm within the ventral diencephalon and the divergence of crossed and uncrossed axons. Dynamic imaging studies have brought the behavior of the RGC axons to life, highlighting the tempo of growth and the various forms of growth cone morphology during the different maneuvers along the pathway. Cellular specializations at the ventral midline have been uncovered, and the molecular mechanisms that orchestrate the formation of the optic chiasm are being revealed. Furthermore, a zebrafish genetic screen has produced mutants that affect RGC axon pathfinding (Baier et al., 1996; Karlstrom et al., 1996; Fig. 7.3). As the genes underlying these defects (Karlstrom et al., 1999) and others seen in mice (Rachel et al., 2000) are identified, additional insights into the mechanisms underlying chiasm development should follow.

The molecular factors critical for chiasm development fall into three broad categories: (1) molecules involved in patterning the retina and ventral diencephalon such that the response properties of the RGCs are encoded properly and the guidance cues in the ventral diencephalon are arrayed correctly (e.g., regulatory genes such as *Vax1*, *Pax2*, and *Brn3b*); (2) inhibitory guidance cues that restrain the RGC axons to their appropriate path and ensure that the chiasm forms at the appropriate position along the anteroposterior axis of the diencephalon (e.g., Slits, ephrins, CSPG); and (3) guidance cues that have a differential effect on ipsilateral and contralateral projecting RGC axons, thereby directing axon divergence at the optic chiasm (ephrinB2). It is clear, though, that many more molecular factors essential for chiasm development remain to be uncovered. It is also important to remember that, in vivo, RGC axons will encounter multiple coexpressed guidance cues simultaneously as they navigate through the chiasm. Thus, in the future, it will be important not only to identify the individual molecules important for chiasm development but also to determine the relative hierarchy of these cues and their interactive effects on RGC axon guidance. In addition, we need to unravel how perturbations in aspects of neurogenesis, as found in albinism, relate to the specification of crossed and uncrossed RGCs.

8 The Development of Eye-Specific Segregation in the Retino-Geniculo-Striate Pathway

BARBARA CHAPMAN

Introduction

In the adult visual system of higher mammals, information from the two eyes is kept separate through the early stages of visual processing. In the lateral geniculate nucleus (LGN), retinal ganglion cell axons from the two eyes project to separate eye-specific layers, and all LGN cells respond only to visual stimulation through one or the other eye. In primary visual cortex, LGN afferents serving the two eyes are segregated into eye-specific patches or stripes in cortical layer IV, forming the anatomical basis for ocular dominance columns (radial columns of cells throughout the depth of the cortex that tend to respond better to visual stimuli presented to one or the other eye). The development of this eye-specific segregation has been widely studied and is used extensively as a model system for the development of specific neuronal connections throughout the nervous system.

Historically, the development of eye-specific segregation was first studied using electrophysiological recordings in primary visual cortex. The pioneering work of Hubel and Wiesel showed that ocular dominance columns can be drastically modified by visual experience during a *critical period* early in development. Raising an animal with one eye closed (monocular deprivation) results in a primary visual cortex where cells can no longer respond to visual stimuli through the eye that was closed and are driven almost exclusively by the eye that had remained open (Hubel and Wiesel, 1970; Wiesel and Hubel, 1965). Transneuronal labeling with radioactive amino acids injected into one eye confirmed that this physiological response to monocular deprivation is associated with a profound reduction in the size of the geniculocortical projection from the closed eye (Hubel et al., 1977; Fig. 8.1). The first hints of the mechanisms underlying the development of eye-specific segregation came from comparing the results of monocular deprivation experiments with those of binocular deprivation experiments in which animals were raised with both eyes closed. In binocularly deprived animals, ocular dominance columns develop normally, with equal inputs to cortex from the two eyes (Wiesel

and Hubel, 1965). This result, together with the fact that ocular dominance columns are present in some species at birth (Horton and Hocking, 1996; Rakic, 1976) clearly indicates that visual experience is not needed for the normal development of ocular dominance columns. Comparison of the results of monocular and binocular deprivation also suggests that development of ocular dominance columns might occur through a competitive process: when neuronal activity in the two eyes is equal, either because both eyes are open (as in normal animals) or both eyes are closed (as in binocularly deprived animals), normal ocular dominance columns form, whereas when the activity in the two eyes is not equal (in monocularly deprived animals), the more active eye has a competitive advantage in maintaining or expanding its LGN afferent connections to the cortex.

This chapter will discuss some of the large number of experiments that have been performed since the groundbreaking work described above. Many of these experiments have been designed to answer the following questions: (1) does the development of eye-specific layers in the LGN follow the same rules as the development of ocular dominance columns? (2) Are there two separate stages of development, an initial phase in which ocular dominance columns are established and a second phase in which they are maintained or undergo plasticity? (3) Is the role of activity in the development and plasticity of eye-specific segregation instructive (patterns of activity actually guide the development of specific neuronal connections) or merely permissive (activity is necessary only to enable other developmental cues that guide connections)?

Development of eye-specific lamination in the lateral geniculate nucleus

The adult pattern of segregated inputs from the two eyes to distinct layers in the LGN is not present early in development. Instead, axons from the two eyes are initially completely overlapping throughout a large portion of the LGN in both carnivores and primates (Linden et al., 1981; Rakic,

FIGURE 8.1. Ocular dominance columns from a normal monkey (*left*) and a monkey subjected to monocular deprivation during the critical period (*right*). In the normal monkey the ipsilateral eye was injected with [^3H]proline, which was transported transneuronally through the LGN and can be seen as the white stripes in the figure. In the normal monkey, the ocular dominance columns from the injected eye (white stripes) and the uninjected eye (dark

stripes) are equal in width. In the monocularly deprived monkey, [^3H]proline was injected into the deprived eye. The white stripes, representing the ocular dominance columns from this deprived eye, are much narrower than those seen in the normal animal or than those from the nondeprived eye (dark stripes) in this animal. (From LeVay et al., 1980.)

1976; Shatz, 1983). During normal development in the carnivore, adult-like eye-specific segregation of afferents gradually appears as axonal branches in inappropriate locations are pruned and branches in appropriate locations grow and elaborate (Sretavan and Shatz, 1986). In the primate, few inappropriate axonal branches are seen during development, and eye-specific segregation of axons appears to occur through the loss of entire retinal fibers innervating inappropriate regions of the LGN (Lachia and Casagrande, 1988; Snider et al., 1998). Evidence that the segregation of retinal axons into eye-specific layers might be occurring through a competitive process in both carnivores and primates came originally from experiments in which one eye was removed from an animal early in development. When the axonal projection from the remaining eye was labeled later in development or in adulthood, axons were found to occupy nearly the entire LGN (Chalupa and Williams, 1984; Rakic, 1981). This indicates that interactions between the afferents from the two eyes, not just interactions between afferents and LGN cells, are necessary for normal eye-specific segregation in the LGN. The normal segregation of retinal afferents into layers in the LGN occurs in utero in most species and before eye opening in others; therefore, this process clearly does not depend on visual experience. However, the process of segregation has been found to depend on spontaneous activity of retinal ganglion cells. Retinal ganglion cells have been shown to be spontaneously active in utero (Galli and Maffei, 1988). Pharmacological blockade of this spontaneous activity prevents the segregation of retino-geniculate afferents (Penn et al., 1998; Shatz and Stryker, 1988), resulting in an LGN where afferents from the two eyes remain overlapping throughout most of the nucleus. The activity blockade,

however, does not prevent axonal growth: axons in treated animals grow extensively (Sretavan et al., 1988). Nor does the activity blockade completely abolish the axons' ability to interact with postsynaptic targets: the axons in treated animals are not confined to the normal layers of the LGN, but they are confined to the LGN itself and do not grow into adjacent nuclei (Sretavan et al., 1988). These results suggest that during normal development a competitive, activity-dependent process is responsible for driving eye-specific segregation in the LGN.

Further evidence for competition between axons from the two eyes during development of eye-specific layers in the LGN comes from experiments in which the amount of neuronal activity in one eye is pharmacologically altered. If spontaneous activity in one eye is completely blocked, then the LGN territory occupied by that silenced eye's ganglion cell axons is reduced, while the territory occupied by axons from the normal eye is expanded (Penn et al., 1998). Conversely, if the amount of spontaneous activity in one eye is pharmacologically increased, that eye's axons gain territory in the LGN (Stellwagen and Shatz, 2002). These experiments show that the more active eye always "wins," regardless of whether it has normal or enhanced levels of activity, while the less active eye always "loses," regardless of whether it has normal or reduced levels of activity. The LGN layers, however, develop normally when both eyes are pharmacologically induced to have more spontaneous activity than normal (Stellwagen and Shatz, 2002), again indicating the importance of relative levels of activity between the two retinæ.

The activity-dependent, competitive processes involved in the development of eye-specific segregation in the LGN

also appear to be important (at least for some period of time) in maintaining segregation. If spontaneous activity is blocked during a developmental time immediately after the retinogeniculate afferents have segregated, the axons actually desegregate and the projections from the two retinas become completely overlapping in the LGN (Chapman, 2000).

Normal development and plasticity of ocular dominance columns

Until recently, it has been generally accepted that the initial development of ocular dominance columns, like the development of eye-specific segregation in the LGN, involves an activity-dependent, competitive process. Transneuronal labeling with radioactive amino acids showed that early in development the geniculate afferents serving one eye spread uniformly along layer IV, suggesting that at this age the projections serving the two eyes are completely overlapping. Gradually, over a period of weeks, fluctuations in the label-

FIGURE 8.2. The development of ocular dominance columns in the cat. In each panel, the ipsilateral eye was injected with [^3H]proline. Different transneuronal labeling patterns are seen at the different developmental stages illustrated in the four panels. At the earliest age, labeling is continuous throughout cortical layer IV; increasingly strong fluctuations in label are seen at later ages. These results were originally interpreted to mean that LGN axons serving the two eyes are initially overlapping in the cortex and gradually segregate out into ocular dominance columns over time. (From LeVay et al., 1978.)

ing density appear and grow stronger, presumably representing segregation of the two eyes' afferents into adult-like ocular dominance columns (Crair et al., 2001; Finney and Shatz, 1998; LeVay et al., 1978; Ruthazer et al., 1999; Fig. 8.2). If activity is blocked in both eyes during development, the segregation into ocular dominance columns is never seen. Instead, the immature pattern of uniform labeling in layer IV is maintained, suggesting that activity is necessary for geniculocortical afferents to segregate into ocular dominance columns (Stryker and Harris, 1986).

However, recent experiments have raised doubts about this view of the development of ocular dominance columns. Injections of neuronal tracers into an individual eye-specific LGN layer in ferrets at different ages show that initially axonal arborizations are very sparse, and it is impossible to tell whether or not axons from the two eyes are segregated. Quite soon after the axons grow into the cortex, however, such LGN injections produce a patchy pattern of labeling in the cortex, reminiscent of ocular dominance columns (Crowley and Katz, 2000; Fig. 8.3). This labeling pattern is seen at postnatal day 16–18 in the ferret, equivalent to E 58–60 in the cat, 2 to 3 weeks earlier than columns were seen in transneuronal labeling studies in cats and ferrets (Crair et al., 2001; Finney and Shatz, 1998; LeVay et al., 1978; Ruthazer et al., 1999).

What could explain the differences between the LGN labeling results, which suggest that columns appear extremely early in development, possibly without a period of initial overlap of axons serving the two eyes, and that the transneuronal results show much later segregation of axons from an initially overlapping projection pattern into columns? The authors of the new study suggest that the transneuronal results might be artifactual (Katz and

FIGURE 8.3. Early ocular dominance columns revealed by injection of label into a single LGN layer in the ferret. Patchy labeling of geniculocortical afferents thought to represent ocular dominance columns can be seen in very young animals 2 to 3 weeks earlier in development than ocular dominance columns are seen with transneuronal labeling techniques. (From Crowley and Katz, 2000.)

Crowley, 2002). The initial uniform labeling pattern seen in the transneuronal study could be due to the fact that “spillover” of the transneuronal label from one LGN layer to another occurs in very young animals. This means that in the youngest animals, LGN axons serving both eyes could have taken up the label, such that the cortical pattern of continuous labeling reflects the result which would be expected if both eyes’ ocular dominance columns were labeled (Crowley and Katz, 2000). However, this explanation cannot account for the fact that other methods of assessing the development of ocular dominance columns, including metabolic labeling with 2-deoxyglucose (Rathjen and Löwel, 2000), electrophysiological recordings (Crair et al., 2001), and optical imaging of intrinsic signals (Crair et al., 2001), are all in agreement with the transneuronal labeling studies, showing no eye-specific segregation before 2 weeks of age in the cat, and gradually developing columns appearing first between 2 and 3 weeks.

Alternatively, it is possible that the differences between the transneuronal labeling pattern and that seen from LGN injections could be explained if the patches seen following LGN injections do not really represent ocular dominance columns. This explanation seems unlikely, given that these patches closely resemble adult ocular dominance columns in their spacing and degree of segregation (Crowley and Katz, 2000). However, such an explanation remains possible given that it has not been feasible to label axons from the two eyes’ LGN layers with different labels to show that the gaps in the patches seen in labeling from one layer are in fact filled in by axons from the other layer. It seems that resolving the differences in results seen with transneuronal labeling versus those seen with LGN injections will have to await further experimentation.

If, in fact, the results from the LGN injection experiments do represent the true story of how ocular dominance columns form, what are the broader implications of these results? The LGN injections show very early appearance of ocular dominance columns without an obvious initial period of overlap of axons serving the two eyes, which can be interpreted to mean that ocular dominance columns form by an activity-independent process, possibly guided by molecular cues in visual cortex (Crowley and Katz, 2000). How could such a view be reconciled with earlier experiments showing that retinal activity blockade prevents the segregation of axons serving the two eyes into ocular dominance columns (Stryker and Harris, 1986)? If ocular dominance columns do in fact form very early in development, the lack of segregation seen with retinal activity blockade might not represent the blocking of the normal development of ocular dominance columns, but might rather represent the desegregation of previously existing columns (Crowley and Katz, 2000) similar to the desegregation of eye-specific layers in the LGN seen with retinal activity blockade (Chapman,

2000). Additional evidence that the initial formation of ocular dominance columns might be activity independent comes from experiments in which both eyes were removed early in development. In such animals, apparent ocular dominance columns could still be seen via injections of tracer into individual LGN layers, showing that at least retinal activity is not needed to form the patchy geniculocortical projections (Crowley and Katz, 1999).

None of these results, however, rule out a role for activity in the development of ocular dominance columns. Even if these results are taken at face value, it is still possible that activity is necessary for column formation. The early appearance of columns visualized by LGN injections still occurs about a week after axons grow into the cortex, so it is possible that spontaneous retinal activity during this time period is needed for the normal formation of columns (Katz and Crowley, 2002). In fact, there is direct evidence that neuronal activity may be important this early in development; the blockade of neuronal activity during the time period when geniculocortical axons are first growing into layer IV has been shown to radically alter their arborizations, prevent normal branching, and interfere with target selection (Catalano and Shatz, 1998; Herrmann and Shatz, 1995). The apparent existence of ocular dominance columns in animals in which both eyes were removed early in development also cannot rule out a role for neuronal activity in the development of columns. Highly correlated activity within LGN layers and less correlated activity between layers may be present in the absence of retinal input and could be sufficient to drive ocular dominance segregation by an activity-dependent process (Katz and Crowley, 2002; Weliky and Katz, 1999). This explanation is supported by the fact that in animals without eyes, ocular dominance columns are apparently maintained, whereas in animals with pharmacologically silenced retinas, ocular dominance columns apparently desegregate; this suggests that LGNs without retinal input must retain the patterns of activity necessary to maintain ocular dominance columns.

Convincing evidence that ocular dominance column formation occurs through activity-independent mechanisms would require the identification of molecular cues involved in the process; so far, no such molecules have been found. On the other hand, there is also little direct evidence that the initial development of ocular dominance columns does require activity. It is clear that a competitive activity-dependent process *can* produce segregated columns from the two eyes resembling cortical ocular dominance columns. One example of such ocular dominance-like segregation is seen in the tectum of the three-eyed frog. In normal frogs, each tectum receives retinal ganglion cell input only from the contralateral eye. However, if a third eye is surgically transplanted into the developing frog, axons from this eye project to an optic tectum, which also receives input from

one of the normal eyes. The axons from the transplanted and normal eyes segregate into a regular pattern of alternating columns in the tectum (Constantine-Paton and Law, 1978; Fig. 8.4). The development of these columns is prevented by retinal activity blockade (Reh and Constantine-Paton, 1985). The tectal ocular dominance columns develop from an initially completely overlapping state by an activity-dependent process, similar to the traditional model of how cortical ocular dominance columns develop. In this system, where normally each tectum is enervated by only one eye, there is no reason to suspect the presence of any molecular cues in the tectum that could guide the development of ocular dominance columns. Realistic-looking ocular dominance columns can also be produced by computational models using purely activity-dependent competitive mechanisms and starting with an initial state of overlapping axons serving the two eyes (Erwin and Miller, 1998; Jones et al., 1991; Miller et al., 1989; Swindale, 1980; Von Der Marlsburg and Willshaw, 1976). Thus ocular dominance columns *could* develop using activity instead of molecules. However, convincing proof that the development of cortical ocular dominance columns *does* involve activity would require, first, that the controversy over the timing of the development of ocular dominance columns be resolved and, second, that experiments blocking activity be redone at the correct developmental time.

Despite the controversy over the timing and mechanisms of the initial establishment of cortical ocular dominance columns, there is good agreement that ocular dominance columns do undergo activity-dependent plasticity during a critical period of development. The first manipulations demonstrating critical period plasticity involved altering visual experience. As discussed in the Introduction, monocular deprivation results in profound changes in the ocular dominance columns, with the closed eye losing much of its cortical territory and most of its ability to drive cortical cells (Hubel and Wiesel, 1970; Hubel et al., 1977; Wiesel and Hubel, 1965). Other manipulations of visual experience during the critical period, such as experimentally induced strabismus, also affect the ocular dominance columns. In strabismic animals, in which the misalignment of the eyes causes the animal to see double, neurons in primary visual cortex become almost exclusively monocular, driven by one or the other eye but not by both (Hubel and Wiesel, 1965; Van Sluyters and Levitt, 1980). This physiological change is accompanied by an anatomical change; the ocular dominance columns seen by transneuronal labeling are sharper in strabismic animals than in normals (Shatz et al., 1977). Visual experience is not necessary, however, to induce ocular dominance plasticity during the critical period. An imbalance in the levels of spontaneous retinal activity between the two eyes in the absence of vision can be produced by pharmacologically blocking all action potentials from one retina

FIGURE 8.4. Tectal “ocular dominance columns” can be seen in three-eyed frogs. *Top*: [^3H]proline was injected into one eye of a normal frog, resulting in labeling of the entire superficial neuropil of the contralateral tectum. *Bottom*: [^3H]proline was injected into one normal eye of a three-eyed frog. Labeling in the contralateral tectum shows a striped pattern of alternating inputs from the labeled eye and the unlabeled supernumerary eye reminiscent of cortical ocular dominance columns. (From Constantine-Paton, 1981.)

while lid suturing the other eye (to prevent form vision) or raising the animals in the dark (to prevent all vision). In such animals, tested after the pharmacological blockade wears off, many more cortical cells respond to vision through the spontaneously active eye than through the eye which had all activity blocked (Chapman et al., 1986). In this regard, plasticity of ocular dominance columns is very similar to the plasticity seen in the segregation of retinal axons in the LGN; the process does not require vision, and the more active eye “wins.”

Even disregarding the controversy over the mechanisms involved in the initial establishment of ocular dominance columns, there is some evidence that ocular dominance plasticity may be distinct from initial ocular dominance development. First, there is a clearly *defined precritical period* during which an imbalance in the activity of the two eyes does not effect ocular dominance, as assessed either physiologically (Crair et al., 1998; Hubel and Wiesel, 1970; Issa et al., 1999; Olson and Freeman, 1980) or anatomically (Crowley and Katz, 2000). Second, during this time period, the cortex is strongly dominated both anatomically and physiologically by input from the contralateral eye (Crair et al., 2001). These

two facts indicate that the simplest version of a competitive, activity-dependent process cannot be operating during this early time period in the development of ocular dominance columns. If competition were acting in the precritical period as it does during the critical period, then decreasing the activity of one retina during this period would result in ocular dominance plasticity. Additionally, if the same rules were followed during the precritical period, then the contralateral eye would maintain or increase its dominance of the cortex, and the ipsilateral eye would have no way of winning back territory such that the two eyes would have almost equal inputs to the cortex, as they do during the critical period. The existence of the precritical period can be interpreted to indicate that the establishment of ocular dominance columns and the plasticity of those columns occur by completely different mechanisms, with the former involving molecular cues and the latter relying on activity-dependent competition (Crowley and Katz, 2000). However, it is also possible that both periods of development show the same activity-dependent competition; early retinal inputs do not drive LGN cells as strongly as descending corticogeniculate inputs (Weliky and Katz, 1999), so the early development of ocular dominance columns could be driven by activity in the geniculocortical loop following the same rules as later activity-dependent plasticity driven by imbalances in retinal inputs once the retinal inputs become stronger (Crair et al., 2001).

Does activity play an instructive or permissive role in the development of the visual system?

It is clear that activity plays an important role in the development and plasticity of eye-specific segregation in the LGN and in at least the plasticity of ocular dominance columns. A long-standing question in the field of visual system development is whether the role of activity is instructive (the development of connections is specifically guided by patterns of activity) or permissive (some threshold level of activity is necessary for connections to be guided by activity-independent cues) (for reviews, see Crair, 1999; Katz and Shatz, 1996; Sur et al., 1999). At its most basic level, this question was answered by the earliest experiments on ocular dominance plasticity. The rearrangements of connections caused by monocular deprivation cannot be explained by a permissive role for activity. If the deprived eye were losing cortical territory merely because it did not maintain a necessary level of activity, then binocular deprivation would result in the loss of inputs to the cortex from both eyes. Similarly, the plasticity of ocular dominance in response to experimentally induced strabismus rules out a purely permissive role for activity. In strabismic animals, the levels of activity in both eyes are normal; it is only the patterns of activity that have been changed by misaligning the two eyes.

It has been proposed that the instructive role of activity could work through “Hebbian” synapses, that is, synapses that are strengthened when pre- and postsynaptic cells fire together and (by extension) weakened when they fire asynchronously (Hebb, 1949). Such synapses between LGN afferents and cortical cells could explain the monocular deprivation effect. Retinotopy in the geniculocortical projection is well established during the critical period, so neighboring LGN afferents giving input to a single cortical cell would tend to be driven together by visual stimuli in the open eye and would therefore tend to activate the postsynaptic cell, strengthening the synapse. Firing in the deprived eye in the absence of vision, on the other hand, would tend to be random, so neighboring LGN afferents giving input to a single cell would be unlikely to fire together. Therefore, the cortical cell would be less likely to reach threshold, weakening the synapse between an active axon and a silent cortical cell. Hebbian synapses could also explain the effects of strabismus, in which neighboring LGN axons from each eye are driven by visual stimuli to fire in synchrony, but the visual stimulation of the two eyes is different, so (unlike in normal vision) there is no synchrony of neighboring axons from the two eyes. In this situation, each eye’s LGN axons will strengthen synapses with any cell where they had an initial advantage and weaken other synapses, resulting in a loss of binocularity in the cortex. Correlated activity in the two eyes driven by vision is important not only for maintaining binocularity during normal development, but also for the physiological and behavioral recovery from monocular deprivation. In kittens subjected to monocular deprivation and then allowed to recover normally with both eyes open, substantial recovery of vision through the deprived eye is seen. If, however, strabismus is induced following the monocular deprivation, recovery of vision in the deprived eye is much less complete (Kind et al., 2002).

One approach to testing whether this sort of patterning of activity might be involved in the development of ocular dominance columns is to produce artificial manipulations of the patterns of activity during development. Such manipulations are obviously difficult to perform, but one such experiment has been successfully completed. In this experiment, kittens were raised with all natural retinal activity pharmacologically blocked, but with artificial activity produced by stimulating electrodes placed in the optic nerves or optic chiasm (Stryker, 1986; Stryker and Strickland, 1984). If stimulation alternated between the two nerves such that the two eyes’ inputs were never firing at the same time, then sharper than normal ocular dominance columns developed, similar to those seen in strabismic animals. If, on the other hand, the same amount of stimulation was performed at the chiasm, so that both eyes’ inputs were always firing at the same time, then no ocular dominance columns were seen and LGN axons from the two eyes remained overlapping (or

desegregated) in visual cortex. These results support a role for Hebbian synapses. When both eyes are equally but asynchronously active (as is also the case in strabismus), both eyes will maintain equal input to the cortex by strengthening synapses to any cells where they had an initial advantage, but binocularity will be lost. When the two eyes are equally and synchronously activated, however, synapses from both eyes onto all cortical cells, are strengthened, resulting in no segregation of the inputs from the two eyes.

Other experiments have provided more direct evidence for the existence of Hebbian synapses involved in the plasticity of ocular dominance columns. If an animal is monocularly deprived, and its cortical cells are pharmacologically silenced without affecting the geniculocortical afferents, then the open eye actually become *less* effective than the deprived eye at driving cortical cells (Reiter and Stryker, 1988), and the open eye *loses* territory in the cortex (Hata and Stryker, 1994). Thus, the effects of monocular deprivation do not depend on the levels of activity in the two eyes, but rather on correlations between pre- and postsynaptic activity. If cortical cells are responsive, they will be better driven by the open eye, so their activity will be correlated with that of the open eye, and the open eye will “win.” If, on the other hand, the cortical cells are silenced, their activity will be not be correlated with the open eye and so the open eye will “lose.” Such Hebbian synapses have been directly demonstrated in another series of experiments in which the activity of LGN afferents was controlled by visual stimulation, and the activity of postsynaptic cortical cells was artificially controlled by current injections (Fregnac et al., 1988). In these experiments the ocular dominance of a cortical cell was determined, and then visual stimulation through one eye was paired with artificial firing of the cell while visual stimulation through the other eye was paired with artificial silencing of the cell. After a period of such pairings, the cell increased its response to visual stimulation through the eye whose stimulation had been paired with postsynaptic firing and decreased its response to stimulation through the other eye. This result shows that when pre- and postsynaptic activity of the cell was correlated, the synapse was strengthened, while when activity was uncorrelated, the synapse was weakened.

The results of such experiments, in which manipulating the patterns of activity by changing the correlations either between two sets of inputs (in alternating or synchronous stimulation experiments) or between inputs and target cells (in experiments manipulating postsynaptic activity) causes altered patterns of connectivity, clearly demonstrate that activity plays an instructive role in the plasticity of ocular dominance columns. It has been more difficult to rule out a purely permissive role for activity in the development and plasticity of eye-specific segregation in the LGN. Since the development of eye-specific segregation in the LGN occurs prior to the development of functional photoreceptors, it has

not been possible to determine the effects of manipulations of visual experience like monocular deprivation or strabismus. Instead, until recently, manipulations of activity in experiments studying LGN development involved reducing levels of activity in one or both eyes (Penn et al., 1998; Shatz and Stryker, 1988; Sretavan et al., 1988). Therefore, the results of these manipulations could merely reflect a permissive role for activity; retinal ganglion cell axons in manipulated animals could have changed their behavior due to lack of a threshold level of activity necessary for them to interact with some molecular cue that would normally guide their connections. The recent experiment pharmacologically increasing levels of activity in one eye rules out such a purely permissive role for activity in LGN development (Stellwagen and Shatz, 2002). It remains to be determined, however, whether patterns of activity are truly instructing the development of eye-specific segregation in the LGN; so far, no experiments have directly addressed this question. It is interesting to note that while activity does not play a purely permissive role in the development of eye-specific segregation, it may play such a role in the development of normal lamination of retinal inputs to the LGN. Activity is clearly involved in the development of layers of retinal input to the LGN; blocking activity blocks the formation of layers (Penn et al., 1998; Shatz and Stryker, 1988; Sretavan et al., 1988). However, a number of experiments show that although normal retinal activity leads to normal *segregation* of retinal afferents to the LGN, it may not in all cases lead to normal *lamination* of those afferents. Such a pattern is seen in animals with coat color mutations which affect the number of retinal axons crossing at the chiasm; in such animals, retinal activity is normal and retinal axons from the two eyes to the LGN segregate, but they segregate into patches instead of into layers (Cucchiari and Guillery, 1971; Guillery, 1969). A similar situation is seen in “rewired” ferrets in which retinal input is surgically rerouted to terminate in auditory thalamus; in these animals retinal activity is normal, and inputs from the two eyes are again segregated into patches instead of layers (Angelucci et al., 1997). Finally, segregation of retinal axons into patches instead of layers is also seen in animals in which the segregation of retinal axons in the LGN has been temporarily blocked during the time when retinal axons normally segregate by either a genetic (Muir-Robinson et al., 2002) or a pharmacological (Huberman et al., 2002) manipulation of activity, and then retinal activity is allowed to return to normal. These results suggest that although lamination of retinal axons in the LGN is activity-dependent, patterns of activity are not driving the layout of the layers. Instead there may be molecular cues in the LGN which are involved in layer formation, and whose proper function requires activity during a specific time period of development. Additional evidence for molecular cues involved in layer formation comes from the study of mutant

dogs lacking an optic chiasm. In normal animals, ipsilaterally projecting fibers come from the temporal (lateral) portion of the retina, while contralateral projections come from the nasal (medial) portion of the retina. In the achiasmatic dogs, all retinal fibers from each eye remain ipsilateral. However, the LGN in these animals is relatively normal, anatomically, with well-developed laminae where temporal retinal fibers project to what would normally be the ipsilateral layer and nasal retinal fibers project to what would normally be the contralateral layer (Williams et al., 1994). This result is consistent with the possibility that molecular affinities between retinal axons from the two sides of the retina and LGN cells from the two laminae guide the development of LGN layers in both normal and achiasmatic animals.

Conclusion

In the past four decades since the initial experiments showing plasticity of ocular dominance columns in response to monocular deprivation, a great deal has been learned about the processes involved in the development of eye-specific segregation in the retino-geniculo-striate pathway. It is clear that activity is important for the development and plasticity of segregation in the LGN and for plasticity of ocular dominance columns. It remains unclear whether activity also plays a role in the initial establishment of the columns. Activity has been shown to play a truly instructive role in the plasticity of ocular dominance columns, and to play more than a purely permissive role in the plasticity of retinal afferent segregation in the LGN. The exact patterning of activity needed to cause plasticity in the cortex and the LGN, as well as the role of activity in the initial development of both ocular dominance columns and LGN layers, remains to be discovered. The possible involvement of activity-independent molecular cues in the initial establishment of ocular dominance columns and in the formation of layers in the LGN also remains an active area of research.

9 The Role of Neural Activity in the Development of Orientation Selectivity

CHIAYU CHIU AND MICHAEL WELIKY

Introduction

In the adult visual cortex, neurons are selectively responsive to particular stimulus features in the visual world. One of the most well-known functional properties of cortical neurons is orientation selectivity, in which cortical cells fire most intensely to lines and edges of specific orientations. Since the discovery of orientation-tuned cells in the primary visual cortex (Hubel and Wiesel, 1962), much attention has been devoted to elucidating the mechanisms underlying its development. Current evidence suggests that orientation selectivity develops in two stages: initial establishment followed by subsequent maturation and stabilization. The earliest emergence of orientation selectivity does not require visual experience, as indicated by the observation of well-tuned cells before or at the time of eye opening (Blakemore and Van Sluyters, 1975; Chapman and Stryker, 1993; Wiesel and Hubel, 1963). However, patterned vision after eye opening is essential to the maturation and maintenance of orientation specificity. Disrupting normal visual experience by binocular lid suture or dark rearing causes orientation tuning to deteriorate (Crair et al., 1998; White et al., 2001). Because visual deprivation significantly reduces the level of neural activity within the visual system, it has remained unclear whether natural physiological levels of activity simply permit the development of orientation selectivity to occur or whether patterns of activity have a deeper instructive role. If activity plays an instructive role in the development of orientation tuning, then spatiotemporally organized patterns of spontaneous or visually driven activity would be expected to drive this process. Correlations in firing between different neurons, when combined with Hebbian synaptic developmental processes, would lead to the strengthening or weakening of distinct synapses. Indeed, recent work reveals that manipulations in the precise correlational structure of neural activity block the maturation of orientation tuning (Chapman and Gödecke, 2000; Ramoa et al., 2001; Weliky and Katz, 1999). These results are consistent with correlation-based models of visual cortical development in which patterned spontaneous activity within the immature visual pathway serves to guide the development of orientation preference (Miller, 1992, 1994).

Historically, the cat has served as the model system for studying the role of visual experience on the development of orientation selectivity (Blakemore and Van Sluyters, 1975; Frégnac, 1979; Pettigrew, 1974; Wiesel and Hubel, 1963). However, research has been limited in the cat due to technical difficulties in performing experimental manipulations in young animals during the time when orientation tuning first develops. The recent shift toward the use of the ferret as an animal model in the study of the development of orientation specificity has enabled researchers to investigate activity-dependent processes at the earliest stages of development. This is because while the ferret visual system is quite similar to that of the cat (Law et al., 1988), the ferret is born approximately 3 weeks earlier in development (Linden et al., 1981). In this chapter, we review the literature on the development of orientation specificity in the cat and ferret in order to better understand the multifaceted role that neural activity plays in this process.

Anatomical and functional organization of the early stages of visual processing

Visual input in the cat and ferret is first processed by the retina and the lateral geniculate nucleus (LGN) before being passed on to the visual cortex (Fig. 9.1). Light hitting the retina of each eye is converted into nerve impulses, which are conveyed to the LGN by retinal ganglion cells. There are two main classes of retinal ganglion cells: ON-center and OFF-center. ON-center cells respond best to a spot of light shone onto the center of their receptive field, whereas OFF-center cells fire most strongly when the central area of the receptive field is not illuminated. Cells within the LGN are segregated into two functionally distinct layers. Layers A and A1 receive input from the contra- and ipsilateral retinas, respectively. LGN cells have circular receptive fields like those of retinal ganglion cells. ON- and OFF-center LGN cells exhibit receptive field properties functionally similar to

FIGURE 9.1. Anatomical and functional organization of the early stages of the visual pathway. In the retina, ganglion cells have ON-center and OFF-center circular receptive fields. Ganglion cell axons project to eye- and center-type specific functional layers within the LGN. In the ferret, each eye projects to a separate functional LGN layer, and these layers are divided into ON and OFF sublaminae which receive input from ON-center and OFF-center retinal ganglion cells, respectively. Receptive fields of LGN cells are similar to those of retinal ganglion cells. Cells within the LGN form

synaptic contacts with layer 4 simple cells in visual cortex. Simple cell receptive fields consist of alternating ON and OFF subregions which are formed by the spatial segregation of LGN ON and OFF cell inputs. This receptive field organization endows simple cells with the property of orientation tuning. Cells within the visual cortex are functionally organized into orientation and ocular dominance columns which are jointly mapped across the cortex. (From Weliky, 2000).

those of their ON and OFF retinal ganglion cell counterparts and are intermixed within each layer in the cat. In the ferret, each A and A1 layer is further divided into ON and OFF sublaminae.

LGN neurons make synaptic connections with layer 4 simple cells in primary visual cortex. The receptive fields of simple cells contain elongated ON and OFF subregions, which are formed by the spatial alignment of LGN ON- and OFF-center cell inputs. The parallel arrangement of these subregions endows simple cells with the property of orientation tuning, in which cells preferentially respond to bars or edges oriented at a particular angle. In addition to simple cells, there are two other types of orientation-selective cells: complex and hypercomplex (Hubel and Wiesel, 1962; Pettigrew et al., 1968). Whereas the receptive field of simple cells has elongated ON/OFF antagonistic parallel zones, complex cells tend to have a somewhat larger receptive field that does not exhibit any antagonistic arrangements. Hypercomplex cells can be discriminated from simple and complex cells by their particularly strong inhibitory zones at one or both ends of the receptive field.

Most of the cells in the visual cortex are orientation selective. In the cat, more than 90% of visual cortical neurons are well tuned to stimulus orientation (Bishop and Henry, 1972; Chapman and Stryker, 1993). The adult ferret cortex, however, contains fewer cells, about 75%, that show orientation-specific responses (Chapman and Stryker, 1993). The orientation-selective cells are not randomly arranged within the cortex but exhibit a highly ordered organization. Neurons with similar orientation preferences cluster together to form iso-orientation domains, which extend vertically through all cortical layers to form orientation columns (Hubel and Wiesel, 1962; Thompson et al., 1983). Single-unit electrophysiological mapping of receptive field properties in the visual cortex has demonstrated that cells within a vertical column exhibit similar orientation preferences, irrespective of laminar position. With the advent of optical imaging technology, the high-resolution visualization of orientation-specific responses over a wide area of cortex has become possible (Blasdel and Salama, 1986; Chapman et al., 1996; Grinvald et al., 1986). Optical imaging of intrinsic signals has revealed a number of unique features of the map in the cat and ferret (Bonhoeffer and Grinvald, 1991; Weliky

et al., 1996). In addition to the continuous progression of orientation selectivity across the cortical surface, orientation maps contain singularities such as pinwheel centers, in which neurons exhibiting the entire range of orientation preferences are found (Maldonado et al., 1997), and fractures, in which orientation selectivity abruptly changes between neighboring cells.

The role of visual experience in the development of orientation selectivity

The role of visual experience in the development of cortical orientation selectivity has been extensively studied. Patterned vision in the cat occurs when the eyes open about a week after birth. However, electrophysiological experiments reveal that orientation-selective cells are already present at around that time (Blakemore and Van Sluyters, 1975; Wiesel and Hubel, 1963). The actual number of orientation-tuned cells in visually naive kittens is controversial. Reported values range from 0% (Pettigrew, 1974) to 20% (Blakemore and Van Sluyters, 1975) to 100% (Wiesel and Hubel, 1963). This disparity has been attributed to the low level of responsiveness of the immature cat cortex to visual stimuli. This problem is bypassed in studies using ferrets because the cortex of young ferrets is very responsive to visual stimulation. Orientation selectivity in the ferret is first detected at postnatal day (P) 23, 9–12 days before eye opening (Chapman and Stryker, 1993). Although only 25% of neurons in these very young animals are orientation specific, many of them exhibit orientation tuning as sharp as that found in the adult. The presence of well-tuned cells before eye opening suggests that visual experience is not necessary for the initial development of orientation selectivity. There is recent evidence that orientation-specific responses can be elicited through closed eyelids (Krug et al., 2001), suggesting that visual experience may occur before natural eye opening. This raises the possibility that visually evoked activity may be involved in the formation of orientation-specific cells prior to eye opening. However, rearing young animals in complete darkness such that they never have normal visual experience does not prevent the emergence of orientation-selective cells (Frégnac, 1979; White et al., 2001). Thus, the earliest emergence of orientation selectivity does not require patterned vision.

There is also considerable evidence to suggest that normal visual experience is unimportant for the formation of orientation maps. Cortical maps of orientation preference are present very early in development in both cats and ferrets. Clear orientation maps can be optically imaged by 2 weeks of age in the cat, regardless of whether the eyes are open or not (Crair et al., 1998). Similarly, organized orientation maps have been observed in P31–P36 ferrets at the time of natural eye opening as shown in Figure 9.2 (Chapman et al., 1996). Because these maps are present even in young ferrets reared

in the dark (White et al., 2001), visual experience prior to eye opening cannot account for their formation. The optically imaged orientation maps in the cat and ferret are initially low in signal amplitude, reflecting the immature state of orientation selectivity at the time. Over the course of about a week, as orientation-specific cells increase in number and in their sharpness of tuning, the orientation map matures appreciably, as reflected by the increase in image signal contrast. Despite these significant changes following natural eye opening, the general layout of the orientation map remains remarkably constant (Chapman et al., 1996; Gödecke et al., 1997). Longitudinal analysis of orientation map development within the same animal reveals that the size, shape, and location of iso-orientation domains do not vary from the time maps are first detected. Such stability in map structure demonstrates that the orientation map is initially established independent of visual experience.

Although the initial emergence of orientation selectivity occurs without normal visual experience, subsequent maturation and maintenance of orientation specificity critically depends on exposure to patterned visual stimuli. Studies in the cat and ferret demonstrate that maturation of orientation tuning proceeds only to a limited extent in the absence of normal vision (Crair et al., 1998; White et al., 2001). Immediately following the time of natural eye opening, there is a period of increasing orientation selectivity, even in animals reared in complete darkness. However, continued blockade of normal visual experience past this period of time leads to a progressive degradation of orientation tuning until most cells have become unselective. In the ferret, differential effects of dark rearing versus binocular lid suture upon the development of orientation tuning have been demonstrated (White et al., 2001). Animals are reared either in the dark or under binocular lid suture for varying periods of time ranging from 1 to 5 weeks after eye opening. Binocular lid suture alters visual experience by allowing only very low spatial and temporal frequencies to be passed through the closed eyelids to the retina, while dark rearing abolishes all light-driven retinal activity. Interestingly, as shown in Figure 9.3, lid suture has a more severe effect upon the maturation of orientation tuning than dark rearing. Like normally reared animals, dark-reared animals show an increase in orientation selectivity up to the age of about 6 weeks, approximately 7 to 12 days after eye opening. Following this initial maturational period, orientation tuning in dark-reared animals declines at a constant rate. In contrast, the level of orientation selectivity in the lid-sutured animals is similar to that in normal animals only up to the time of eye opening. With continued deprivation, lid-sutured animals show an immediate decrease in orientation selectivity that is maintained at a steady level after this time. Reduced levels of orientation tuning were observed at all time points after eye

FIGURE 9.2. Development of orientation maps revealed by chronic optical imaging. Single-condition orientation maps recorded at six different ages in one animal. Each row of the figure shows orientation maps recorded in the left primary visual cortex of one ferret at the age indicated at the *left* of the row. Each column of single-condition maps shows orientation maps recorded in response to a particular orientation of a moving square-wave grating (0° = horizontal). For each map, caudal is *up* and medial is to the *left*. The curve in the *upper left corner* of each map indicates the location of the caudal pole of the cortex, behind which the skull

remained intact over the cerebellum. The approximate location of the area 17/18 border can be seen in each image as a *line* rostral to which no orientation activity is seen. In this example, the first clear orientation maps can be seen at P33. Early maps are stronger for horizontal and vertical orientations than for the two obliques. Individual iso-orientation domains remain stable over time and do not change their position, shape, or size. The four *red arrows* shown in each horizontal single-condition map highlight this stability by pointing to particular features in the map. Scale bar, 2 mm. (From Chapman et al., 1996.)

opening in lid-sutured animals compared to dark-reared animals. While these results confirm previous findings that orientation selectivity and orientation maps can develop in the absence of visual experience, they extend these previous findings by demonstrating that visual experience needs to consist of appropriate spatial and temporal frequencies to be effective in driving the subsequent maturation of orientation selectivity.

In the ferret, the development of orientation selectivity occurs in a layer-specific manner (Chapman and Stryker,

1993). At postnatal weeks 4–5, the majority of cells within all cortical layers are unselective for stimulus orientation. Significant differences in the degree of orientation specificity between cortical layers are observed during week 6, when the proportion of cells that are orientation selective has increased only within layers 2/3. Further maturation of orientation selectivity within layer 6 lags behind by about a week or two such that by week 8, the distribution of orientation specificity within layer 6 is equivalent to that within layers 2/3. In contrast, there is very little development of ori-

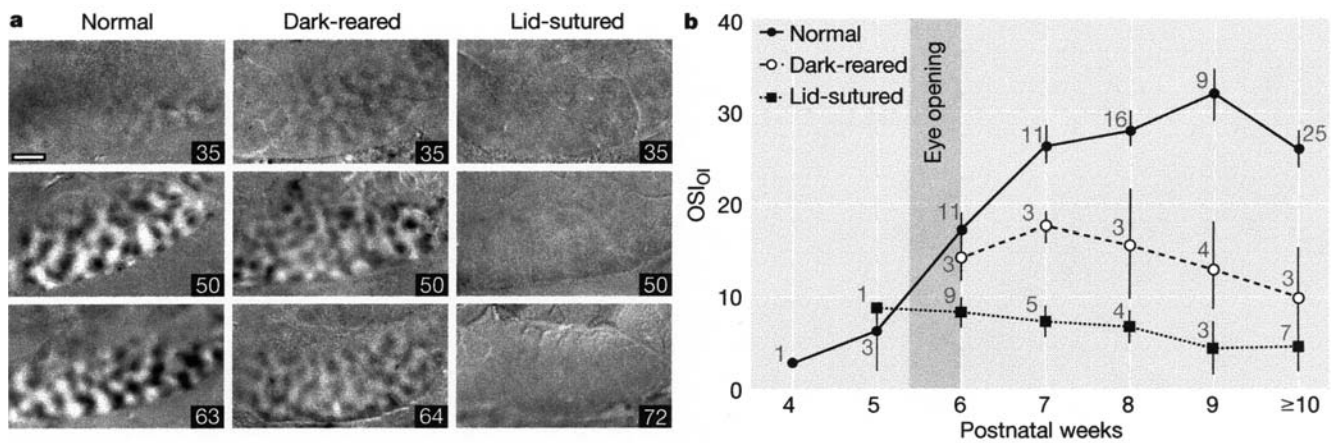

FIGURE 9.3. Quantitative assessment of orientation preference in normal and visually deprived ferrets. *A*, Cardinal difference images show the increase in selectivity seen in normal ferrets after eye opening, the substantial development of the map in dark-reared ferrets, and the devastating effects of lid suture (numbers indicate postnatal age; scale bar: 1 mm). *B*, Plot of OSI_{oi} (mean \pm standard

error) versus postnatal age for each treatment group (numbers next to symbols indicate sample size). After week six, rearing condition was significant ($F_{2,99} = 3.3$, $P < 0.05$), as was the condition/age interaction ($F_{8,99} = 3.6$, $P < 0.001$) with significant differences among all conditions ($P < 0.01$, *post hoc* Tukey-Kramer Honestly Significant Difference). (From White et al., 2001).

entation selectivity in layer 4. Cells within this layer remain relatively unselective for orientation even in adult ferrets. Preventing patterned vision by binocular lid suture for more than 7 weeks results in a reduction in the level of orientation selectivity within layers 2/3 and 6 when compared to normally reared animals at equivalent ages. However, the degree of orientation selectivity in layer 4 is unaffected by visual deprivation.

In the case of the orientation map, visual experience has been demonstrated to play little or no role even late in development. Following 3 weeks of visual deprivation, at a time when selectivity rapidly degrades, clear orientation maps can still be obtained in kittens (Crair et al., 1998; Gödecke et al., 1997). These maps exhibit the same orderly arrangement of cells, with an orientation preference similar to that of normally reared animals. Likewise, in the ferret, even after 64 days of dark rearing, orientation maps are well expressed (White et al., 2001). Experiments rearing kittens in visual environments with a limited set of orientations further reinforce the idea that orientation maps develop independently of visual experience (Sengpiel et al., 1999). These “stripe-rearing” studies demonstrate that although visual experience has been restricted to a narrow range of stimulus orientations, neurons in these animals still exhibit preferences for orientations to which they had never been exposed. This initially experience-independent establishment of orientation specificity results in the formation of a normal orientation map.

Moreover, it has been demonstrated in reverse monocular occlusion experiments that exposure to different visual experiences in the two eyes cannot cause different orientation maps to form (Gödecke and Bonhoeffer, 1996). In

kittens raised with exclusively monocular visual experience for several weeks, the orientation map for the open eye develops. However, the map for the deprived eye cannot be detected, indicating either that the circuitry underlying map formation for the occluded eye is not present or that the connections are intact but cannot be seen by traditional optical imaging techniques. Monocular deprivation has been shown to dramatically decrease the effectiveness of the sutured eye in driving cortical cells, such that most of the cortex is dominated by the open eye (Hubel and Wiesel, 1963). Following reverse occlusion, the orientation map for the originally deprived eye is detectable. This may reflect recovery in the strength and efficacy of the synaptic connections from that eye to the cortex rather than reestablishment of the circuitry underlying map formation. In support of this possibility, there is evidence of a weak residual orientation map for the deprived eye in the cat (Crair et al., 1997). Detailed analysis of the orientation maps for the two eyes optically imaged at separate times during development reveals that they are identical despite never having common visual experience. Thus, the organization of orientation maps is determined and maintained by mechanisms independent of visual experience.

Mechanisms of activity-dependent development

It has been shown that neural activity is necessary for the development of orientation selectivity. Chronically silencing the cortex by infusion of tetrodotoxin (TTX), a sodium channel blocker, completely prevents the maturation of orientation specificity in ferrets (Chapman and Stryker, 1993). At postnatal week 7 and beyond, when orientation

selectivity should have reached adult levels, the number of orientation-selective cells in the TTX-treated animals remains low. The distribution of orientation specificity in these experimental animals is equivalent to that seen in normal animals at postnatal week 4, corresponding to the time when TTX treatment is initiated. Thus, orientation specificity fails to develop in the absence of neural activity. While this experiment demonstrates that neural activity is crucial in the development of orientation selectivity, the precise role of activity cannot be determined.

Current concepts of how activity contributes to the development of neural circuits in general, and of orientation selectivity specifically, revolve around activity playing either a permissive or an instructive role. In a permissive capacity, natural physiological levels of activity simply allow developmental processes to occur, whereas other molecular or genetic mechanisms specify and guide these processes. When activity levels are substantially reduced, these other mechanisms fail to function. For example, manipulations in which neural activity within the visual pathway is pharmacologically blocked (Chapman and Stryker, 1993) or visual experience is abolished, such as in dark rearing (Frégnac, 1979; White et al., 2001), remove a significant portion of neural activity from the visual pathway. For this reason, results from these experiments can only be used to support a permissive role of activity in the development of orientation tuning; such approaches cannot determine whether it is the specific pattern of activity that is important or just the presence of this activity. In order to address directly the instructive role of activity in the development of orientation selectivity, it must be demonstrated that specific manipulation of the spatiotemporal patterns of neural activity disrupts this process.

Recent experiments have tested whether patterns of neural activity carried within the separate ON- and OFF-center pathways are necessary for the development of orientation selectivity in visual cortex (Chapman and Gödecke, 2000). Daily intravitreal injections of DL-2-amino-4-phosphonobutyric acid (APB), an mGluR6 receptor agonist which selectively blocks visually driven activity within the developing ON-center pathway, are made into both eyes starting at P21 in the ferret and continued throughout the period of orientation selectivity maturation until P45–P54. These APB injections completely block the maturation of orientation selectivity, suggesting that neural activity within both ON- and OFF-center visual pathways is required for normal development of orientation specificity. Furthermore, there is a critical period to this activity-dependent process. Orientation selectivity cannot be rescued when APB treatment is continued past P50, and no effects on orientation tuning have been observed when APB injections begin late in development. However, because APB suppresses ON responses, the overall level of activity is reduced in the visual

system. It is also unclear to what extent APB affects spontaneous activity. Therefore, it cannot be determined directly whether orientation selectivity fails to develop following repeated injections of APB due to a reduced level of activity (spontaneous or visually driven) or due to the disruption of specific patterns of correlated activity between ON- and OFF-center cells. A more recent result that is crucial for the proper interpretation of this experiment is that at P21 when the injections were begun, the ON and OFF pathways are not fully segregated. This is demonstrated by the finding that 70% of retinal ganglion cells are multistratified and exhibit both ON and OFF responses (Wang et al., 2001). Segregation of the ON and OFF pathways occurs gradually such that the proportion of ON to OFF ganglion cells decreases to about 12% at P45–P55. Importantly, APB blocked both ON and OFF responses in these multistratified ganglion cells, demonstrating that APB eye injections were likely more disruptive than was previously believed.

Chronic electrical stimulation of the optic nerve has been used to introduce abnormal levels of correlated activity between ON- and OFF-center retinal ganglion cells within the visual pathway in the ferret without reducing the overall level of activity (Weliky and Katz, 1997). In this study, the optic nerve is artificially stimulated only 10% of the time. Despite having normal activity 90% of the time, the orientation tuning of stimulated animals is significantly disrupted, although not completely abolished. Laminar analysis of orientation tuning in control and stimulated animals shows that the disruption is confined to the upper and lower cortical layers. In control animals, cells within the upper and lower cortical layers have significantly sharper orientation tuning than cells located within intermediate layers, which exhibit weak selectivity. Cells within intermediate layers in both stimulated and control animals exhibit similarly weak orientation selectivity; however, in stimulated animals, cells within the upper and lower layers are also weakly tuned. This suggests that chronic stimulation preferentially disrupts intrinsic cortical circuits underlying the sharpening of orientation tuning within superficial and deep cortical layers, similar to the effect seen in binocularly deprived animals (Chapman and Stryker, 1993). While orientation tuning is disrupted, the spatial organization of the orientation map remains unaffected. Optical imaging of orientation preference maps reveals a normal size, spacing, and pattern of orientation domains; however, the magnitude of the signal in these maps is on average 1.6 times weaker than that in control animals. This reduction in signal amplitude would be expected from the extracellular recordings that demonstrate reduced orientation selectivity of individual cells. Since the period of stimulation spanned both pre- and post-eye opening, these results cannot be used to discriminate between the role of spontaneous activity and visually driven activity in the development of orientation selectivity.

Nevertheless, it validates the importance of normal patterns of neural activity in this process.

A recent finding provides a mechanism at the molecular and cellular levels by which the disruption of normal patterns of correlated neural activity may perturb the development of orientation selectivity. With the use of antisense oligonucleotides, Ramoa et al. (2001) demonstrate that the development of orientation selectivity is prevented when cortical *N*-methyl-D-aspartate (NMDA) receptor function is suppressed. NMDA receptors have been postulated to act as a correlation detector for pre- and postsynaptic activity (Bourne and Nicoll, 1993). Under normal conditions, the NMDA receptor is nonfunctional due to a voltage-dependent Mg^{2+} blockade. Mg^{2+} is released when the postsynaptic membrane is sufficiently depolarized by the synchronous firing of a large number of presynaptic cells. In this way, NMDA receptor function may serve to preferentially strengthen the connections between pre- and postsynaptic cells that fire together, thereby causing these cells to wire together. When NMDA receptor function is reduced, the correlational structure of activity in the ON and OFF visual pathways cannot be as reliably conveyed to the postsynaptic cell, thereby disrupting the development of neural connections that underlie orientation selectivity.

These experimental results fit well with a correlation-based model in which activity-dependent interactions within the developing ON- and OFF-center pathways drive the ON/OFF subfield segregation of oriented simple cell receptive fields (Miller, 1994). There are three primary components to this model. First, it presumes that coactive neurons tend to strengthen their inputs to the same postsynaptic cells according to a Hebbian-style rule. Second, the model incorporates an element of competition such that only the synapses of one group of coactive neurons will remain on a given postsynaptic cell, while other groups are eliminated. Finally, computer simulations show that the process of simple cell ON/OFF subfield segregation requires specific patterns of correlated activity among the LGN ON and OFF inputs (Fig. 9.4). In this model, the like center-type inputs (both ON-center or both OFF-center) should be more correlated than the opposite center-type inputs at small retinotopic distances, but at larger retinotopic distances the opposite center-type inputs should be more coactive than the like center-type inputs. In this way, ON and OFF inputs would segregate according to the Hebbian rule so as to form the characteristic elongated parallel zones of ON/OFF subregions, thus conferring orientation selectivity on the simple cells. Such a model can explain the differential effects of binocular lid suture and dark rearing on the development of orientation selectivity in the ferret (White et al., 2001). Abnormal visual experience through light-scattering eyelids may coactivate converging ON- and OFF-center LGN inputs to target layer 4 cells over a broader spatial scale than

FIGURE 9.4. Model requirements for development of simple cell receptive fields. Correlation-based mechanisms of synaptic development lead a cell to acquire a “most-correlated” set of inputs. For such a set to consist of ON-center and OFF-center inputs from spatially segregated adjacent regions, as in the simple-cell receptive field at the right (*white*: ON inputs; *black*: OFF inputs), these inputs must tend to fire together. This is illustrated at the *top left*: a local group of ON-center cells should tend to fire together and to be coactive with OFF-center cells in adjacent regions. This statistical tendency can be summarized by a correlation function, C^{ORI} (*bottom left*). C^{ORI} describes, for a given retinotopic separation between two inputs, the degree to which two inputs of the same center type (both ON-center or both OFF-center) tend to be more coactive than two inputs of opposite center types (one ON-center and one OFF-center). If, as illustrated, C^{ORI} is positive at smaller retinotopic separations (meaning that same center-type pairs are more coactive than opposite center-type pairs at those separations) but negative at larger retinotopic separations (opposite center types more coactive than same center types), then simple cells will form under correlation-based development of geniculocortical (GC) weights. (From Miller et al., 1999.)

in normal animals. This has the effect of increasing the correlation of these inputs, thus inhibiting their further segregation into ON- and OFF-center bands within layer IV simple cell receptive fields (Miller et al., 1999). It is possible that orientation tuning is less severely disrupted in dark-reared animals because patterns of spontaneous activity, which have components appropriate for the continued maturation of orientation tuning, are preserved under this condition, while in lid-sutured animals these endogenous patterns of spontaneous activity are overwhelmed by visually evoked activity having an improper correlational structure.

If neural activity plays an instructive role in the establishment of orientation selectivity, dark-rearing studies demonstrate that this must occur early in development using spontaneously generated activity. As early as birth, periodic waves of action potentials propagate across the ferret retina (Meister et al., 1991). Thus, these retinal waves generate a pattern of correlated activity in which neighboring retinal ganglion cells are more coactive than those that are separated by larger retinotopic distances. Furthermore, spontaneous activity among like and opposite center-type cells

within the developing LGN has a highly specific correlational structure (Weliky and Katz, 1999). Correlated activity is higher between like center-type cells and weaker between opposite center-type cells within the same eye-specific layer. At the level of the cortex, synchronous bursts of activity occur over large visual cortical regions (Chiu and Weliky, 2001). Multielectrode recordings reveal long-range spatial patterns of coincident activity between discrete cortical patches, which may link iso-orientation columns. However, this relationship between patterns of correlated activity and the organization of orientation selectivity is yet to be established.

While the exact mechanisms guiding the development of orientation selectivity are not well understood, it has become increasingly clear that neural activity is intimately involved in the process. Before eye opening, patterns of spontaneous activity may drive the initial establishment of orientation selectivity and orientation preference maps. After eye opening, it has been suggested that the maturation of orientation selectivity requires appropriate patterns of neural activity evoked during visual experience. In this way, both endogenous and visually driven activity appears to play important roles in the development of orientation selectivity at different times.

Conclusions

By using new methods to manipulate and record spatiotemporal patterns of neuronal activity directly within the developing visual pathway, the mechanisms by which activity shapes and refines the orientation tuning of visual cortical cells is becoming better understood. These studies reveal highly organized patterns of correlated neuronal activity within different levels of the developing visual system, and demonstrate that manipulation of these patterns can dramatically disrupt the normal development of orientation selectivity. However, it remains unclear whether these activity patterns drive the initial establishment of orientation selectivity or determine the layout of orientation preference maps. For example, the finding that orientation maps are initially established without visual experience suggests either that spontaneous activity may drive this process or that their layout is determined by molecular or genetic factors. While recent results provide evidence that neuronal activity can play an instructive role in shaping cortical circuits during development, it is likely that neuronal activity plays a more complex role that may be either instructive or permissive during different developmental periods. Experiments will need to be designed to distinguish between the potential roles that genetic factors, molecular targeting cues, and neuronal activity play in the development of orientation tuning.

10 Mechanisms of Plasticity in the Visual Cortex

NIGEL W. DAW

Introduction

The visual cortex has been a model for plasticity in the nervous system ever since the pioneering work of Wiesel and Hubel (1963). It is a model for neural plasticity at the synaptic level, the best illustration of the nature-nurture controversy about the development of the nervous system, and the best example of the mechanisms that underlie clinical deficits in development. In particular, monocular deprivation, produced by closing the eyelids of one eye, which corresponds to unilateral cataract in the human, has significant physiological and anatomical results. These underlie the resulting amblyopia (poor vision which has no obvious cause in the retina) that can amount to total unilateral blindness in severe cases. Thus, the anatomy and physiology can be correlated with behavioral consequences by studying the visual system.

Many forms of plasticity have been studied in the visual cortex. While the physiology has been studied in most forms and the anatomy in many, most experiments concerned with biochemical mechanisms have been done on three: ocular dominance plasticity, orientation and direction plasticity, and long-term potentiation and long-term depression. These are the three forms that will be discussed in this chapter.

Ocular dominance plasticity

Ocular dominance plasticity is a shift in the ocular dominance of cells in the visual cortex, that is, a shift in whether the cells are dominated by the left eye, the right eye, or both. Changes in ocular dominance are found with monocular deprivation, strabismus, anisometropia, and other conditions. Most experiments on mechanisms have been done with monocular deprivation, which leads to total dominance by the nondeprived eye after a few days in young animals (see Chapters 8 and 14). There is a critical period for these effects lasting from eye opening to close to puberty. Animals are most susceptible early in the critical period around 4–5 weeks in the cat (Olson and Freeman, 1980), 4 weeks in the rat (Fagiolini et al., 1994; Guire et al., 1999) and mouse (Gordon and Stryker, 1996),

and 6 weeks in the ferret (Issa et al., 1999), these four species being the ones usually used for experiments on mechanisms.

At the present time, almost everybody thinks of ocular dominance shifts in terms of changes at glutamate synapses: for example, the effect of the GABA agonist muscimol on ocular dominance shifts is interpreted in terms of the hyperpolarization that it produces in glutamate cells (Reiter and Stryker, 1988). There may also be long-term changes in the inhibitory postsynaptic potentials produced at GABA synapses. Suppression of input from the amblyopic eye by the normal eye in strabismus suggests some increase in inhibitory interactions (Harrad et al., 1996). An early paper pointed out that administration of the GABA antagonist bicuculline brings back binocular input after monocular deprivation (Duffy et al., 1976). However, it is also true that bicuculline can make cells more binocular in normal animals, to a similar extent as it does in monocularly deprived animals (Sillito et al., 1981), so the possibility of an effect at GABA synapses has been discounted. Unfortunately, the techniques required to test long-term changes at GABA synapses in monocularly deprived animals are difficult and time consuming, so it seems unlikely that the question will be investigated much more in the near future.

Orientation and direction plasticity

Orientation and direction selectivity is an important feature of cells in the visual cortex, distinguishing them clearly from the cells found in the lateral geniculate nucleus. Orientation selectivity can be tested with stationary or moving bars or gratings. In practice, moving stimuli are almost always used because results can be obtained more quickly. A cell is said to be selective for orientation of the stimulus if the response along one axis is significantly larger than the response along the perpendicular axis. If the response in one direction along the preferred axis is significantly better than the response in the opposite direction, the cell is also said to be direction selective.

Several mechanisms contribute to orientation selectivity. The original suggestion by Hubel and Wiesel (1962) that

cortical cells receive input from a set of lateral geniculate cells with receptive fields lined up along the preferred orientation axis is supported by a variety of experiments (Chapman et al., 1991; Ferster et al., 1996; Reid and Alonso, 1995). There are also lateral inhibitory connections within visual cortex that contribute to orientation selectivity (Crook et al., 1997; Hata et al., 1988; Sillito, 1979; Tsumoto et al., 1979). Orientation selectivity is a dynamic property which increases and then decreases with time after the presentation of a stimulus, suggesting that recurrent excitatory connections within cortex also contribute (Pei et al., 1994; Ringach et al., 1997). Direction selectivity, on the other hand, is believed to be primarily due to lateral inhibitory connections (Crook et al., 1997; Sillito, 1977); according to the model worked out for rabbit retina (Barlow and Levick, 1965; Wyatt and Daw, 1975), although some excitatory influences may play a role (see Rivadulla et al., 2001).

The critical period for changes in direction selectivity ends earlier than the critical period for ocular dominance. Direction selectivity cannot be changed significantly after 7 weeks of age, when ocular dominance is still mutable (Berman and Daw, 1977; Daw and Wyatt, 1976). Indeed, animals reared to 5 weeks of age with the left eye open looking at a drum continually moving to the left, then reared from 5 to 12 weeks of age with the right eye open looking at a drum continually moving to the right, have a majority of cells dominated by the right eye and preferring movement to the left (Daw et al., 1978). Whether the same is true for orientation selectivity is not known. Orientation selectivity is fully developed, while ocular dominance is still mutable in the ferret, in which the characteristic has been most carefully studied (Chapman and Stryker, 1993; Chapman et al., 1996). However, the end of the critical period for orientation selectivity has not been tested by starting a regime that should disrupt or alter orientation selectivity at different ages.

Long-term potentiation and long-term depression

Long-term potentiation (LTP) and long-term depression (LTD) test plasticity at the synaptic level. LTP is an increase in the size of the excitatory postsynaptic potential (EPSP), and LTD is a decrease in the size of the EPSP lasting for more than 30 minutes. LTP is commonly produced by high-frequency stimulation and LTD by low-frequency stimulation (Kirkwood and Bear, 1994a, 1994b). Most recordings are made in layer 3/2, with stimulation of layer 4 or white matter, measuring field potentials in slices of visual cortex. LTP can also be seen in the visual cortex of the intact animal from stimulation of the optic nerves (Tamura et al., 1992) and from intracellular or whole cell recordings of single cells in slices (Artola and Singer, 1987; Dudek and Friedlander,

1996). The result also depends on the state of the GABA system and the polarization of the cell: for example, 50 Hz applied to white matter produces LTP with 0.3 μ M bicuculline, LTD with 0.1–0.2 μ M bicuculline, and neither without bicuculline (Artola et al., 1990). LTP of inhibitory postsynaptic potentials (IPSPs) also occurs (Komatsu and Iwakiri, 1993).

A more direct way to measure LTP and LTD is to impale a cell, stimulate its input to produce an EPSP, and also elicit an action potential (AP) by depolarizing the cell. LTP occurs when the EPSP precedes the AP by 0–20 msec and is maximal with an interval of 10 msec (Feldman, 2000). LTD occurs when the AP precedes the EPSP by 0 to 100 msec or more and is maximal with an interval of 15–25 msec. The maximal amplitude of the LTP is larger than that of the LTD. Clearly, high frequency produces LTP because the magnitude of the LTP is larger for short intervals, and low frequency produces LTD because the magnitude of the LTD is larger for long intervals.

Of course, cells in vivo do not fire in a regular fashion, either with a constant high frequency or with a constant low frequency. However, the results from pairs of connected cells can be used to predict what happens with simulated random firing comparable to firing in vivo. The model that best fits the data is one which includes interactions between an AP and its nearest neighbors, but not neighbors farther away, and ignores the contribution from LTD if there is also a contribution from LTP (Sjöström et al., 2001). Recordings from pairs of layer 5 cells in visual cortex show that random firing produces LTP with an average frequency greater than 35 Hz and LTD with an average frequency less than 35 Hz (Sjöström et al., 2001), in agreement with results from constant frequency stimulation.

The magnitude of LTP and LTD changes with age in a complicated fashion. Several forms of LTP decrease with age: LTP in layers 2–3 in the rat from stimulation of white matter between 2 and 4 weeks of age (Kato et al., 1991; Kirkwood et al., 1995) and LTP of IPSPs in layer 5 cells of rat visual cortex between 2 and 10 weeks of age (Komatsu, 1994). LTP in layers 2/3 from stimulation of layer 4 is constant with age (Kirkwood et al., 1995). Only one set of measurements (Komatsu et al., 1988) shows either LTP or LTD increasing as plasticity for ocular dominance plasticity increases and decreasing as ocular dominance plasticity decreases. Recordings from rat show LTP increasing early in development but maximal at 11–20 days of age (Perkins and Teyler, 1988), before the critical period for ocular dominance starts (Fagiolini et al., 1994; Guire et al., 1999). Thus, the majority of results show LTP and LTD declining as the cortex becomes more plastic for ocular dominance changes, as well as over the period during which the cortex becomes less plastic for ocular dominance shifts. This point, of course, raises the question: does one associate a

decline in LTP with an increase or a decrease in plasticity? Until this question is answered, there will be doubt about the claim that LTP and LTD are closely related to ocular dominance plasticity.

Rearing in the dark

Rearing in the dark extends the critical period for ocular dominance plasticity. That is, animals reared in the dark to several months of age, then monocularly deprived, have a larger ocular dominance shift than animals reared in the light and monocularly deprived for the same period of time (Cynader and Mitchell, 1980). Rearing in the dark also delays the start of plasticity (Mower, 1991), so that early in the critical period the ocular dominance shift occurs more slowly (Beaver et al., 2001a). This produces the interesting result that dark-reared animals are *less* plastic than normal at 5–6 weeks of age, equally plastic at 8–9 weeks of age, and *more* plastic than normal at 12–20 weeks of age. This provides a very powerful criterion to distinguish factors related to plasticity from factors related to activity. Factors related to plasticity should be less active than normal in dark-reared animals at 5–6 weeks and more active than normal in dark-reared animals at 12–20 weeks, or vice versa (antiplasticity factors), whereas factors related to activity should steadily increase or decrease with age.

Rearing in the dark reduces LTD and increases LTP (Kirkwood et al., 1996; Sermasi et al., 2000). This tallies with the observation that cats reared in the dark to 12–20 weeks of age are more plastic than normal. Unfortunately, this experiment has not been done with cats reared in the dark to 5 weeks of age compared to cats reared in the dark to 12–20 weeks of age. If there is a true parallel between LTP, LTD, and ocular dominance plasticity, one would expect LTP to be reduced and LTD to be increased in cats reared in the dark to 5 weeks of age.

The importance of activity

The effects of visual deprivation are specific to the deprivation. For example, monocular deprivation affects ocular dominance but not direction selectivity; rearing in an environment continually moving in one direction affects direction selectivity but not ocular dominance; rearing in a pattern of vertical stripes reduces the percentage of cells responding to horizontal bars; rearing in a pattern of horizontal stripes reduces the percentage of cells responding to vertical bars; and so on. Clearly, these results depend on the pattern of electrical activity reaching the visual cortex from the retina. Thus, it is not surprising that abolition of this activity by infusion of TTX abolishes the ocular dominance shifts from monocular deprivation (Stryker and Strickland, 1984).

The initial establishment of ocular dominance and orientation columns proceeds in the absence of patterned activity by some molecular process that is not yet understood (Crowley and Katz, 2000, 2002; see Chapter 8). The columnar arrangement may then be degraded if patterned activity is disrupted by TTX (Stryker and Harris, 1986). However, this chapter is concerned with postnatal changes that occur as a result of visual deprivation, so mechanisms involved in the initial development will not be considered further.

Evaluation of factors involved in plasticity

As factors that may be involved in plasticity are considered, we will evaluate six questions: (1) Do antagonists to the factor disrupt ocular dominance plasticity? (2) Is orientation plasticity disrupted? (3) Is LTP disrupted? (4) Is LTD disrupted? (5) Does the activity or concentration of the factor increase as cortex becomes more plastic and decrease as the cortex becomes less plastic, or vice versa? (6) Is the concentration or activity of the factor smaller in dark-reared animals at 5–6 weeks of age and larger at 12–20 weeks of age, or vice versa? Not many factors have been tested for all these criteria, but the evidence is rapidly accumulating, and a handful of factors clearly fulfill all criteria.

Instructive factors and modulatory factors

We will distinguish between factors that affect the instructive pathway for plasticity, factors that may modulate this instructive pathway, and factors that are involved with both. Given that plasticity is driven by the pattern of activity reaching the visual cortex from the retina, glutamate receptors are clearly on the instructive pathway, and so are calcium and second messengers activated by glutamate receptors. Modulatory factors include state of attention, state of sleep, nonspecific signals from the thalamus, eye movements, and the transmitters that carry signals about these states, such as noradrenaline, acetylcholine, and serotonin. Amongst the neurotrophins, trkB ligands [brain-derived neurotrophic factor (BDNF) and neurotrophic factor 4/5 (NT4/5)] are located on the instructive pathway (Silver and Stryker, 2001), while the trkA ligand, nerve growth factor (NGF), is located on the modulatory pathway coming from the basal forebrain (Domenici et al., 1994b; Silver et al., 2001). Kinases and phosphatases activated by calcium and second messengers, immediate early genes activated by the kinases and phosphatases, and eventually the genes responsible for the formation and degradation of synapses are affected by both instructive and modulatory influences. We will discuss the instructive factors first and the modulatory factors second.

N-methyl-D-aspartate receptors

N-methyl-D-aspartate (NMDA) receptors have long been postulated to be important in plasticity because the NMDA channels are both ligand gated and voltage sensitive (Mayer and Westbrook, 1984; Nowak et al., 1984). Thus, activation of NMDA receptors produces a nonlinear response, which can be measured in visual cortex (Fox et al., 1990), with a nonlinearity that is predicted by the properties of the channels (Fox and Daw, 1992). The nonlinearity makes it more likely that the postsynaptic cell will fire when the presynaptic cell fires, and consequently more likely to fulfill Hebb's postulate that synapses are strengthened when pre- and postsynaptic cells fire together (Hebb, 1940).

Antagonists at the NMDA receptor reduce ocular dominance plasticity (Bear et al., 1990). The specificity of this result was questioned on the grounds that the NMDA receptor antagonist might reduce activity and therefore act like TTX (Miller et al., 1989). However, ocular dominance plasticity is reduced by treatments that affect NMDA receptors but have little effect on activity (Daw et al., 1999a; Roberts et al., 1998). NMDA receptor antagonists abolish some forms of LTP (Artola and Singer, 1987; Kimura et al., 1989) and LTD (Kirkwood and Bear, 1994b) but not others (Kato, 1993; Komatsu et al., 1991). In addition, antisense oligonucleotides for NMDA receptors reduce orientation selectivity but not direction selectivity, emphasizing the difference in mechanism between these two properties (Ramoa et al., 2001).

Overall levels of NMDA receptors increase with age to the peak of the critical period for ocular dominance plasticity and then decline (Bode-Greuel and Singer, 1989; Gordon et al., 1991; Reynolds and Bear, 1991). The NMDA receptor consists of the NMDA receptor 1 (NR1) subunit, found in all receptors, in combination with NR2 subunits in various combinations. The NR1, NR2B, and NR2A subunits all increase with the rise of plasticity and then decline with the fall in plasticity (Chen et al., 2000). The NR2B subunit is reduced in 5-week dark-reared cats compared to normal and increased in 20-week dark-reared cats (Chen et al., 2000). There is downregulation of the NMDA contribution to the visual response which can be seen by recording from single cells in these layers (Fox et al., 1989; Tsumoto et al., 1987). This downregulation is also delayed by rearing in the dark (Fox et al., 1991, 1992). Thus, NMDA receptors are clearly involved in plasticity in the visual cortex, by all the criteria listed above, with the NR2B subunit being most closely related to plasticity. However, overexpression of the NR2B subunit does not affect ocular dominance plasticity (Philpot et al., 2001).

There is a switch during development from the NR2B subunit to the NR2A subunit, which is delayed by rearing in the dark (Carmignoto and Vicini, 1992) and can be altered

quite rapidly (Quinlan et al., 1999). Receptors with the NR2A subunit have a shorter open time. This reduces the probability of overlap of firing between pre- and postsynaptic cells and the chance that the Hebb postulate will be fulfilled, and also affects the amount of calcium that will enter the cell through NMDA receptor channels. The switch to NR2A is correlated with a decrease in LTP between P0 and P7 (P, postnatal day) in the rat (Carmignoto and Vicini, 1992), and the presence of NR2B is correlated with increased plasticity in the cat (Chen et al., 2000). Thus, greater NMDA function is related to plasticity by a variety of experiments.

Metabotropic glutamate receptors

Metabotropic glutamate receptors may also be a mediator for plasticity, because they release calcium from internal stores in the cell and affect various second messengers such as cAMP. Moreover, glutamate stimulation of phosphoinositide turnover follows the critical period for ocular dominance plasticity in cat visual cortex (Dudek and Bear, 1989). There are three groups of metabotropic glutamate receptors. Group I (mGluR's 1 and 5) has facilitatory postsynaptic actions in the visual cortex (Jin et al., 2001), as it does in other parts of the nervous system, affects phosphoinositide metabolism, and increases cAMP. Groups II (mGluR's 2 and 3) and III (mGluR's 4, 6, 7, and 8) have depressive presynaptic actions (Beaver et al., 1999, 2002a; Jin and Daw, 1998), also similar to their actions in other parts of the nervous system, and decrease cAMP. Group II mGluR's and mGluR5 are developmentally regulated and affected by rearing in the dark, but mGluR1 is not (Beaver et al., 1999; Reid and Romano, 2001; Reid et al., 1997). Most of the changes during development and with dark rearing do not correlate with plasticity, except for the point that Group II mGluR's disappear from layer 4 between 3 and 6 weeks of age, when ocular dominance columns are segregating, and this disappearance is delayed by rearing in the dark (Beaver et al., 1999; Reid and Romano, 2001). Thus, the variation in glutamate-stimulated phosphoinositide turnover must be due to a variation in phosphoinositide metabolism rather than a variation in mGluR receptors (Daw et al., 1999b).

The general mGluR antagonist, α -methyl-4-carboxyphenylglycine (MCPG), does not affect ocular dominance plasticity (Hensch and Stryker, 1996). However, MCPG is not very potent. It acts as an antagonist against the mGluR agonist aminocyclopentane-trans-1, 3-dicarboxylic acid (ACPD), but is not effective against glutamate-stimulated phosphoinositide (PI) turnover or glutamate-stimulated spike adaptation (Huber et al., 1998a). Recent work shows that the Group I antagonist *N*-phenyl-7-(hydroxylamino)cyclopropa[b]chromen-1a-carboxamide

(PHCCC) does reduce ocular dominance plasticity slightly, while the mGluR5 antagonist 2-methyl-6-(phenylethynyl) pyridine hydrochloride (MPEP) does not (Fischer et al., 2001), implying that the effect is due to mGluR1. Since it is mGluR5 that is developmentally regulated, rather than mGluR1, the significance of this result is unknown. There is agreement that LTP is not affected by MCPG (Haruta et al., 1994; Hensch and Stryker, 1996; Huber et al., 1998a), but some forms of LTD and reversal of LTP do depend on mGluRs (Haruta et al., 1994; Hensch and Stryker, 1996; Kato, 1993). In summary, metabotropic glutamate receptors may play a role in ocular dominance plasticity in the visual cortex, but the role is weak compared to that of NMDA receptors.

Calcium and calcium-stimulated kinases and phosphatases

Activation of NMDA receptors lets calcium into the cell (Takahashi et al., 1993). Calcium has been implicated in synaptic plasticity in the hippocampus by several experiments (Lynch et al., 1983; Mulkey and Malenka, 1992; see also Malenka and Nicoll, 1999). The current hypothesis is that small increases in calcium that persist over a long period of time lead to depression, and large increases produced over a short period of time lead to potentiation (Lisman, 1989; Yang et al., 1999). It is therefore almost a tautology that calcium must be involved in ocular dominance plasticity in the visual cortex. Unfortunately, nobody has been able to think of an experiment to test the involvement of calcium in ocular dominance plasticity directly, because calcium is involved in so many other cell processes that any disruption of the calcium system would have numerous effects besides its effect on ocular dominance plasticity, and it would be hard to control for the other effects. Indirect evidence involves mainly experiments with LTP and LTD and changes during development.

Both LTP and LTD are blocked by injection of calcium chelators into the cell (Brocher et al., 1992a; Komatsu and Iwakiri, 1992; Yoshimura et al., 1991). In some situations, LTP is blocked but not LTD (Kimura et al., 1990). Presumably this occurs because the block is partial, in accordance with the hypothesis that low rises in calcium lead to LTD, while large transient rises lead to LTP (Hansel et al., 1997). The hypothesis is also supported by simultaneous measurements of calcium and LTP or LTD (Yasuda and Tsumoto, 1996). LTP at inhibitory synapses also depends on calcium (Komatsu and Yoshimura, 2000).

Some developmental changes in calcium correlate with ocular dominance plasticity, and some do not. Binding sites for voltage-dependent calcium channels in the cat decrease steadily with age, during the period when plasticity is increasing (14–28 days), as well as during the period that

plasticity is decreasing (28–70 days), suggesting that they are related to activity rather than plasticity (Bode-Greuel and Singer, 1988). Rearing in the dark has no effect on these binding sites (Bode-Greuel and Singer, 1988). Calcium currents decline in layer 4 and increase in layer 3 between 5 weeks and adulthood in the cat (Bode-Greuel and Singer, 1991). Unfortunately, animals at ages earlier than 28 days were not tested. Calcium uptake through NMDA receptors in the cat declines steadily between 26 and 90 days of age, with few measurements before 28 days of age, again unfortunately for the interpretation of the relationship to plasticity (Feldman et al., 1990).

Calcium stimulates a number of kinases and phosphatases. The hypothesis is that high levels of calcium stimulate kinases to produce potentiation, and low levels stimulate phosphatases to produce depression (Lisman, 1989, 2001). Experiments that have been done in the visual cortex have used primarily α -calcium/calmodulin kinase II (α CaMKII) and calcineurin. In mice mutant for α CaMKII, ocular dominance plasticity was greatly diminished in half of the cases, and in the other half it was normal (Gordon et al., 1996). A more specific mutant that cannot autophosphorylate shows ocular dominance plasticity for long periods of monocular deprivation but not for short periods (Tara et al., 2002). LTP is reduced by about 50% and LTD by about 30% in 4- to 5-week α CaMKII mutant mice, and LTP is almost abolished in adult mutants, in which LTD is minimal (Kirkwood et al., 1997). Thus, α CaMKII has a larger effect in the less plastic cortex. The calcineurin inhibitor FK506 blocks induction of LTD in slices of rat visual cortex (Torii et al., 1995) and makes the induction of LTP more likely (Funauchi et al., 1994). Much of this is consistent with the hypothesis, but the exact role of α CaMKII is not clear.

In summary, calcium is almost certainly an important link in plasticity in the visual cortex, between activation of glutamate receptors and activation of various kinases and phosphatases. However, more NMDA receptors is what makes the cortex more plastic at the peak of the critical period, not more of some property of calcium or calcium channels. There is no evidence that any property of calcium or calcium channels corresponds to both the rising and falling phases of the critical period or is affected by dark rearing in the same manner as plasticity. In other words, calcium is a link but is not the factor that makes the cortex plastic.

GABA

The role of the GABA system in ocular dominance plasticity is complicated and interesting. Monocular deprivation combined with infusion of the GABA_A receptor agonist muscimol leads to an ocular dominance shift toward the deprived eye, known as a *reverse ocular dominance shift* (Reiter

and Stryker, 1988). Infusion of bicuculline has a less pronounced but similar effect, with no effect on orientation selectivity (Ramoia et al., 1988). The hypothesis is that the postsynaptic cell is hyperpolarized and not firing, while the presynaptic terminals are not affected, and the connections between the more strongly activated eye are weakened relative to the less activated eye. Anatomical experiments show that terminals from the deprived eye occupy a larger space in the area affected by muscimol relative to the space occupied by the terminals of the nondeprived eye (Hata and Stryker, 1994). The primary effect is retraction of terminals from the nondeprived eye: terminals from the deprived eye do not change much over the 2 weeks of monocular deprivation tested (Hata et al., 1999). This demonstrates a mechanism for weakening at specific terminals in ocular dominance plasticity, rather than a specific mechanism for strengthening accompanied by a general mechanism for weakening. Since the weakening takes place in the absence of activity in the postsynaptic cell, it seems likely that there is a trophic factor released by the postsynaptic cell independent of activity, and that the less active presynaptic afferents serving the deprived eye have a lower requirement for trophic support.

There are two forms of the enzyme that synthesizes GABA, which is glutamic acid decarboxylase: GAD65 and GAD67. GAD67 is found primarily in soma and dendrites. GAD65 is found primarily in presynaptic terminals and is responsible for the rapid production of GABA in response to stimuli. Ocular dominance plasticity is abolished in mice that are mutant for GAD65 and can be brought back again by infusion of the benzodiazepene agonist diazepam, which increases the open probability and channel conductance of the GABA_A receptor in a use-dependent manner (Hensch et al., 1998). Diazepam brings forward both the start and the end of the critical period (Iwai et al., 2001). LTD is reduced in these mice (Choi et al., 2001) but LTP is not affected, nor is orientation selectivity or receptive field size (Hensch et al., 1998).

Mice that overexpress the trkB ligand BDNF produce an excess of GABA (Huang et al., 1999). LTP produced in layer 3 by stimulation of white matter in these mice declines with age by 22 rather than 30 days and can be brought back by infusion of picrotoxin (Huang et al., 1999). GAD65 develops early, and so does visual acuity (Huang et al., 1999). These mice also have a precocious critical period for ocular dominance plasticity (Hanover et al., 1999).

A confusing array of hypotheses has been put forward regarding these results. The suggestion from the result that LTP in BDNF-overexpressing mice ends early was that increased production of GABA brings plasticity to an end (Huang et al., 1999). This is also the suggestion for the result that LTP in layer 3 declines with age with stimulation of

white matter but not with stimulation of layer 4: there is a layer 4 plasticity *gate* which closes as GABA develops with age and brings plasticity to an end (Kirkwood and Bear, 1994a). The suggestion from the precocious critical period in both BDNF-overexpressing mice and GAD65 knockout mice treated with diazepam is that an increase in GABA starts the critical period rather than brings it to an end, and that this sets in train a series of reactions involving other factors, which eventually brings the critical period to an end (Iwai et al., 2001). However, GABA antagonists may also produce plasticity in adult animals (Harauzov et al., 2001). How could this happen if the critical period had already been brought to an end by other processes? Moreover, it obviously does not make sense to say that GABA leads to increased plasticity at early ages, decreased plasticity at intermediate ages, and increased plasticity again in the adult. Thus, we are left in a quandary.

In spite of this quandary, we can still say that the GABA system can be modulated to affect plasticity in a variety of ways. However, the GABA system itself is not correlated with the critical period or affected by monocular deprivation or by dark rearing in the same way that plasticity is affected by dark rearing. GAD65 immunoreactivity in deprived and nondeprived eye columns is not affected by either 2 or 7 days of monocular deprivation (Silver and Stryker, 2000). There are no differences in the density or laminar distribution of GABA-positive neurons between normal and dark-reared cats (Mower et al., 1988). The expression and laminar distribution of GAD67 and GAD65 are similar in normal and dark-reared cats (Mower and Guo, 2001). The GABA_A subunits α_1 and α_3 increase to 10 weeks of age with a small decline after that, and the subunit α_2 decreases steadily with age (Chen et al., 2001). There are increases in these subunits in dark-reared animals compared to normal at both 5 and 20 weeks of age (Chen et al., 2001). Other changes are found in dark-reared animals, such as a reduction in GABAergic neurons in the deprived eye columns of adult macaque monkeys (Hendry and Jones, 1986) and an increase in the mRNA for GAD in dark-reared animals compared to normal (Neve and Bear, 1989), but these results can all be related to activity rather than plasticity. Thus, the GABA system is likely to be a link in the chain of processes involved in plasticity, controlled by BDNF and possibly other factors, just as calcium is a link controlled by NMDA and metabotropic glutamate receptors.

Cyclic AMP and protein kinase A

Protein kinase A (PKA) is clearly an important factor in plasticity in the visual cortex. PKA inhibitors abolish ocular dominance plasticity (Beaver et al., 2001b) and induction of LTP and LTD (Liu and Daw, 2001). Mutants missing the

R1 β subunit of PKA have normal ocular dominance plasticity, but this is almost certainly due to upregulation of the R1 α subunit to compensate (Hensch et al., 1996). Cyclic AMP activates PKA, and cAMP produced by the metabotropic glutamate agonist, ACPD, follows the critical period for ocular dominance plasticity closely (Reid et al., 1996). In dark-reared animals, the amount of cAMP is reduced at 5 weeks of age and increased at 15 weeks of age compared to normal in agreement with the effects of monocular deprivation. Thus, there is a close correlation between cAMP and plasticity. This is not due to variations with age and dark rearing in the number of metabotropic glutamate receptors (Reid et al., 1997; Reid and Romano, 2001). What controls the variations is the amount of cAMP between birth and 15 weeks of age, with a decline after that which is due to a decline in metabotropic glutamate receptors (Daw et al., 1999b; Reid et al., 1996).

The effect of protein kinase inhibitors on orientation selectivity is complicated. PKA inhibitors do not affect orientation selectivity in normal animals. Orientation selectivity is also normal in monocularly deprived animals, assayed by stimulating the nondeprived eye. However, orientation selectivity is degraded in animals with monocular deprivation plus PKA inhibitors in both deprived and nondeprived eyes (Beaver et al., 2002b). The hypothesis is that monocular deprivation degrades orientation selectivity as seen through the deprived eye, that PKA inhibitors maintain binocularity, and that the deprived eye instructs the nondeprived eye to reduce orientation selectivity in both eyes.

Other protein kinases and phosphatases

Nitric oxide affects LTP in the hippocampus, and so does its target, protein kinase G (PKG) (Izumi and Zorumski, 1993; O'Dell et al., 1991; Schuman and Madison, 1991; Zhuo et al., 1994). However, neither affect ocular dominance plasticity in the visual cortex (Beaver et al., 2001b; Reid et al., 1996; Ruthazer et al., 1996). In the visual cortex, LTP is abolished by PKG antagonists, but LTD is not (Liu and Daw, 2001). This suggests that ocular dominance plasticity can get underway with depressive processes in place but potentiating processes absent, which is reminiscent of the anatomical finding that ocular dominance shifts are seen after retraction of terminals from the deprived eye, with no changes in the terminals from the nondeprived eye (Antonini and Stryker, 1993, 1996).

Preliminary studies suggest that protein kinase C (PKC) inhibitors also do not affect ocular dominance plasticity (Daw and Beaver, 2001). However, the membrane form of PKC follows the critical period for ocular dominance plasticity (Sheu et al., 1990). The effect of protein kinase C in

LTP and LTD, and the effect of dark rearing to a variety of ages on PKC, have not been studied.

Mitogen activated protein (MAP) kinase is affected by activity and is downstream of neurotrophins and other kinases, so it could therefore be a point of convergence for several signals involved in plasticity (Grewal et al., 1999). MAP kinase inhibitors abolish ocular dominance plasticity and LTP (Di Cristo et al., 2001) without affecting orientation selectivity. Exactly where MAP kinase fits into the pathways involved in plasticity, which signals feed into it, and where it acts downstream remain to be worked out.

An intriguing recent paper shows that there are two phosphorylation sites on GluR1 receptors (Lee et al., 2000). One is phosphorylated by CaMKII, associated with LTP, and dephosphorylated by protein phosphatase 1 and protein phosphatase 2A, associated with depotentiation. The other is dephosphorylated by protein phosphatase 1 and protein phosphatase 2A, associated with LTD, and phosphorylated with protein kinase A, associated with dedepression. Unfortunately, nobody has yet tested the role of PP1 and PP2A in ocular dominance plasticity.

CREB

Cyclic AMP activates the calcium/cAMP response element binding protein known as CREB, which in turn affects protein synthesis. CREB is therefore an obvious candidate for involvement in plasticity. Monocular deprivation for at least 12 hours during the critical period leads to a delayed and persistent expression of CREB (Pham et al., 1999). Injection of a dominant negative form of CREB using herpes simplex virus abolishes ocular dominance plasticity in the affected region but does not affect the recovery from monocular deprivation (Liao et al., 2001). The activation of CREB depends on BDNF and MAP kinase but not on calcium (Pizzorusso et al., 2000). CREB can, in turn, activate the genes for BDNF and c-Fos, demonstrating a feedback loop in the pathway (Pham et al., 1999). However, the metabotropic glutamate agonist, ACPD, intensifies immunostaining for CREB in neurons in all layers before the critical period, in layer 4 at the peak of the critical period, and in glial cells after the critical period, and rearing in the dark delays these changes (Reid, 2001). Moreover, CREB DNA binding activity is not appreciably modulated during development (Kaminska et al., 1995). Thus, CREB may just be another link in the chain, although the observation that it affects ocular dominance shifts from monocular deprivation but not recovery after this, suggesting that it may be a link only in the chain leading to degradation, is most intriguing (Liao et al., 2002). The role of CREB in LTP and LTD in the visual cortex has not been studied. In summary, the

role of CREB in ocular dominance plasticity needs to be evaluated further.

BDNF

BDNF has numerous effects on plasticity in the visual cortex. One of the first observations was that infusion of BDNF into the visual cortex inhibits the formation of ocular dominance columns in layer 4 of the cortex (Cabelli et al., 1995). This appears to be due to a proliferative action of BDNF, which occurs in kittens but not in cats (Hata et al., 2000). Interestingly, the same result is obtained with infusion of trkB-IgG, which binds BDNF (Cabelli et al., 1997). Presumably, BDNF acts by leading to nonspecific sprouting, and its antagonist acts by halting retraction when the trophic factor does not bind to its receptor. When monocular deprivation is combined with infusion of BDNF, the result is a shift toward the deprived eye and a loss of orientation selectivity, which is seen in kittens during the critical period but not in adult animals (Galuske et al., 1996, 2000). Results seen with the other trkB ligand, NT4/5, are fairly similar, but the reverse ocular dominance shift is not noticeable (Gillespie et al., 2000; Lodovichi et al., 2000).

This last result, the reverse ocular dominance shift, is reminiscent of the reverse ocular dominance shift seen with the GABA receptor agonist, muscimol. The two are related, because activity regulates cortical inhibition through BDNF (Rutherford et al., 1997). As mentioned above, mice that overexpress BDNF have a precocious rise in GABA (Huang et al., 1999), and so should behave like mice given a GABA receptor agonist. There are also similarities in the precocious critical period for ocular dominance plasticity produced by BDNF-overexpressing mice and mice treated with the GABA potentiator diazepam (Hanover et al., 1999).

BDNF blocks LTD and enhances LTP, while trkB antagonists block LTP and enhance LTD (Akaneya et al., 1996, 1997; Huber et al., 1998b), although the result may depend on the location of the stimulation electrode (Sermasi et al., 2000). The LTP produced by BDNF is found in young rats at 13–17 and 19–24 days but not in adult rats, lasts for 4–8 hours, then decreases over 15–16 hours (Jiang et al., 2001). Experiments with cells in culture show that the LTD blocked by BDNF is an LTD at glutamate synapses onto glutamate cells due to a presynaptic action of BDNF (Kumura et al., 2000). Whole cell recordings show that BDNF increases the size of EPSCs through an increase in the probability of release, suggesting a presynaptic mechanism for that phenomenon as well (Carmignoto et al., 1997). NMDA and AMPA currents are equally potentiated, supporting this conclusion.

The mechanism of action of BDNF needs to be clarified. Several authors have suggested that BDNF may be transported retrogradely to activate presynaptic neurons, but

direct evidence shows that it is transferred from presynaptic to postsynaptic neurons more than the reverse (Kohara et al., 2001). BDNF is expressed in pyramidal neurons, which are glutamate neurons, but not in interneurons, which are GABA neurons (Aoki et al., 2000; Gorba and Wahle, 1999). Its receptor, trkB, is expressed on both glutamate and GABA neurons, mainly parvalbumin neurons, and at geniculocortical synapses (Aoki et al., 2000; Gorba and Wahle, 1999; Silver and Stryker, 2001). Putting all of this together, BDNF should be released by glutamate neurons to activate both glutamate and GABA neurons. In fact, BDNF increases the release of glutamate but not GABA (Sala et al., 1998) and increases EPSCs (Rutherford et al., 1998). On the other hand, chronic overexpression of BDNF increases GABA function (Huang et al., 1999).

There is some relationship between BDNF and the critical period. mRNA for BDNF follows the critical period for ocular dominance plasticity in the rat quite well, whereas mRNA for NGF does not (Schoups et al., 1995).

Activity affects BDNF, and so does light. Dark rearing decreases BDNF, but this occurs at all ages including adulthood and so may be an activity effect (Castrén et al., 1992; Lein and Shatz, 2000; Schoups et al., 1995). The decrease produced by monocular deprivation in the contralateral cortex in the rat may be a similar effect (Bozzi et al., 1995; Rossi et al., 1999). It seems likely that the effects on BDNF are activity effects, whereas the effects of BDNF on the system are plasticity effects.

Gene expression and protein synthesis

Protein synthesis must be involved in ocular dominance plasticity if some synapses are to be created and others destroyed. The protein synthesis that is required occurs in the visual cortex rather than the lateral geniculate nucleus (Taha and Stryker, 2002). With modern techniques of molecular biology, it has now become possible to identify genes that are particularly related to plasticity (Nedivi et al., 1996; Prasad and Cynader, 1994; Prasad et al., 2001). They include the obvious candidates, such as proteins for neurotransmitter release, receptors, postsynaptic density, neurofilament assembly, cell-cell interaction, cell remodeling, and general house-keeping. As in the hippocampus, protein synthesis is not required for rapid LTP, depending on NMDA receptors, but is required for a more slowly developing form of LTP, depending on L-type calcium channels (Kurotani et al., 1996).

The most stringent criterion for a candidate plasticity gene is to test whether it is downregulated in dark-reared animals at 5 weeks of age compared to normal and upregulated in dark-reared animals at 20 weeks of age (Mower, 1991), or vice versa, as well as whether it is upregulated at the peak of the critical period compared to before and afterward. Genes that are simply upregulated in dark-reared animals com-

pared to normal at one particular age may be related to activity rather than plasticity. This most stringent criterion has turned up some interesting candidate plasticity genes (cpgs) and some candidate antiplasticity genes (capgs). One is a gene that is probably involved in dendritic and axonal arbor restructuring and synaptic maturation, known as *cpg-15* (Lee and Nedivi, 2002). Another is the mouse homolog of one of the *Drosophila* uncoordinated genes, *Munc13-3*, which codes for a presynaptic protein at glutamate receptors (Yang et al., 2002). Some mitochondrial genes also fulfill the stringent criteria (Yang et al., 2001). So does the immediate early gene *Fos* (Mower and Kaplan, 1999).

Few immediate early genes have been tested for their relationship to plasticity using knockout mice. One of the few is *egr1* (Mataga et al., 2001). In these mice, ocular dominance plasticity is normal after both brief and long-term occlusion of one eye. However, *egr1* is modulated by light and dark. Thus, it is an activity factor rather than a plasticity factor.

Of course, the real question in relation to gene expression and protein synthesis is: what controls the array of genes involved in the formation of axon terminals, dendritic spines, and synapses, as opposed to the array of genes involved in their degradation, and how are levels of calcium, PKA, and other factors involved in plasticity related to turning on one set of genes and turning off the other? Could *Fos* turn on the genes used for synapse formation, and could some other immediate early gene turn on the genes used for synapse degradation? So far, the only clue is the observation that CREB is involved in monocular deprivation but not in recovery from monocular deprivation (Liao et al., 2002).

Effect of modulatory states on ocular dominance plasticity

The state of the nervous system affects plasticity. The clearest example of this is the effect of sleep. Six hours of sleep after 6 hours of monocular deprivation enhances the effect of the monocular deprivation, but 6 hours of wakefulness in the dark does not (Frank et al., 2001). There are nonspecific afferents to the cortex coming from the intermedullary laminae of the thalamus, and stimulation of these also accentuates plasticity (Singer and Rauschecker, 1982). As mentioned above, ocular dominance plasticity is not seen in animals paralyzed and anesthetized with halothane in nitrous oxide plus oxygen, but ocular dominance changes can be seen if the eyes are moved mechanically in these animals (Freeman and Bonds, 1979). Presumably the state of attention also affects plasticity, although the point has not been specifically tested in relation to ocular dominance. While it is the afferents from the retina that instruct plasticity, there are clearly also modulatory influences.

Role of modulatory transmitters

Signals about the state of the nervous system come from the basal forebrain, carried by acetylcholine; from the locus coeruleus, carried by noradrenaline; from the raphe nuclei, carried by serotonin; from the midbrain, carried by dopamine; and from the intermedullary nuclei of the thalamus, carried by glutamate. In the first four cases, it is quite easy to distinguish the role of the modulatory pathways from the role of the instructive pathways by interrupting these pathways or applying antagonists to these transmitters. An early experiment suggested that abolition of the noradrenaline pathway by lesions of the dorsal noradrenergic bundle with injections of 6-hydroxydopamine (6-OHDA) abolishes ocular dominance plasticity (Kasamatsu and Pettigrew, 1979). Later experiments showed that this result was due to nonspecific effects induced by the high concentrations of 6-OHDA used: lower doses of 6-OHDA, and other treatments more specific to the noradrenaline pathway, do not have the same result (Daw et al., 1985; Gordon et al., 1988). However, antagonists to α -adrenergic receptors do have a very small effect on the ocular dominance shift (Kasamatsu and Shirokawa, 1985).

Antagonists to muscarinic acetylcholine receptors reduce ocular dominance plasticity somewhat and also affect orientation selectivity, probably through their action on M_1 receptors (Gu and Singer, 1993). Excitotoxic lesions of the cholinergic cells in the basal forebrain also reduce ocular dominance plasticity, and a combination of this treatment with lesioning of the dorsal noradrenergic bundle by 6-OHDA essentially abolishes ocular dominance plasticity (Bear and Singer, 1986). Bear and Singer also showed that high doses of 6-OHDA antagonize the action of acetylcholine, but it was not certain whether the combined action of the basal forebrain and dorsal noradrenergic bundle lesions could be attributed to acetylcholine alone. Serotonin neurotoxins and a combination of antagonists to 5-HT₁ and 5-HT₂ receptors (5-HT, 5-hydroxytryptamine) also reduce ocular dominance plasticity (Gu and Singer, 1995). The role of dopamine in visual cortex plasticity has not been studied. Thus, acetylcholine and serotonin afferents definitely have an effect, but evidence about other modulators is uncertain. The modulatory pathways also facilitate (Brocher et al., 1992b; Kirkwood et al., 1999; Kojic et al., 1997) or depress (Edagawa et al., 2001) LTP and LTD.

Several aspects of the modulatory pathways are developmentally regulated. Some rise to a peak with the critical period for plasticity and then decline. Included are 5-HT levels, 5-HT receptor binding, α -adrenergic receptor binding (Jonsson and Kasamatsu, 1983), acetylcholinesterase-positive fibers in layers 4–6 (Bear et al., 1985), and a transient clustering of 5-HT_{1C} receptors in layer 4 and lower layer 3 during the critical period (Dyck and Cynader,

1993). Several experiments have observed the effect of dark rearing on modulators, but none has been tested with the stringent criterion mentioned above.

How modulators might act

How the modulatory pathways might act on ocular dominance plasticity is not definitely known. Acetylcholine agonists increase the response of cells in the visual cortex to visual stimuli (Sato et al., 1987; Sillito and Murphy, 1987). Noradrenaline has been said to change the signal-to-noise ratio in these cells, but later experiments have questioned this point (Eco-Stengel et al., 2002; Videen et al., 1984). Serotonin enhances responses to excitatory amino acids (Nedergaard et al., 1987), particularly NMDA responses (Reynolds et al., 1988). Acetylcholine, noradrenaline, and serotonin all affect multiple receptors, with different results. This is particularly clear in the case of noradrenaline, where stimulation of the locus coeruleus can have both facilitatory and depressive effects on visual responses in the visual cortex, depending on whether α_1 , α_2 , β_1 , or β_2 receptors are activated (Sato et al., 1989). Thus, all the modulators can affect the activity of cells in the visual cortex, and thereby affect the probability that the postsynaptic cell will fire when the presynaptic cell fires.

There are also effects on various second messengers. Phospholipase C and phosphoinositides, with release of calcium from intracellular stores, are activated by acetylcholine M_1 and M_3 receptors, noradrenaline α_1 receptors, and serotonin 5-HT₂ receptors. Adenylate cyclase is inhibited by acetylcholine M_2 receptors, noradrenaline α_2 receptors, and serotonin 5-HT₁ and 5-HT₅ receptors. Adenylate cyclase is activated by noradrenaline β receptors and serotonin 5-HT₄ and 5-HT₆ receptors (Hardman et al., 2001). The increase in calcium elicited by glutamate can be enhanced by noradrenaline (Yang et al., 1996). All of these are second messengers involved in the instructive pathways, onto which the modulatory pathways may also converge.

NGF

NGF has little effect on plasticity in the visual cortex of the cat. NGF does not affect the development of geniculocortical endings into ocular dominance columns (Cabelli et al., 1995; Silver et al., 2001), nor does the antagonist at its receptor, trkA-IgG (Cabelli et al., 1997). Infusion of NGF into the visual cortex does not affect ocular dominance changes from monocular deprivation in kittens during the critical period (Galuske et al., 2000; Gillespie et al., 2000; Silver et al., 2001). An orientation selectivity map is not seen in the deprived eye, presumably because the deprived eye no longer drives cortical cells (Galuske et al., 2000; Silver et al., 2001). Interestingly, the same treatment in adult animals leads to a paradoxical

shift toward the deprived eye (Galuske et al., 2000; Gu et al., 1994). Infusion of NGF into the ventricle can lead to a small reduction in the ocular dominance shift, which could be due to activation of trkB receptors, due to the high concentrations used (Carmignoto et al., 1993). In any case, the results do not add up to a role for NGF in ocular dominance plasticity, particularly since the effects are noticeable in adult cats more than in kittens during the critical period.

Results in the rat are somewhat different. Most of the earlier experiments were done by infusion of NGF into the ventricle, and consistently showed that this treatment prevents the shift in ocular dominance from monocular deprivation (Maffei et al., 1992). Moreover, injection of antibodies to NGF into the ventricle late in the critical period (P45) produces an ocular dominance shift (Domenici et al., 1994a). A more recent experiment, with activation of trkA by infusion directly into the visual cortex, leads to a similar effect (Pizzorusso et al., 1999). Indeed, the effect is greater with NGF than with BDNF (Lodovichi et al., 2000). Thus, the results in the rat are clearly different from those in the cat. This does not seem to be a methodological difference in infusion sites, since both intracortical and intraventricular infusions have been used in both species. There could be more cross-reactivity between the various growth factors and their receptors in the rat, in which distances are smaller, so that effective concentrations can be higher at the site of action. The cholinergic projections from the basal forebrain may be wider and more powerful in the rat. Perhaps such differences over a wider area of brain could even lead to different attention or behavioral states sufficient to affect plasticity. There is also a well-known species difference in the acetylcholine systems: there are no intracortical acetylcholine cells in the cat, whereas some bipolar cells in the rat cerebral cortex are cholinergic (Eckstein and Baughman, 1984). However, it is not known whether the intracortical acetylcholine cells in the rat have trkA receptors on them (Domenici et al., 1994b) or how these cells might affect ocular dominance plasticity. Thus, the species differences remain unresolved.

Similar confusion reigns concerning LTP and LTD, where all the experiments have been done on the rat, so that no species differences occur. Some investigators have found that NGF does not affect LTP (Akaneya et al., 1997) or LTD (Akaneya et al., 1996), while others have found that it does (Carmignoto et al., 1997). Other experiments show that delivery of NGF through the recording pipette can block the maintenance phase of LTP, acting in the same manner as blockade of muscarinic receptors, and that LTP may be reintroduced by muscarine later in the critical period (Pesavento et al., 2000). Whatever the final resolution of these conflicting results, the lack of agreement suggests that NGF is not an important component of the generation of either LTP or LTD.

Growth factors and acuity

A small number of studies have investigated the effect of growth factors on acuity, with intriguing and unexplained results. Acuity is reduced in the deprived eye of monocularly deprived animals, and this reduction is prevented by infusion of NGF into the ventricle in both rats (Domenici et al., 1991) and cats (Fiorentini et al., 1994). In addition, antibodies to NGF reduce acuity in normal animals (Berardi et al., 1994). Proliferation of axons and dendrites by NGF would not be expected to improve acuity, and nobody knows whether the acetylcholine system affects acuity, so the mechanism of action here is not understood. With BDNF the results are more understandable. Mice that overexpress BDNF show premature development of acuity (Huang et al., 1999). Since BDNF leads to an accelerated development of inhibition, and since inhibition is known to reduce the size of the receptive fields of cells, which can be related to an improvement in acuity, there is a logical explanation for this result.

Relationship of ocular dominance plasticity, LTP, and LTD

The results are all summarized in Table 10.1, and looking at it is a good way to think about the relationship between

ocular dominance plasticity, LTP, and LTD. If both LTP and LTD are abolished or substantially reduced by antagonists to a factor, then so is ocular dominance plasticity in most cases (see NMDA receptors, PKA, and BDNF). If a factor facilitates LTP and LTD, then its antagonist generally has some effect on ocular dominance plasticity (see acetylcholine, noradrenaline, and serotonin). Where either LTP or LTD is reduced, but not the other, ocular dominance plasticity remains. Ocular dominance plasticity may be found with LTD present and LTP absent (see PKG: Liu and Daw, 2001; and GAD65: Choi et al., 2001) or with LTP present and LTD absent (see the mGluR receptor antagonist MCPG, references above), or with LTP and LTD and depotentiation absent but a form of pairing potentiation present (see PKA ($\text{RI}\beta$) mutants: Hensch et al., 1998). Thus, it seems that both LTP and LTD must be totally abolished for ocular dominance plasticity to be abolished. In other words, neither LTP by itself nor LTD by itself is necessary for ocular dominance plasticity to occur.

Bringing back plasticity in older animals

The holy grail for most people working on plasticity is to find some factor that will bring back plasticity in older animals. Most intriguing here are recent observations that inhibition

TABLE 10.1
Summary of the effects of various factors on plasticity in the visual cortex

Factor	Ocular Dominance	Orientation Selectivity	LTP	LTD	Critical Period	Dark Rearing
NMDA receptors	Yes	Yes	Some forms	Some forms	Yes	Yes
mGluR's	mGluR1	Not tested	No	Partial	No	Maybe

Serotonin	Reduced	Reduced	Yes	Yes	Yes	Not tested
NGF	No	No	Conflicting	Conflicting	No	No

Note: The second column states whether ocular dominance plasticity is affected by an antagonist to the factor; third column, whether orientation selectivity is affected; the fourth and fifth columns, whether LTP and LTD are affected; the sixth column, whether the factor or its receptor peak with the critical period for plasticity; and the seventh column, whether dark rearing affects the factor and plasticity similarly, according to the strict criterion that distinguishes candidate plasticity factors from candidate activity factors.

of the GABA system can do this in rats, with inhibition of GAD by mercaptopropionic acid, or inhibition of GABA_A receptors by their antagonist picrotoxin (Harauzov et al., 2001). This, of course, is reminiscent of the plasticity gate hypothesis, in which development of the GABA system in layer 4 is suggested to bring plasticity to an end (Kirkwood and Bear, 1994a; Komatsu, 1983). Given the differences that have been found between the rat and cat in the action of NGF, and the diversity of findings on the role of GABA in plasticity, these experiments will need to be repeated in the cat and/or ferret to demonstrate the generality of the finding.

Several treatments that increase the activation of PKA (cholera toxin, forskolin, and dibutylyl cAMP) lead to changes in ocular dominance in adult animals with monocular deprivation (Imamura et al., 1999). So does infusion of noradrenaline into the cortex of adult cats (Kasamatsu and Pettigrew, 1979) and stimulation of the locus coeruleus (Kasamatsu et al., 1985). However, all of these changes amount to a loss of binocular cells rather than a shift toward the nondeprived eye. The PKA activator Sp-8-Cl-cAMPS, given late in the critical period, leads to a slightly larger shift toward the nondeprived eye than is seen in untreated animals, but the effect is not statistically significant (Beaver et al., 2001b). NGF given to the adult animal with monocular deprivation leads to a shift toward the deprived eye (Galuske et al., 2000; Gu et al., 1994). Thus, none of these treatments leads to what could be considered a restoration of plasticity as seen in the critical period, that is, a significant shift toward the nondeprived eye after monocular deprivation. Two treatments do. One is infusion of the noradrenaline precursor L-threo-3,4-dihydroxyphenylserine, done in a limited series of three 7- to 8-month-old cats (Mataga et al., 1992). The other is degradation of chondroitin sulphate proteoglycans in the extracellular matrix by chondroitinase-ABC (Pizzorusso et al., 2002). Hopefully, these observations will be followed up. The general conclusion is that many more explorations will be necessary before the holy grail is found.

Synthesis of results

It is tempting to suggest that there are two parallel series of reactions involved in ocular dominance plasticity (Fig. 10.1). One leads from afferent activity to NMDA and metabotropic glutamate receptors to entry of calcium into the cell, to activation of adenylate cyclase, production of cAMP, and activation of PKA and CaMKII. The other leads from afferent activity to activation of BDNF and the GABA system. They may converge at the level of MAP kinase or CREB. They must diverge to produce decreases in physiological efficacy as well as increases in physiological efficacy, and expansion of anatomical connections as well as retraction of anatomical connections.

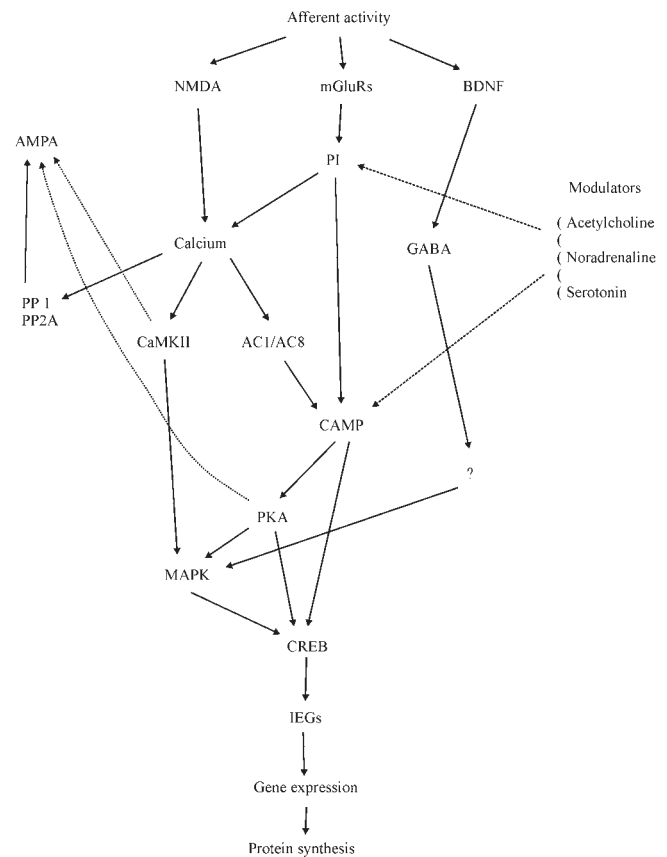

FIGURE 10.1. Factors involved in plasticity in the visual cortex.

Unfortunately, the situation is more complicated than this. There are feedback pathways. For example, PKA and CaMKII can phosphorylate the AMPA receptor GluR1, and protein phosphatases 1 and 2A can dephosphorylate it (Lee et al., 2000). There are points of divergence. For example, high levels of calcium have been proposed to activate kinases and low levels to activate phosphatases (Lisman, 1989, 2001). There are also examples of convergence. For example, CaMKII, PKA, MAPK, and neurotrophins all activate CREB (see Mower et al., 2002). New interactions and intermediaries are continually being discovered.

Few biologists reveal their basic assumptions. In the case of visual cortex plasticity, most people assume that LTP and LTD are related to ocular dominance plasticity, but almost nobody explains how. One possible hypothesis is that there is a pair of pathways, one leading from high levels of activity in the nondeprived eye to expansion of axons and dendrites, the other leading from low levels of activity in the deprived eye to retraction of axons and dendrites (Fig. 10.2A). This can accommodate the Hebb hypothesis, and also the concept of competition if the postsynaptic cell fires only when several nondeprived eye inputs fire together, or when both eyes are nondeprived and their firing is coordinated. However, it is simplistic. Inter alia, neither LTP nor

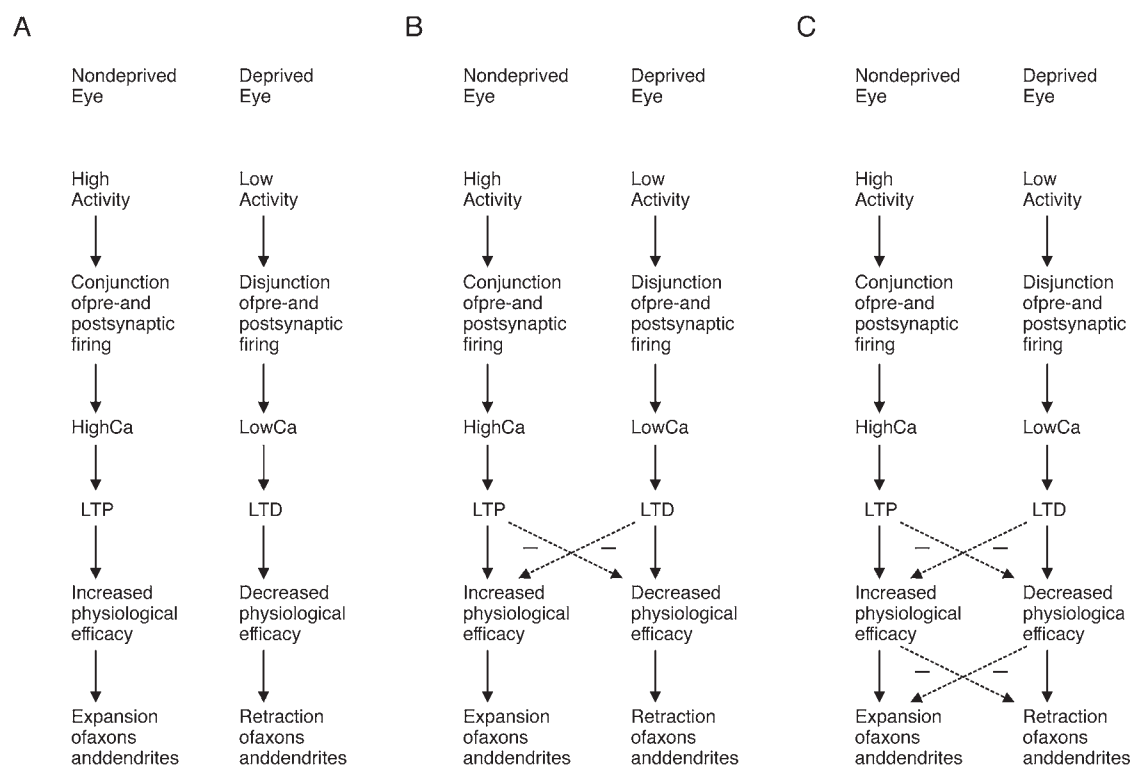

FIGURE 10.2. Three possible assumptions about plasticity. *A*, Increased physiological efficacy is assumed to result from LTP and decreased efficacy from LTD. *B*, Increased physiological efficacy can result from either LTP or LTD, and so can decreased physio-

logical efficacy. *C*, Expansion of axons and dendrites can result from either increased or decreased physiological efficacy, and so can retraction of axons and dendrites.

LTD is necessary for ocular dominance plasticity. In other words, ocular dominance plasticity can occur with either LTP or LTD present and the other absent. This suggests that an interaction must occur, as illustrated in Figure 10.2*B* and shown by Tsumoto and Suda (1979). This could be one place where GABA influences and the balance between excitation and inhibition come in. Other interactions might also occur between changes in physiological efficacy and anatomical alterations (Fig. 10.2*C*).

Another fundamental question is: where in the pre- and postsynaptic cells does all of this take place? Broadly speaking, there are four possibilities—local postsynaptic reactions in the dendritic spine; local presynaptic reactions in the presynaptic terminal; conveyance of signals to the nucleus in the postsynaptic cell for gene expression; and conveyance of signals to the nucleus in the presynaptic cell, also for protein synthesis (Fig. 10.3). Ocular dominance changes after 4 days of monocular deprivation in the mouse are abolished by the protein synthesis inhibitor cycloheximide when infused into the visual cortex but not when infused into the lateral geniculate nucleus (Taha and Stryker, 2002). This must mean that no new axon terminals are created in this period, since it is hard to believe that a new axon terminal could be created without protein synthesis. Can the changes in physiological efficacy that take place over the first 2 days

be accounted for entirely in terms of local reactions? This question remains unanswered. From work in the hippocampus we know that CaMKII and PKA are both located in the postsynaptic density (PSD), and both can phosphorylate AMPA receptors (Colledge et al., 2000; Lee et al., 2000; Lisman and Zhabotinsky, 2001). AMPA receptors can also be inserted into the PSD to make the postsynaptic response larger and removed from it to make the postsynaptic response smaller (Feldman et al., 1999). On the other hand, protein synthesis is required for late LTP in the hippocampus (Huang et al., 1994; Krug et al., 1984), which occurs in an hour or so, so perhaps it is also required for the physiological changes in ocular dominance plasticity which can be seen after a few hours.

The question of which of the changes are presynaptic and which postsynaptic is also unanswered. To address this question, one really needs a slice preparation with whole cell or intracellular recording where one would, of course, be looking at LTP and LTD rather than ocular dominance plasticity. Most investigations of LTP and LTD in the visual cortex have involved field potentials rather than intracellular recordings, so very few investigations on the point have been carried out. However, one does have some information from indirect evidence. For example, nitric oxide, which has been shown to be a feedback factor in the hip-

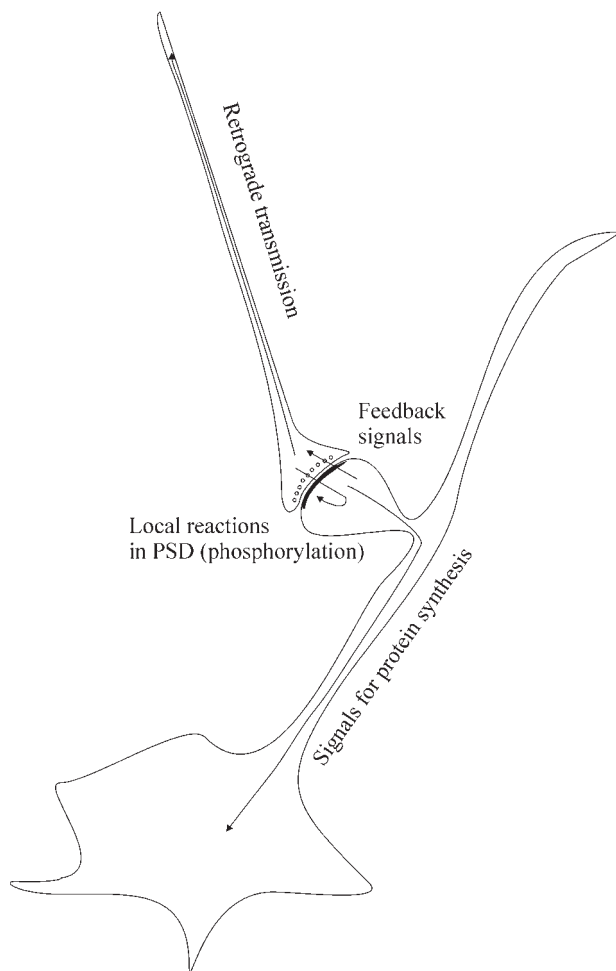

FIGURE 10.3. Four places where plasticity changes can occur: pre- or postsynaptic local reactions and pre- or postsynaptic gene expression.

pocampus, released by the postsynaptic cell to activate cGMP and PKG in the presynaptic cell, is not involved in ocular dominance plasticity, because neither nitric oxide synthase inhibitors nor PKG inhibitors affect ocular dominance plasticity (Beaver et al., 2001b; Reid et al., 1996; Ruthazer et al., 1996).

Thus, it is clear that there is a long way to go. It is unfortunate that LTP and LTD are not necessary precursors to ocular dominance plasticity, because this means that experiments done on LTP and LTD, which can be done rapidly, have to be repeated with ocular dominance plasticity, where results come more slowly. It is also unfortunate that results obtained with LTP and LTD in the hippocampus do not always apply to the visual cortex, as evidenced by the role of PKG. However, it is clear that several factors are necessary for ocular dominance plasticity, have greater activity at the peak of the critical period, and are affected by dark rearing, just as ocular dominance plasticity is affected. These include NMDA receptors, PKA, and BDNF. These are the factors

that contribute to plasticity during the critical period, and probably their lack is responsible for the absence of plasticity at other times. The modulatory factors acetylcholine, noradrenaline, and serotonin may also be more active during the critical period. Other factors, such as calcium and GABA, are important links in the chain of processes without which plasticity would not occur, but these are not the factors that make the cortex more plastic at the peak of the critical period. Thus, an enormous amount has been learned in the past 10 years, and progress continues to be rapid. The problem will finally be resolved when one can construct a composite figure in which the elements of Figures 10.1 and 10.2 can both be mapped onto Figure 10.3.

Acknowledgments

The author's work described in this review is supported by PHS Grants EY00053 and EY11353. The author is a Senior Scientific Investigator for Research to Prevent Blindness. I thank the members of my laboratory, Quentin Fischer, Shaolin Liu, Yan Rao, Xue-Feng Wang, and Yupeng Yang, and also Hiromichi Sato and Satoshi Shimegi, all of whom have made comments on the manuscript.

11 Ontogenesis of Cortical Connectivity

HENRY KENNEDY AND ANDREAS BURKHALTER

AN UNDERSTANDING of the neuronal mechanisms underlying visual perception has played a major role in shaping our understanding of how the brain extracts information concerning the world. In turn, insight into the development of this process is enormously conditioned by existing theories of brain function.

Over the last century, anatomical and physiological studies have provided a description of the point-to-point connectivity of the visual system where neighboring relations in the retina are conserved in their central projections. Hence, the primary visual cortex has been shown to contain a retinotopic map of the visual world in which each point is represented by neurons with specialized receptive fields that encode basic visual features. Initially, the primary visual cortex was thought to function as the cortical retina before relaying its activity to additional areas in the surrounding association cortex. It was in the association cortex that the important but highly mysterious business of seeing was thought to take place. Increasingly, the system came to be construed as being hierarchically organized, and successive levels were thought to subserve progressively higher functions. Essentially, the visual system was seen to be a highly passive system, whereby information in the retinal image was extracted in central structures, as reflected in the changing receptive field organization at successive levels (Hubel, 1995). The understanding of corticogenesis, which evolved in parallel, was that the early development of the cortex was dictated by the peripheral sense organ (Van der Loos and Woolsey, 1973), whereas later stages were dictated by the sensory experience of the animal (Blakemore and Cooper, 1970).

Recently, our understanding of the neuronal mechanisms underlying vision has shifted from a passive role of analysis of the retinal image to one of inference and the construction of constancy. Increasingly, the visual system is seen as a dynamic one where the individual stations are involved together in a computational process aimed at determining the probabilities of feature constellations in the visual environment (Scannell and Young, 2002; Young, 2000; Young, 2001; Zeki, 1993). In some ways, this modern synthesis has much to do with the Platonic understanding of the brain, in which the sensory impressions were compared to ideas of the world. In parallel to the release of central states from the dictatorship of the sensory periphery, developmental biologists are increasingly detecting the intrinsic constraints,

largely of a molecular nature, which determine early neuronal development of higher levels of the visual system (Rakic, 1988).

One can argue, therefore, that our understanding of the development of the brain being environmentally driven or, alternatively, determined by internal constraints has largely been influenced by theories of brain function. The intrinsic and extrinsic control of cortical development has been epitomized in protomap and protocortex theories (O'Leary, 1989; Rakic, 1988). Although these theories have been considered by some to be antagonistic, it is becoming increasingly clear that normal development of the cortex involves a synthesis of both intrinsic and extrinsic control (Yuste and Sur, 1999).

Early studies of cortical connectivity tended to be dominated by a view that immature connections were imprecise and that mature patterns of connections were largely the consequence of pruning of exuberant, early-formed connections (Innocenti et al., 1977). More recently, it has become clear that, although some early-formed connections undergo pruning, others exhibit precise connectional features from the onset of their formation (Dehay et al., 1988a). Distinguishing between these two possibilities is important because different contributions of each might be expected to underlie the development of very different functions. In this chapter, the authors shall attempt to give an up-to-date account of where development of the connectivity of the visual cortex is thought to be driven by activity in the periphery and where connectivity is prespecified, presumably by molecular cues that lay down the basic structure of the system.

It is becoming increasingly evident that the physiology of the visual cortex can be interpreted usefully in terms of feed-forward and feedback mechanisms underlying the hierarchical organization of the cortex (Felleman and Van Essen, 1991; Lamme and Roelfsema, 2000; Shao and Burkhalter, 1996). This approach provides a conceptual framework for interpreting the feedforward input from the thalamus to the cortex in terms of the recurrent excitation provided by the intracortical and intercortical processing (Douglas et al., 1995; Shao and Burkhalter, 1996). This approach turns out to be highly innovative because instead of viewing the role and development of geniculostriate and corticocortical connectivity as separate entities, it shows that these two sets of connections, in fact, share key features. Hence, the

development of feedforward projections from the thalamus to the cortex exhibits common features with the development of feedforward corticocortical connections; moreover, there are fundamentally different developmental mechanisms operant in the feedback and feedforward pathway.

Development of thalamocortical pathways

When Torston Wiesel presented his Nobel address, he pointed out that his and David Hubel's pioneering work on the effects of sensory deprivation on the development of the functional architecture of the visual cortex had been inspired by early eighteenth century speculation that congenital blindness resulted in defective visual perception, presumably as a result of malformation of the brain (Von Senden, 1960). Earlier, Hubel and Wiesel had demonstrated that adjacent territories of area 17 receive input alternatively from the right and left eye. These so-called ocular dominance columns had been explored both by single-unit recording in the cortex, as well as by injections of anterograde tracers in the eye, followed by transsynaptic transport of the tracer to area 17 (Hubel and Wiesel, 1962, 1977). To investigate the role of the sensory periphery, they carried out similar experiments in normal kittens as well as kittens having one eye, closed throughout development. These experiments suggested that, during normal development, the ocular dominance columns emerge from an immature stage in which input from the two eyes overlaps. If one eye is closed during development, then only the experienced eye drives most neurons in the adult (Wiesel and Hubel, 1963). Transsynaptic labeling has shown that, following monocular deprivation, there is an expansion of the columns receiving input from the open eye and a reduction of the columns receiving input from the deprived eye (LeVay et al., 1980). These experiments gave rise to the concept that, during normal development, the geniculate afferents conveying responses to the right and left eye initially are extensive and, therefore, overlap. Because binocular deprivation allowed segregation of the two sets of inputs while segregation was prevented by blockade of activity (Stryker and Harris, 1986), it was thought that the formation of ocular dominance columns depended on competitive interactions between inputs from both eyes during a so-called critical period. These experiments emphasized the role of sensory experience in shaping neuronal connections and defined a time window during which sensory experience has a profound effect on the development of the brain.

Although experiments involving monocular deprivation clearly show that the brain is susceptible to deprivation, they fail to elucidate the role of experience during normal development. Further, they have failed to provide insight into the normal process of development at the cellular level. It was assumed for many years that the segregation of ocular dominance columns was attributable to pruning of the thalamic

axonal arbor in layer 4 of the primary visual cortex. However, few experiments have actually attempted to examine this issue. When single geniculostriate axonal arbors have been examined at different developmental stages, the main event that is documented is the progressive increase in total axon length and complexity of axonal arbors (Antonini and Stryker, 1993; Friedlander and Martin, 1989). Pruning of extended branches either does not happen, or happens very rarely.

The role of visual experience in constructing ocular dominance columns was challenged by a study involving newborn monkeys. After prolonged in utero development and, therefore, in the absence of stimulation of the retina, the left and right eye inputs to the cortex were found to be well segregated into ocular dominance columns (Horton and Hocking, 1996; Rakic, 1976). This led to the suggestion that spontaneous activity, possibly originating in the periodic waves of excitation in the immature retina, drove segregation (Galli and Maffei, 1988; Meister et al., 1991; Mooney et al., 1993; Wong et al., 1993). However, a number of studies have suggested that the development of ocular dominance columns can actually proceed relatively normally in the total absence of the retina. Cytochrome oxidase-rich blobs in layers 2/3 in the monkey relate to the ocular dominance columns (Hendrickson, 1985; Hendry and Yoshioka, 1994) and have been shown to develop in the absence of the retina (Dehay et al., 1989; Kennedy et al., 1990; Kuljis and Rakic, 1990) and to show a normal periodicity (Kennedy et al., 1990). More direct evidence for the formation of ocular dominance columns in the absence of the retina has recently been obtained from studies of neonatal enucleated ferrets in which tracer injection in the lateral geniculate nucleus (LGN) revealed alternating stripes of label in the striate cortex (Crowley and Katz, 1999). Not only did ocular dominance columns appear to develop independently of the retina, but they were shown to appear well before the critical period and the period in which geniculostriate axons had been thought to undergo refinement and retraction (Crowley and Katz, 2000). Further, geniculate axons formed ocular dominance columns shortly after innervation of layer 4, and at this early stage, imbalance caused by removal of one eye fails to change the periodicity of the input to the cortex (Crowley and Katz, 2000). Although these results do not exclude a role for the sensory periphery in central development, they suggest that molecular cues play a major role in the formation of ocular dominance columns.

The influence of visual experience on the development of orientation columns has a long and controversial history. Unlike ocular dominance columns, where experimental manipulations quickly establish developmental plasticity, the effects of deprivation on the development of orientation columns has been a highly disputed issue (Blakemore and Cooper, 1970; Hirsch and Spinelli, 1970; Stryker and Sherk,

1975). The issue has recently been reexamined using optical imaging of orientation columns during development in normal and deprived animals. This work shows that, in agreement with earlier observations, orientation selectivity develops independently of visual experience, but neuronal activity is required to fine-tune and maintain the orientation map into adulthood (Crair et al., 1998; Sengpiel et al., 1999; White et al., 2001; Wiesel and Hubel, 1974). Although activity may not be necessary for the development of orientation columns, cross-modal rewiring experiments strongly suggest that visual afferents can create orientation columns in the auditory cortex (Sharma et al., 2000).

The emerging consensus on the development of the functional architecture of the cortex is that the construction of both orientation and ocular dominance columns is largely activity independent, but that the fine-tuning and maintenance of columns during the critical period depends on activity. These findings imply that early development of the columnar organization relies on molecular markers that may tag columns in the early phase of thalamic innervation of the cortex and that may share certain features with molecules known to be expressed in the embryonic cortex (Donoghue and Rakic, 1999; Flanagan and Vanderhaeghen, 1998).

Development of corticocortical pathways

During phylogeny, there is a progressive shifting of visual processing to more central structures of the brain. One consequence is that, in the mammal, more than 90% of the synapses in the brain occur in the cerebral cortex. Quantitative investigation of the cortex shows that 95% or more of synapses in the cortex are of cortical origin (Kennedy and Falchier, unpublished). One consequence of these figures is that developmental processes of the corticocortical pathways could have a major impact on the development of visual function.

It is now firmly established that the connectivity of infragranular-layer neurons is determined during the last round of mitosis in the ventricular zone prior to migration to the cortical plate (Polleux et al., 1998a; Polleux et al., 2001). Hence, commitment to a corticothalamic, corticocortical, and corticospinal fate is made independently of environmental influences in the cortical plate (Arimatsu et al., 1999; Koester and O'Leary, 1993; Polleux et al., 1997). There is evidence that specification of neuronal phenotype in the supragranular layers occurs at a later stage, so one might expect the determination of corticocortical neurons to be influenced more by epigenetic factors than is the case with other cortical connections. (McConnell, 1988). For many years, the callosal pathway linking the two hemispheres was the major model for the study of the develop-

ment of cortical connectivity. Because the callosal connections in the adult are largely concentrated at the areal boundaries of area 17, the demonstration that these connections are initially more widespread suggested that elimination of so-called exuberant connections is largely responsible for forming the adult connectivity pattern (Innocenti et al., 1977). Although the elimination of exuberant callosal connections has been demonstrated in a wide range of species, its generality is nevertheless questioned by the fact that this developmental phenomenon does not occur in area 17 of primates and rats (Dehay et al., 1988b; Chalupa et al., 1989; Hernit et al., 1996). This further raises the question of how important axon retraction is in the development of other types of cortical connections.

The connections of the cortex can be subdivided into two broad categories in which developmental control seems to differ. Intrinsic cortical connections (also known as intra-areal, horizontal, lateral, or tangential connections) link neurons within a cortical area, whereas extrinsic (or inter-areal) cortical connections link neurons in different cortical areas. In numerical terms, intrinsic connections constitute the vast majority of cortical connections, whereas extrinsic connections have been demonstrated to have much sparser connectivity (Kennedy et al., 2000).

HORIZONTAL INTRINSIC CONNECTIONS Horizontal intrinsic connections have been implicated in the elaboration of receptive field properties of individual neurons, including mediating inhibitory and excitatory effects from outside the classical receptive field (Das and Gilbert, 1999). Long-distance horizontal connections in superficial layers originate from pyramidal and spiny stellate neurons and form periodic clusters (Gilbert and Wiesel, 1979; Martin and Whitteridge, 1984; McGuire et al., 1991; Rockland and Lund, 1982). These connections have been shown to preferentially link columns with similar orientation preferences (Gilbert and Wiesel, 1989; Ts'o et al., 1986; Weliky and Katz, 1994), and similar or dissimilar ocular dominance columns (Livingstone and Hubel, 1984; Malach et al., 1993; Yoshioka et al., 1996).

Although developmental studies agree that the clustered connectivity that is characteristic of the adult emerges from a nonclustered juvenile situation, there is some uncertainty as to what extent this involves the elimination of inappropriate connections or the addition of appropriate connections. Studies that have focused on the maximum extent of connectivity have claimed tangential extensions of 10 mm in the kitten, compared to the adult configuration of 2 to 4 mm (Luhmann et al., 1986). This contrasts with later studies showing that the maximum extent of connections does not change significantly during development (Callaway and Katz, 1990, 1991; Lubke and Albus, 1992a, 1992b). These

later studies agree that, in kittens, clusters are formed by the end of the second postnatal week, shortly after eye opening. The studies by Callaway and Katz (1990) claim that crude clusters are present at the end of the second postnatal week and are later refined. However, the idea of a prolonged period of cluster refinement has been challenged by Lubke and Albus (1992a, 1992b), who showed that adult-like clusters are already present at the end of the second week. Lubke and Albus argue that the apparent late refinement of clusters seen by Callaway and Katz could be the consequence of using relative large tracer injections. Studies of the formation of clustered horizontal connections further differ on the reported effects of visual deprivation. Whereas dark rearing appeared to delay cluster refinement in some studies (Callaway and Katz, 1991; White et al., 2001), the rapid formation of clustered tangential connections was not influenced by dark rearing in the study of Lubke and Albus (1992a, 1992b).

The consensus remains that it is the emergence of clusters, rather than the restriction of tangential extent, that characterizes the formation of horizontal connections. However, the size of the tracer injection may govern whether one observes late refinement of cluster formation and an effect of dark rearing (Lubke and Albus, 1992b). Although one cannot exclude the possibility that increasing injection size introduces an experimental artifact, there is another possibility. Using paired injections of two distinguishable tracers with known interinjection separation, it is possible to examine the topographic organization of connections of large populations of neurons in the visual cortex. Such experiments show that, during development, the divergence and convergence values of intrinsic connections in area 17 remain constant for most area-17 neurons. However, a small contingent of neurons, less than 2%, do show much higher divergence values in the immature cortex than in the adult cortex (Kennedy et al., 1994). Thus, small injections or injections of single cells tend to emphasize the connectivity of the majority of neurons and may fail to detect the refinement of a subpopulation of neurons with widespread connections. The developmental significance of this subpopulation of immature corticocortical neurons with large divergence values remains to be explored.

VERTICAL INTRINSIC CONNECTIONS How information flows through the cortex is determined by the specific set of connections linking the cortical layers (Gilbert, 1983; Martin and Whitteridge, 1984). Throughout development, interlaminar connections show high target specificity, and the linking of cortical layers appears not to involve elimination of inappropriate connections (Callaway and Katz, 1992; Callaway and Lieber, 1996; Dantzker and Callaway, 1998; Katz and Callaway, 1992). These results suggest that layer-specific cues enable developing axons to form appropriate

connections at early stages of axonal outgrowth. The role of intrinsic influences has been examined in *in vitro* experiments. Immature cortical slices maintained in culture show that layer-specific connections of layers 5/6, but not 2/3, develop in the absence of extrinsic influences (Bolz et al., 1992; Butler et al., 2001; Dantzker and Callaway, 1998; Yamamoto et al., 1992).

The intrinsic cortical cues, which are used by growing axons interconnecting the cortical layers, are thought to be both molecular and activity dependent in origin. Axons from presumptive layer 6 precursors preferentially grow on membranes prepared from layer 4, the laminar targets of layer 6. This finding supports the notion that molecular surface bound cues promote axonal growth of layer 6 neurons on layer 4 (Castellani and Bolz, 1997). However, layer 6 neurons apparently require activity to contact their targets in layer 4 correctly. This has been demonstrated experimentally by maintaining cortical slices in the presence of the sodium channel blocker tetrodotoxine (TTX), which blocks spontaneous activity. In normal development, layer 6 axons grow through layer 5 and form axonal branches in layer 4. However, in the presence of TTX, layer 6 neurons form extensive branches in layer 5 (Callaway and Lieber, 1996; Dantzker and Callaway, 1998). In contrast, layer 5 neurons show normal targeting and specifically contact layers 2/3 in the absence of spontaneous activity (Butler et al., 2001).

The ability of infragranular layers to form layer-specific connections is independent of extrinsic cortical factors, and these connections, therefore, develop normally *in vitro*. This contrasts with the supragranular layers, which apparently fail to form layer-specific connections *in vitro*, suggesting that neurons in layers 2/3 depend on extrinsic factors for their appropriate development (Butler et al., 2001). Layers 2/3 are the major source of feedforward projections to higher cortical areas, and feedforward neurons in these layers receive monosynaptic input from feedback projections from these same areas (Johnson and Burkhalter, 1997). One possibility is that the feedback projections from higher areas are required for the normal development of the layer 2/3 interlaminar connectivity.

INTERAREAL CONNECTIVITY In all mammals, the visual cortex is divided into multiple distinct areas that are organized into a hierarchical network (Coogan and Burkhalter, 1993; Felleman and Van Essen, 1991; Krubitzer and Huffman, 2000). Individual areas often show different cytoarchitectures, have distinct inputs and outputs, and emphasize the representation of specific attributes of the retinal image (Van Essen and Gallant, 1994). These functional specializations are reflected in receptive field properties that, in the primary visual cortex, encode simple features, such as the orientation of light bars or edges, and

that in higher areas represent increasingly more complex aspects of the visual scene (Felleman and Van Essen, 1991). The neuronal activity at different levels of the cortical hierarchy critically depends on ascending connections linking lower with higher visual cortical areas (Vanduffel et al., 1997). These all-important inputs are provided by a surprisingly small number of feedforward connections that account for only 1% to 3% of asymmetric synapses in the target region (Anderson et al., 1998; Johnson and Burkhalter, 1996). Feedforward inputs terminate principally in layer 4 in a topographically organized fashion (Maunsell and Van Essen, 1983; Price et al., 1994; Rockland and Pandya, 1979; Rockland and Virga, 1990). It is thought that these inputs contribute to the construction of progressively larger and more complex receptive fields at successive levels of the hierarchy (Felleman and Van Essen, 1991). In addition to these functions, feedforward connections channel inputs into the ventral and dorsal processing streams that are specialized for the representation of visual objects and spatial relationships (Maunsell and Newsome, 1987).

Pathways leading from higher to lower areas are provided by feedback connections. There is every indication that these connections are at least as numerous as the feedforward connections (Johnson and Burkhalter, 1996; Kennedy et al., 2000). Unlike feedforward pathways, feedback connections terminate outside of layer 4 and distribute their outputs over more extensive parts of the visuotopic map than do feedforward projecting neurons (Perkel et al., 1986). Widespread feedback connections not only provide input from noncorresponding regions of the map, but also are thought to combine signals from distinct processing streams (Rockland et al., 1994; Rockland and Virga, 1989; Zeki and Shipp, 1988).

The physiological role of feedback connections has been most effectively studied by reversible cooling of higher cortical areas and recording of the effects on neuronal responses in lower areas. Experiments in monkeys have shown that feedback inputs from both V3 and V2 to V1 facilitate responses to stimuli moving within the classical receptive field (Sandell and Schiller, 1982) and enhance suppression from outside the receptive field (Hupé et al., 1998). These effects suggest that feedback connections are involved in the discrimination of objects relative to the background. However, indirect evidence strongly suggests that feedback connections mediate top-down influence that result from attention, memory retrieval, and imagery (Chelazzi et al., 2001; Ishai and Sagi, 1995; McAdams and Maunsell, 2000; Motter, 1994; Naya et al., 2001).

In a widely held view, perceptual abilities are, to a large extent, determined by the organization and processing capabilities of feedforward and feedback circuits interconnecting areas at different hierarchical levels. Networks of such enormous complexity must vary in their detailed synaptic

organization. These differences may account for the wide range of cognitive abilities among individuals. Variability in hierarchical networks may arise from both the implementation of genetic programs and the patterns of activation during development. To determine the role of each of the factors in the development of feedforward and feedback connections, a number of studies have investigated when and how inter-areal pathways acquire a lamina specific and topographic organization, segregate into functionally distinct channels, form specific hierarchical relationships, and acquire distinct balances of excitation and inhibition.

INTER-AREAL CONNECTIONS OF PREPLATE NEURONS The earliest inter-areal connections are formed before the cortical plate by neurons of the marginal zone. A major population of cells in the primordial layer 1 are Cajal-Retzius (CR) neurons that constitute a diverse group of neurons composed of derivatives of the subpial granular layer of the preplate and the neuroepithelium behind the olfactory bulb (Meyer and Wahle, 1999). Some CR neurons send out axons that are completely confined to layer 1, extend for millimeters, and are long enough to interconnect different cortical areas (Derer and Derer, 1990; Marin-Padilla, 1984). Unlike inter-areal projections of cortical plate neurons that branch mainly at the end of the pathway, axons of CR neurons branch near the cell body, mainly issuing boutons of passage and distributing outputs over large parts of the cerebral cortex (Derer and Derer, 1990). This projection pattern indicates that connections of CR neurons are not point-to-point and are not designed to preserve the spatial relationship of sensory maps. Instead, they may provide a network for synchronizing activity of pyramidal neurons in different areas (Schwartz et al., 1998). The most fascinating feature of these connections is that they are not permanent. In fact, in the rat and monkey, they are eliminated in the first 1 to 3 weeks after birth owing to the death of CR neurons (Derer and Derer, 1990; Huntley and Jones, 1990). The reason for their demise remains unknown, but some of the consequences have been documented. One of these is that ablation of CR neurons in newborn mice arrests the migration of neurons to superficial layers of cerebral cortex (Super et al., 2000). Similar experiments in the developing hippocampus have further shown that CR neurons are necessary for the development of the lamina-specific innervation by afferents from the entorhinal cortex (Del Rio et al., 1997). In the mature cerebral cortex, layer 1 is thought to be strongly innervated by inter-areal feedback connections (Coogan and Burkhalter, 1993; Rockland and Virga, 1989). By contrast, feedforward inputs to layer 1 are sparse (Coogan and Burkhalter, 1993; Felleman and Van Essen, 1991). These distinct laminar innervation patterns emerge during development. Interestingly, feedforward connections acquire

their lamina specificity during a period in which layer 1 is occupied by CR neurons (Knutsen et al., 1997; Patel et al., 1999). However, as soon as CR neurons begin to vacate the marginal zone, feedback connections start to innervate layer 1. Whether these events are causally related is not known. However, the synchrony in which they occur suggests that CR neurons may play a gatekeeper role for the innervation of layer 1.

Support for this idea derives from experiments in cortical slices that show that high levels of a chemorepellant near the marginal zone keep pyramidal cell axons away from layer 1 (Polleux et al., 1998b). The postulated repulsion of feedforward axons may be caused by a factor that is secreted by CR neurons. At first glance, this scenario seems to contradict the growth-promoting activity attributed to hippocampal CR neurons (Del Rio et al., 1997). However, the recent demonstration that attraction and repulsion depends on the intracellular amount of cyclic nucleotides (Song et al., 1998) suggests that the different responses may be attributable to diverse concentrations of second messengers in neocortical and paleocortical projection neurons.

During late fetal or early postnatal development, subplate neurons, a different, perhaps better known, population of short-lived preplate neurons (Luskin and Shatz, 1985), form connections with subcortical structures (De Carlos and O'Leary, 1992; McConnell et al., 1989). Intracortical connections of subplate neurons also have been observed within the subplate, as well as to the cortical plate, and have been reported, in one study, to extend to the homotypic areas of the opposite hemisphere (Antonini and Shatz, 1990; Friauf et al., 1990). There is currently no evidence that subplate neurons form inter-areal connections. Thus, the postulated role of subplate neurons as pioneer neurons that provide a scaffold for the development of cortical pathways might only apply to descending pathways (De Carlos and O'Leary, 1992; McConnell et al., 1989), but some researchers dispute that such a scaffold role ever applies in descending pathways (Clasca et al., 1995).

FEEDFORWARD CONNECTIONS In vivo retrograde tracing experiments in the visual cortex of fetal monkeys and DiI tracing studies in the fixed brains of monkeys and humans have demonstrated that feedforward connections from lower to higher cortical areas emerge prenatally during the third trimester of gestation (Barone et al., 1996; Burkhalter et al., 1993; Coogan and Burkhalter, 1988). In the cat, feedforward connections from area 17 to area 18 are well established at birth (Kennedy et al., 1994; Price and Blakemore, 1985a; Price et al., 1994), suggesting that they emerge at late fetal stages. In rodents, the earliest connections between V1 and V2 were observed at postnatal day 1 (Coogan and Burkhalter, 1988; Knutsen et al., 1997; Patel, 1994; Patel et al., 1999). Relative to the time point when neuronal

migration ends (Ignacio et al., 1995; Rakic and Nowakowski, 1981; Shatz and Luskin, 1986), the onset of the formation of inter-areal connections in cats is 2 to 3 weeks earlier than in rodents and primates.

In newborn kittens, feedforward connections from area 17 to area 18 originate from superficial and deep layers (Price and Blakemore, 1985a; Price et al., 1994). As development proceeds, the number of projection neurons in upper layers increases to a peak, after which it declines to the adult level (Price et al., 1994). Quantitatively similar developmental processes have been observed in forward pathways of the monkey visual cortex. Here, feedforward projections from V1 to V4, V2 to V4, and V3A to V4 in both the adult and the fetus principally originate from supragranular layers (Barone et al., 1996; Batardière et al., 2002; Coogan and Van Essen, 1996).

In the adult cat, feedforward projecting neurons from area 17 to area 18 form distinct clusters (Gilbert and Kelly, 1975) that contain cells with similar receptive field properties (Gilbert and Wiesel, 1989). Retrograde tracing studies have shown that, at birth, projection neurons in superficial and deep layers are distributed uniformly and that the clusters emerge during the first 3 postnatal weeks (Bullier et al., 1984; Price and Blakemore, 1985b). Although these findings suggest that inappropriate connections are eliminated, the demonstration in newborn kittens that anterogradely labeled feedforward connections from area 17 form distinct clusters in deep layers of area 18 (Price and Zumbroich, 1989) clearly indicates that feedforward connections develop with a high degree of spatial precision. A complementary retrograde study has shown that this is true for the bulk of feedforward connections, and has further demonstrated that inappropriate feedforward connections in newborn kittens are the result of a small population of neurons with widespread axonal connections (Kennedy et al., 1994). Most of these connections are formed by supragranular neurons (Caric and Price, 1996). This mode of development is not a peculiarity of cat area 17 to area 18 connections. In the monkey, the earliest (embryonic day 112) feedforward projecting neurons from V2 to V4 are clustered and are in register with regions of high acetylcholinesterase activity (Barone et al., 1996). Similar clusters, albeit weaker, have been observed after white matter injections of E129 fetuses. Clusters in older animals were more distinct than in animals at an early stage of development. Together, these findings indicate that feedforward axons grow to roughly the correct location and then enter gray matter, after which axon arbors undergo minor remodeling. In the monkey, this process is largely complete at birth. Although these results strongly argue for precise target selection by feedforward axons, it remains unknown whether similar mechanisms guide the development in the vertical dimension to form connections with the correct layers.

FEEDBACK CONNECTIONS Retrograde and anterograde tracing studies have shown that cortical feedback connections emerge at about the same time as feedforward connections. In the monkey, feedback connections to V1 begin to form at E108 (Fig. 11.1; Barone et al., 1995; Coogan and Van Essen, 1996). In humans, they are present at 37 weeks

of gestation (Burkhalter et al., 1993). In the cat, feedback connections to areas 17 and 18 are present at birth, indicating that they emerge at late fetal stages (Batardière et al., 1998; Dehay et al., 1984; Kato et al., 1991). In mice and rats, sparse feedback connections are present at postnatal day 1 (Knutsen et al., 1997; Patel et al., 1999).

FIGURE 11.1. Schematic representation of the development of inter-areal feedforward and feedback connections in monkey visual cortex (Barone et al., 1995; Barone et al., 1996; Batardière et al., 2002). The development of the laminar and tangential distribution of axon arbors is inferred from the distribution of retrogradely labeled neurons; it has not yet been shown directly by anterograde tracing of axonal connections. The diagram illustrates a highly dichotomous strategy of the development of feedforward and feed-

back connections. Feedforward connections are complete early in prenatal life, and their development largely depends on directed growth and target recognition mechanisms that do not involve large-scale elimination of inappropriate axons. In contrast, the development of feedback connections requires prolonged remodeling, massive postnatal pruning of early-formed axon connections, and elaboration of branches. *AChE*, acetylcholinesterase-rich bands in area V2 (Barone et al., 1995).

In vivo retrograde tracing studies in the cat and monkey have shown that, early in development, feedback connections are formed by both supragranular and infragranular neurons (Barone et al., 1995; Batardière et al., 1998; Kato et al., 1991; Kennedy et al., 1989; Meissirel et al., 1991). For unknown reasons, DiI tracing in fixed tissue of monkey and human visual cortex has failed to reveal early feedback connections from upper layers (Burkhalter et al., 1993; Coogan and Van Essen, 1996), and similar results have been reported in the developing rat visual cortex (Coogan and Burkhalter, 1988). Recent experiments in mouse visual cortex with biotinylated dextran amine, however, have revealed feedback projecting neurons originating from upper layers (Q. Wang and A. Burkhalter, unpublished observations), suggesting that technical reasons may account for the failure to label upper-layer neurons in some earlier studies. Regardless, it is clear from experiments in the cat and monkey that many feedback connections from upper layers are transient and gradually eliminated over a prolonged period that begins at fetal stages and ends about 1 to 2 months after birth (Barone et al., 1995; Batardière et al., 1998; Batardière et al., 2002). The elimination of upper layer neurons leads to both a reduction in the overall strength of the connection and a small increase in the topographic precision (Barone et al., 1995; Batardière et al., 1998; Batardière et al., 2002). In contrast, during maturation, deep-layer connections become stronger and more widespread, presumably by delayed ingrowth of axons into the target (Barone et al., 1995). All of these insights have been obtained by retrograde tracing experiments; it will be critical to see with anterograde labeling techniques whether, and in what way, the present concepts need to be revised.

Studies in rodents show that feedback axons reach their final laminar targets several days after feedforward connection (Knutsen et al., 1997; Patel et al., 1999). This is consistent with the notion that feedback connections mature over a longer period than do feedforward connections. At this point, the most important fact is that shaping of the feedback pathway takes longer than that of the feedforward pathway and involves more extensive remodeling of early connections, which, to a significant degree, occurs after birth. Comparison of rodent and primate development shows that essentially similar processes are involved, with the first formed connections stemming from the infragranular layers (Batardière et al., 2002; Coogan and Burkhalter, 1988). This suggests that the major role of pathfinding resides in the axonal outgrowth of infragranular-layer neurons when distances to be covered between cortical areas are relatively short compared to those in later stages, particularly in the monkey. This is followed by a later overshoot of the numbers of supragranular-layer neurons projecting in feedback pathways and the subsequent massive reduction of projections from supragranular layers.

Quantitative studies of the visual cortex in adult monkeys have shown that feedforward connections have a higher percentage of supragranular projection neurons than do feedback connections, and that, in each type of pathway, the percentage of supragranular neurons is correlated with the relative hierarchical rank of a given area (Barone et al., 2000). Recently, this framework has been used to interpret results from retrograde tracing of connections of V4 in the developing monkey visual cortex (Batardière et al., 2002). These studies have revealed that the hierarchical relations of extrastriate areas are invariant during development.

Clearly, feedforward and feedback pathways develop according to different strategies. Feedforward pathways are created largely through directed growth and target recognition and do not involve large-scale axon elimination. Feedback pathways, in contrast, require substantial and prolonged refinement of early-formed connections. Most interestingly, the relative rank of areas in the cortical hierarchy is established prenatally, weeks before the inter-areal connections have acquired their mature laminar, compartmental, and topographic organization. This implies that the identity, in terms of connectivity, of individual areas in monkey visual cortex is already specified at the time when feedforward and feedback connections first emerge. Therefore, it seems unlikely that inter-areal connections play a major role in the specification of cortical areas.

EFFECTS OF VISUAL DEPRIVATION The role of visual experience in the development of inter-areal connections has been studied mainly in the feedforward pathway. Studies of kittens raised with both eyes sutured closed—from before natural eye opening to up to 80 days postnatally—have revealed no apparent effects on clustering of neurons projecting from area 17 to 18 (Price and Blakemore, 1985a) or on the size and shape of axonal projections in area 18 (Zufferey et al., 1999). Furthermore, the retraction of early-formed connections from deep layers is independent of visual stimulation. However, in monocularly deprived kittens, the clusters of feedforward projecting neurons in area 17 are ~10% larger, suggesting a minor role of binocular competition in the refinement of topographic mapping (Price et al., 1994). These findings are consistent with the notion that, at the present level of resolution, feedforward connections are largely specified prenatally and that the development and maintenance are largely independent of patterned visual stimulation. Whether similar rules apply to the development of feedback connections is an interesting question. The protracted development that in monkey continues for weeks after birth certainly offers the opportunity for epigenetic influences on these connections.

SYNAPTIC ORGANIZATION So far, the issue of connectivity at the global level has been addressed. However, the actual

response of neurons to visual stimuli is the consequence of the activation by excitatory projection neurons of local excitatory and inhibitory neurons in the projection target. Based on the cortical processing of thalamocortical inputs, it was proposed that the local excitatory and inhibitory interactions are performed by a canonical circuit that is similar throughout cortex (Douglas and Martin, 1991). The key features of the model are that cortical activation is produced by a small number of afferent synapses whose excitatory effects are opposed by weak intracortical inhibition that, in turn, controls access to large numbers of excitatory, recurrent, intracortical connections that amplify the primary response. It has been shown recently that the basic structure of the canonical circuit applies to inter-areal feedforward and connections (Johnson and Burkhalter, 1996). In rodent, cat, and monkey visual cortex, mature inter-areal feedforward and feedback connections form asymmetrical synapses on pyramidal and nonpyramidal neurons (Anderson et al., 1998; Johnson and Burkhalter, 1996; Lowenstein and Somogyi, 1991). In adult rats, about 10% of both feedforward and feedback inputs between areas V1 and V2 are sent to nonpyramidal cells that all belong to the same family of parvalbumin expressing GABAergic neurons (Gonchar and Burkhalter, 1999). The remaining 90% of connections are formed on pyramidal neurons.

Stimulation of feedforward or feedback inputs to pyramidal cells elicits monosynaptic excitatory responses followed by disynaptic inhibition (Dong et al., 1999; Shao and Burkhalter, 1996; Shao et al., 1996). Although postsynaptic excitation is similar in both pathways, inhibitory responses in the feedback pathway are smaller and less frequent than in the feedforward pathway (Dong et al., 1999; Shao and Burkhalter, 1996). One factor that might contribute to this difference is that feedback inputs terminate on thinner GABAergic dendrites than do feedforward inputs (Gonchar and Burkhalter, 1999). During development, this pathway difference emerges, after animals open their eyes 14 days postnatally, by selective elimination of feedback synapses from thick GABAergic dendrites (Yamashita et al., 2000). In parallel with these structural changes, during the third and fourth postnatal week, inhibition generated by feedback inputs becomes weaker, whereas inhibition in the feedforward circuit increases (Dong et al., 1999; Shao and Burkhalter, 1998). In mice raised with one eye closed for 36 days, this transformation of the feedback circuit is arrested, and inhibition of pyramidal neurons remains as strong as in the feedforward circuit (Dong et al., 2001). The effect is specific to the binocular region of area 17, suggesting that the development of intracortical inhibition is influenced by competitive mechanisms. The transformation of inhibition in the feedback pathway from a level that is similar to the feedforward circuit to a significantly lower amount fails to occur in BDNF-overexpressing mice (Dong et al., 2000).

This suggests that the pathway-specific balance of excitation and inhibition in inter-areal circuits is determined by the activity-dependent competition for a neurotrophic factor. Further studies are needed to determine whether, in BDNF-overexpressing mice, feedback synapses fail to retract from thick GABAergic dendrites (Yamashita et al., 2000).

Conclusion

Distinguishing between feedforward and feedback projections in the cortex suggest that they follow different sorts of developmental control. The feedback connections appear to undergo prolonged maturation in which inappropriate connections are eliminated so that activity-mediated processes can be implemented. Feedforward projections show directed growth and target selection and are precociously formed, suggesting that molecular guidance mechanisms may be more predominantly used in these pathways. Studies suggest that similar differences in the development of feedforward and feedback pathways are to be found in the ascending pathways. The terminal arbors of retinal feedforward projection to the LGN show progressive increases in size and target appropriate territories (Kennedy et al., 2001; Snider et al., 1999). As discussed earlier, similar findings characterize the feedforward projections from the LGN to the visual cortex. Not much is known about the development of feedback projections from the cortex to the thalamus, but interestingly, in the adult, corticogeniculate arbors span several layers of the LGN (Murphy and Sillito, 1996). This is in sharp contrast to the feedforward input from the retina to the LGN. These results suggest similar developmental mechanisms in feedback and feedforward projections at different levels and hint that they may share common physiological functions. In this respect, the role of feedback projections to the LGN in controlling mode of firing (Sherman, 2001) may prove to be significant for understanding the role of corticocortical feedback projections onto feedforward neurons (Johnson and Burkhalter, 1997). At the level of the cortex, the development and maintenance of feedback projections that perform the processing of retinal inputs necessary for the segmentation and interpretation of the visual scene (Lamme and Roelfsema, 2000) may depend on visual experience.

12 Neural Limitations on Visual Development in Primates

LYNNE KIORPES AND J. ANTHONY MOVSHON

NEWBORN PRIMATES see poorly. Their visual capacities improve over time, with a course that varies somewhat depending on the measure used to define visual function and the species studied. Many common measures of vision reach adult levels by the age of about 1 year in macaque monkeys and about 5 years in humans; during the period of maturation, performance typically improves roughly 10- to 30-fold. Figure 12.1 caricatures the effect on vision of two of these measures, spatial resolution and sensitivity to spatial contrast. The panel on the left shows a cityscape as seen by an adult, whereas the panel on the right shows the same scene transformed to represent the view of a newborn infant. The “infant view” has been spatially lowpass-filtered (blurred) and reduced in contrast.

Figure 12.2 shows developmental measurements of spatial resolution (Kiorpes, 1992a; Movshon and Kiorpes, 1988) and contrast sensitivity (Boothe et al., 1988) taken from macaque monkey infants. Figure 12.2A shows grating activity data from a group of young monkeys tested cross-sectionally; Figure 12.2B shows a series of contrast sensitivity functions measured longitudinally in two representative individual animals. Figure 12.2B emphasizes that different animals develop at different rates, so in Figure 12.2C we show the range of sensitivity and resolution values measured across a population of six monkeys. Both resolution and sensitivity develop smoothly over the first 6 to 12 months of life. These functions mature somewhat more rapidly when measured electrophysiologically using a visual evoked potential (VEP) technique in monkeys (Skoczenski et al., 1995) and humans (Kelly et al., 1997; Norcia et al., 1990; Chapter 13; see also Peterzell et al., 1995). This discrepancy between techniques is not surprising given that the VEP signal arises from the summed activity of visual cortical neurons. As we discuss later, neurons in infant visual cortex are considerably more mature than behavior would suggest.

We want to understand the processes that limit visual development. In the first part of this chapter we will consider what aspects of visual system organization and function limit performance in newborn infants, and what factors develop to permit attainment of adult level of visual performance. We are also interested in the modifiable mecha-

nisms that are responsible for the altered visual development that occurs when normal vision is disrupted, and in the second part of the chapter we will explore the neural factors responsible for this behavioral plasticity.

Visual input

Many aspects of the eye and the optical and retinal elements involved in the initial encoding of the visual stimulus improve postnatally. The macaque eye grows by about 40% from infancy to adulthood, increasing the magnification of the retinal image (Blakemore and Vital-Durand, 1986a; Williams and Boothe, 1981). The quality of the eye’s optics improves over the same span (Williams and Boothe, 1981), increasing the resolution and contrast of the retinal image. Even in the absence of neural changes, the increased retinal magnification would cause a proportionate improvement in visual resolution as long as retinal sampling was held constant. The optical changes are less likely to be important for infant vision, as they primarily affect spatial frequencies well beyond the behavioral resolution limit at any age. So optical factors seem unlikely to account for more than about a 40% change in visual resolution. Retinal changes, however, may be more significant.

Hendrickson and her colleagues have shown that the morphology and distribution of cone photoreceptors undergo marked changes after birth in both humans and monkeys (Hendrickson and Kupfer, 1976; Hendrickson and Yuodelis, 1984; Packer et al., 1990; Yuodelis and Hendrickson, 1986). The foveal concentration of cones that is characteristic of adult retinae is much less marked in neonates; during development, cones migrate toward the center of the fovea. Figure 12.3A shows this effect in data from five macaque monkeys aged 1 week to adult. The data in Figure 12.3A are plotted in terms of units of visual angle, so they incorporate both the effects of retinal changes and the effects of eye growth (which act in the opposite direction to the increase in retinal cone density created by migration). The combination of these factors changes the linear sampling density of the foveal cone mosaic by about a factor of 3 from 1 week to adulthood. This change is captured in Figure 12.3A by plotting the Nyquist frequency of the retinal

FIGURE 12.1. Simulation of the visual worlds of an adult and young infant primate. To create the simulated image on the right, the image on the left was convolved with a Gaussian, the σ of which was 1° ; the image contrast was reduced by a factor of 5. The angular width of the view shown is approximately 10° .

mosaic, the highest spatial frequency that can be accurately reconstructed from samples spaced like foveal cones; this value grows from about 18 cycles/degree at 1 week to about 55 cycles/degree in adulthood. Comparing these values with the behavioral measurements of resolution in Figure 12.2A shows that in no case does the spacing of foveal cones seem to impose an important limit on visual resolution. Figure 12.3A shows that much of the change in foveal cone density takes place by 4 weeks of age in macaques, but the period over which the photoreceptor array matures to its final adult levels is still somewhat unclear. Peak cone density is approximately 75% of adult density by 6 months of age in monkeys, and only about 50% of adult density by 4 years of age in humans (Hendrickson, 1992, 1993).

While photoreceptor migration is taking place, the structure of individual cones is also changing. Initially, their outer segments are short and stubby; but they develop over time to achieve the elongated, slender morphology of adult photoreceptors. This maturation permits the outer segment to capture light efficiently; in the immature retina, a far higher fraction of incident quanta fails to be absorbed by photopigment than in the adult retina (Banks and Bennett, 1988; Brown et al., 1987). Foveal cone outer segments appear generally adult-like by 12 weeks of age in monkeys and 15 months in humans; however, elongation of outer segments continues over the first year in monkeys and beyond 4 years in humans (Hendrickson, 1992, 1993).

The effects of such diverse factors as changes in the size and optical quality of the eye and changes in the morphology and distribution of receptors are critical for the performance of central visual mechanisms, but can be difficult to work out intuitively. They can conveniently be analyzed with

the theory of the “ideal observer” (Geisler, 1984, and Chapter 52, Ideal Observer Analysis). An ideal observer model uses the properties of optics and early visual elements to calculate ideal performance given just the early limitations; the cascade of factors is schematically shown in Fig. 12.3B. The ideal observer simulates each of the early steps in seeing from the incidence of light at the cornea to its absorption and representation by the photoreceptor array. The ideal observer is internally noise-free; its performance is limited only by the Poisson fluctuations in the number of photons absorbed by photoreceptors. As such, it is not a model of the nervous system; rather, it simulates the performance of a perfect nervous system limited only by the optical and photoreceptor apparatus available. It therefore provides an objective benchmark against which the performance of real, imperfect observers can be measured.

Following the work of Geisler (1984) and Banks and Bennett (1988), we created an ideal observer model for the infant macaque monkey and used it to compare real and ideal performance (Kiorpes et al., 2000b). We modeled ideal performance at three ages: 1 week, 4 weeks, and 24 weeks. To make as accurate a model as possible, we made as many measurements as possible from the same macaque species from which the behavioral data were drawn. The key parameters for the model at the different age points are listed in Table 12.1. The photoreceptor and cone density data and pupil diameters were measured directly from *Macaca nemestrina* monkeys; the other values were taken or estimated from the literature. The structure of the ideal observer model is shown in Figure 12.3B. To determine contrast threshold for each of a set of stimulus conditions chosen to be

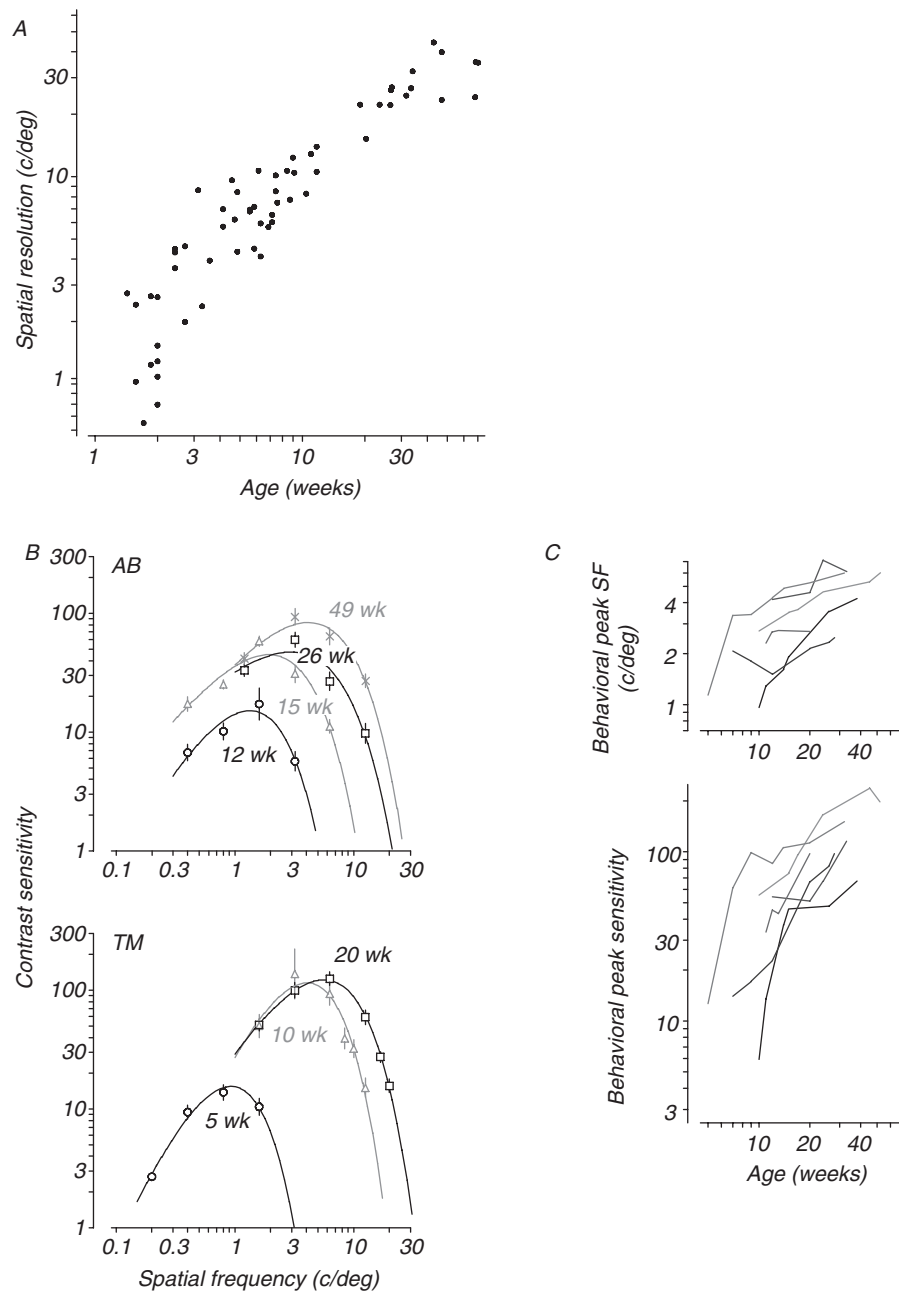

FIGURE 12.2. The development of spatial vision in infant macaque monkeys. *A*, Spatial resolution data from a set of 17 normal infant macaques (taken from Kiorpes, 1992a; Movshon and Kiorpes, 1988). The measure of spatial resolution was grating acuity, the highest spatial frequency at which a grating could reliably be distinguished from a uniform field of the same luminance. Animals younger than 16 weeks were tested using a forced-choice, preferential looking technique. Older animals were tested in a standard two-choice operant discrimination task. *B*, Spatial contrast

sensitivity functions, measured using operant techniques, in two infant macaques at a range of ages (as indicated) (data from Boothe et al., 1988). Error bars indicate the standard error of the mean threshold determined by Probit analysis. *C*, The range of rates of development of spatial contrast sensitivity in six infant macaques. Each line represents the course of contrast sensitivity development in an individual monkey. The two plots indicate the horizontal and vertical positions of the peaks of the measured contrast sensitivity functions. (Redrawn from Movshon and Kiorpes, 1988.)

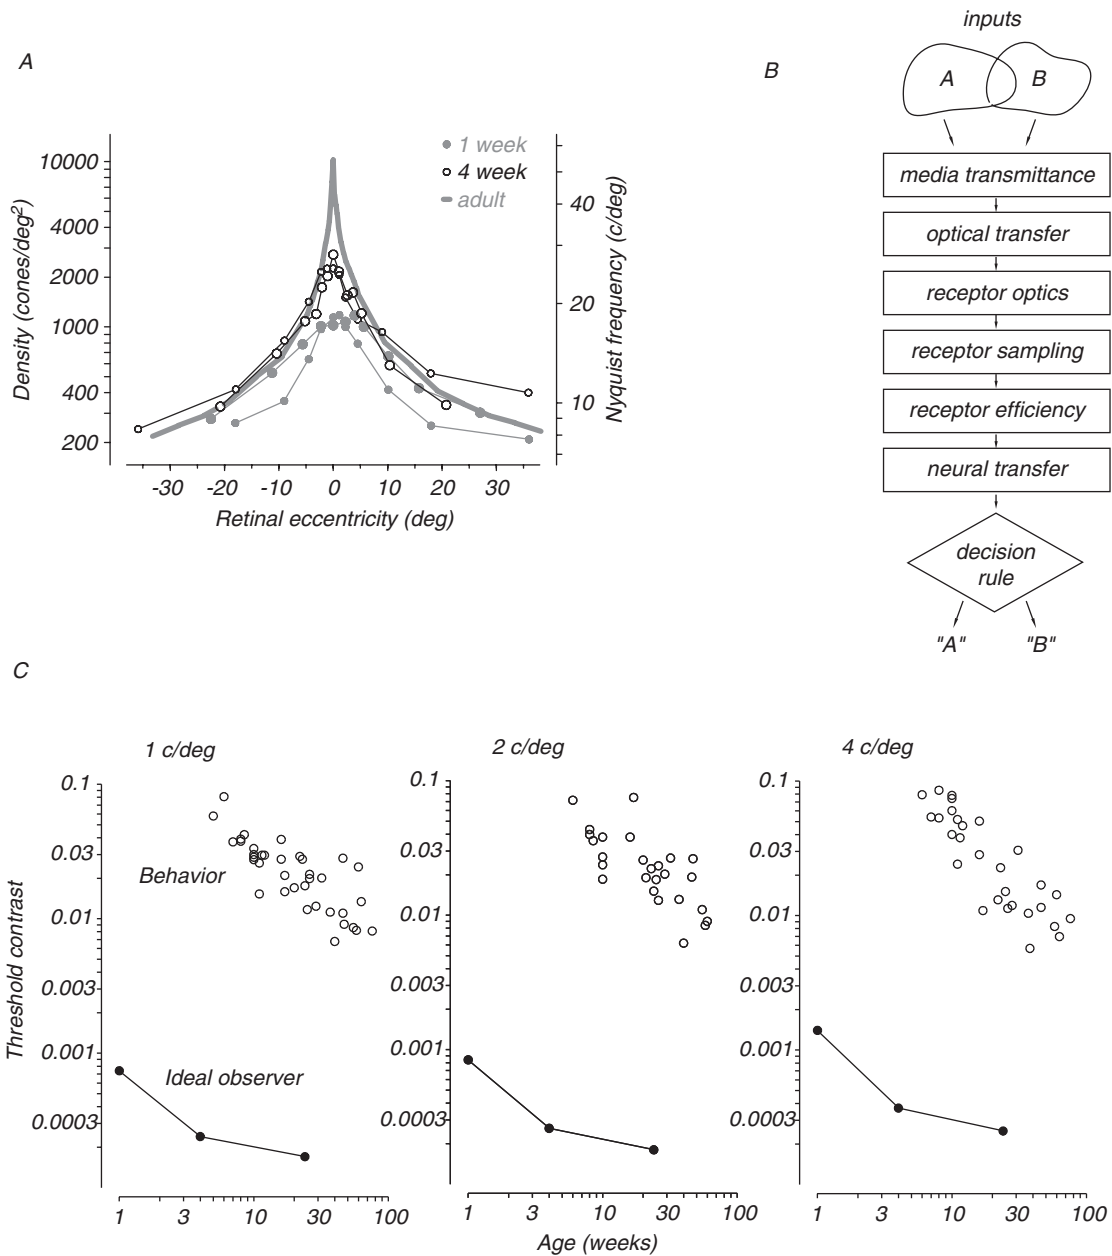

FIGURE 12.3. Assessing the influence of retinal development on spatial vision. *A*, Cone density along the horizontal meridian of the visual field in five macaque monkeys, aged 1 week to adult. Density is expressed on the left ordinate in units of areal density in visual space, and on the right ordinate as the Nyquist frequency of a perfect hexagonal array. The Nyquist frequency is the highest spatial frequency that can be accurately reconstructed from a given set of sample points. (Unpublished measurements by C. Henry,

M. J. Hawken, J. A. Movshon, and L. Kiorpes). *B*, A schematic illustration of the stages of analysis in an ideal observer model (after Geisler, 1984). See text for details. *C*, Comparison of contrast thresholds for macaques and for the macaque ideal observer model (Kiorpes et al., 2000b). Simulated thresholds for the ideal observer are shown as solid symbols connected by lines. Real thresholds, measured behaviorally in 13 macaques, are shown as open symbols (data from Kiorpes and Movshon, 1998).

TABLE 12.1

Key parameters for macaque ideal observer simulations

	1 Week	4 Weeks	24 Weeks
Line spread function width at half height (min arc)	2.25	1.69	1.33
Pupil diameter (mm)	4.8	5.3	6
Posterior nodal distance (mm)	10.91	11.84	13.52
Cone density (cone/mm ²)	37268	110374	202905
Outer segment diameter (μm)	1.94	2.09	1.79
Outer segment length (μm)	13.6	31.8	40.0

comparable to conditions used to gather data from monkeys, we simulated responses to a stimulus and a blank (inputs A and B). We filtered the inputs by the transfer function for the eye, sampled the stimulus using the measured photoreceptor mosaic, incorporated Poisson photon noise, computed the likelihood of a stimulus or blank, and chose the more likely (“A” or “B”). We repeated this process 1000 times for each condition, compiled the resulting data into psychometric functions, and analyzed them exactly as we analyze behavioral data. The results of these simulations for gratings of three spatial frequencies at the three chosen ages are shown in Figure 12.3C as filled points connected by lines. Comparable behavioral measurements are shown as isolated open symbols.

The first point to note is that the absolute sensitivity of the ideal observer is at least 100 times higher than the monkeys’; in other words, the animals’ quantum efficiency was no better than 1%. This value is comparable to that determined in humans (Banks and Bennett, 1988; Geisler, 1984; Pelli, 1990) and reflects the fact that observers do not seem to be capable of using all the information available in the pattern of photoreceptor quantum absorptions. However, ideal observer simulations are nonetheless useful for comparing *relative* performance, here given by the relative shapes of the trends for real and ideal observers. Developmental changes in sensitivity shown by the ideal observer are largely confined to the first 4 postnatal weeks, whereas the bulk of the change measured behaviorally takes place after 4 weeks. Therefore, very little of the change in contrast threshold beyond 4 weeks can be accounted for by changes in the visual periphery in macaque monkeys. Banks and Bennett (1988) performed a similar analysis in human infants, arguing that peripheral factors play a somewhat more prominent role in the development of contrast sensitivity. Our conclusions differ from theirs for two reasons: first, photoreceptors in infant monkeys are somewhat more mature than in human infants; second, we used a more realistic calculation to estimate the way that photopigment absorptions depend on outer segment morphology. In any case, our conclusions and Banks and Bennett’s differ only in detail, and suggest that the great bulk of postnatal develop-

ment in contrast sensitivity depends on neural factors and not on optical and retinal maturation.

Subcortical visual structures

Largely for technical reasons, little is known about the development of the physiological organization of retinal ganglion cell receptive fields. In cats, Rusoff and Dubin (1977) reported the presence of adult-like center responses within a week of eye opening in kittens; however, receptive field surrounds were weak compared to adult surrounds. Because the optical quality of the kitten eye is poor (Bonds and Freeman, 1978), the maturity of retinal neural circuits is not easy to assess from these data. There have been no studies of ganglion cell receptive fields in infant monkeys.

The primary recipients of information from the retina, the lateral geniculate nucleus (LGN) and superior colliculus (SC), have been studied in infant primate, as has the nucleus of the optic tract (NOT), which receives a small but direct input from the retina (Kourouyan and Horton, 1997; Telkes et al., 2000).

The organization of the optokinetic system, whose visual inputs come through the NOT and the dorsal terminal nucleus of the accessory optic system, is qualitatively adult-like between 5 and 12 weeks after birth (Distler et al., 1999), but there is little quantitative information available on neuronal sensitivity or receptive field organization in these structures. The functional organization and receptive field properties of neurons in newborn monkey SC are remarkably mature (Wallace et al., 1997). Topographic organization is adult-like in the neonate, as are many receptive field properties. However, receptive field sizes—particularly for neurons with receptive fields near the fovea—are larger in the newborn than in the adult. Visual responses are also more sluggish throughout the SC, and visual latencies are significantly longer than in adults. Wallace et al. (1997) have argued that the retinotectal input is the primary determinant of SC response properties in infants, with little contribution from corticotectal projections. They have suggested that the immaturities of SC response properties may be explained by postnatal maturation of retinotectal myelination and changes in the retina itself. This conclusion is based on the assumption that the properties of cortical receptive fields in infants are quite immature; however, as documented later in this chapter, neurons in the primary visual cortex are surprisingly mature in infants. Thus it is equally plausible that the visual responses of SC neurons in infants primarily reflect the properties of afferent input from cortex, as they do in adults (Schiller et al., 1974).

The development of receptive field properties of LGN cells in Old-World primates has been studied more extensively than SC and NOT (Blakemore and Vital-Durand,

1986a; Hawken et al., 1997; Movshon et al., 1997). Like SC neurons, LGN cells in newborn monkeys often respond sluggishly to visual stimuli, and they have longer latencies than are found in adults. Blakemore and Vital-Durand (1986a) have found visual latencies to be mature by about 10 weeks of age. There is an overall improvement in visual responsiveness and spatial resolution in both parvocellular and magnocellular layers of the LGN over the first postnatal year in macaque monkeys, and Blakemore and Vital-Durand reported a sevenfold improvement in the visual resolution of LGN cells over this period. Moreover, Hawken and colleagues (1997) have demonstrated that the overall envelope of neuronal contrast sensitivity shows a profile much like that of behavioral development, with contrast sensitivity and spatial resolution developing concurrently. They found an early rapid development of contrast sensitivity over the first 2 months, followed by a more gradual progression to adult levels by about 8 months of age. Taken together, these studies suggest that the development of LGN spatial properties matches behavioral development, and that the properties of LGN cells or their afferents set an important limit on vision during development (Movshon and Kiorpes, 1993). Our own results (Movshon et al., 1997), however, present a somewhat different picture.

To compare behavioral development to physiological changes in LGN responses, we recorded from LGN cells in 1-week-, 4-week-, and 24-week-old macaque monkeys, and made quantitative measurements of their responses to spatial targets. For comparison with behavioral measurements, we concentrated on two aspects of LGN responses: sensitivity to contrast and sensitivity to spatial frequency. The results are shown in Figure 12.4, which places the data from the LGN in direct comparison with the behavioral data from Figure 12.2C. The shaded range and left-hand ordinates on each plot represent the changes in the position of the peak of the contrast sensitivity function (CSF) measured behaviorally. The symbols and right-hand ordinates represent the results of our LGN recordings. Each symbol represents the geometric mean (\pm the standard deviation of the distribution) of measurements from our whole population of LGN cells. The filled symbols show data from magnocellular neurons, whereas the open symbols represent data from parvocellular neurons. The upper plot shows values of the characteristic spatial frequency—this is the spatial frequency at which the response of the receptive field (RF) center mechanism, inferred from a fitted difference-of-Gaussians model, falls to $1/e$ of its peak (Enroth-Cugell and Robson, 1966; Linsenmeier et al., 1982). The lower plot shows values of responsivity, the slope of the initial linear segment of the contrast-response function, measured with optimal drifting grating targets (Linsenmeier et al., 1982). There is an improvement in both the sensitivity and spatial resolution of LGN cells between birth and 6 months, but a comparison

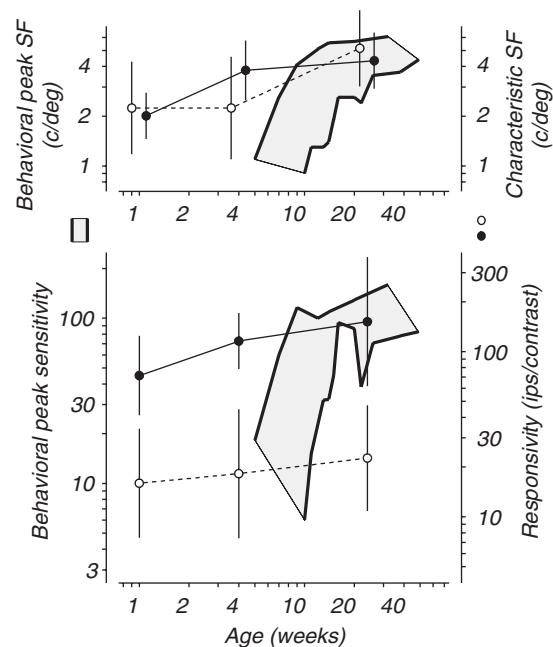

FIGURE 12.4. Comparison of behavioral contrast sensitivity development with the development of spatial contrast sensitivity in LGN neurons. The gray zone in each part of the figure represents (using the left-hand ordinates) the range between the slowest and fastest development in a population of six monkeys tested longitudinally (Boothe et al., 1988). The upper plot shows the development of the spatial frequency at which peak contrast sensitivity was observed; the lower plot shows the development of the peak contrast sensitivity value. The symbols and lines represent (using the right-hand ordinates) population data obtained from 355 LGN neurons recorded from 10 monkeys aged 1 to 24 weeks. Each symbol represents the geometric mean of the measured values of characteristic spatial frequency and responsivity in impulses per second (IPS) for parvocellular (*open circles*) and magnocellular (*filled circles*) neurons (see text for details). The error bars indicate ± 1 SD to convey a sense of the span of the underlying distribution. Note that the right- and left-hand ordinates are arbitrarily shifted so that the data sets meet at adult levels; no absolute relationship is implied.

of the physiological and behavioral data shows that the magnitude of the change is far too small to account for the observed behavioral changes. Moreover, although the physiological changes are, by most measures, largely complete by the age of 4 weeks, most behavioral changes occur later. We conclude that developmental changes in LGN response properties—and, by inference then, in the retinal afferents to LGN—are modest and do not account for behavioral change. In fact, the changes in LGN cell properties are similar to those expected of an ideal macaque observer (Fig. 12.3C), which as we have discussed is also an inadequate account of behavioral development. Our results differ from those presented in earlier reports (Blakemore and Vital-Durand, 1986a; Hawken et al., 1997) primarily in that we found far more adult-like spatial receptive fields in our youngest animals than they did. The difference may be

attributable to the different anesthetic techniques used. (Our studies used opiate anesthesia, whereas those of Blakemore and his colleagues used a combination of N₂O and barbiturates.)

Visual cortex

The primary visual cortex (V1) has long been known to show considerable postnatal modifiability by visual experience; moreover, the development of visual cortical response properties is seriously disrupted by visual deprivation. There is compelling evidence that normal vision is required for normal cortical development, and that abnormal vision can distort cortical development. This has led to the widespread view that the visual cortex is very immature at birth and that its development is actively “instructed” by visual input. An alternative view is that visual experience is not required to instruct development, but is merely “permissive,” allowing the normal sequence of developmental events to take place (for reviews, see Movshon and Kiorpes, 1990; Movshon and Van Sluyters, 1981). A crucial piece of evidence that distinguishes these views is the status of the visual cortex in very young animals. If, as initially claimed, the visual cortex of neonates is responsive to visual stimuli and contains at least some neurons with adult-like selectivity (Hubel and Wiesel, 1963), it would seem unlikely that visual experience served as a strong instructor for development. If, however, the neonatal visual cortex contains few neurons with adult-like responses, the argument for a strong active role for visual experience in visual development is much more plausible (Blakemore and Van Sluyters, 1975; Pettigrew, 1974). This debate initially centered on development in kittens, but the same differences of view have been recapitulated in the literature on development in monkeys (Blakemore, 1990; Blasdel et al., 1995; Chino et al., 1997; Movshon and Kiorpes, 1993; Wiesel and Hubel, 1974).

To revisit these questions and to explore the relationship between the development of physiological response properties of V1 cells and behavioral visual development, the authors recorded from cells in macaque monkeys, aged 1 week, 4 weeks, 16 weeks, and adult (Movshon et al., 1999, 2000), and made quantitative measurements of the animals’ responses to spatial stimuli. We studied a variety of response properties at each age point, including receptive field size and spatial frequency tuning, selectivity for orientation and direction of motion, and selectivity for stimulus area as an indication of the strength of receptive field surrounds. Figure 12.5 shows the development of six derived measures that summarize these developmental data. In each case, the algebraic or geometric mean value for the measure is given (\pm the standard deviation of the distribution; details of the analyses are given in the figure legend).

FIGURE 12.5. Development of the receptive field (RF) properties of V1 neurons in macaques (from Movshon et al., 1999, 2000). Each panel of the plot represents the development of a particular receptive field property in a study of 453 V1 neurons representing the central 5° of the visual field, recorded from 11 animals at the indicated ages. Each point represents the mean or the geometric mean, as appropriate, of the values measured for all neurons recorded at a particular age; the error bars indicate ± 1 SD to convey a sense of the span of the underlying distribution. In sequence from the top, the parameters displayed are *receptive field size*, defined as the size of an otherwise optimal patch of grating that elicited at least 95% of the maximum response (Cavanaugh et al., 2002); *spatial resolution*, defined as the highest spatial frequency at which the cell gave a response of at least 10% of its maximum; *spatial bandwidth*, defined as the ratio between the highest and lowest spatial frequencies giving at least half-maximal response, expressed in octaves; *orientation tuning*, defined as the change in orientation from the peak that causes the response to fall by one half; *direction index*, defined as $1 - np/p$, where p is the response to an optimal grating moving in the preferred direction and np is the response to the same grating moving 180° from the preferred; *surround suppression*, defined as the fractional reduction in response resulting from the enlargement of an optimal-size patch of grating to cover the full screen (Cavanaugh et al., 2002).

The two upper graphs in Figure 12.5 show the development of the spatial scale of V1 receptive fields by plotting receptive field size and spatial resolution for grating stimuli as a function of age. Both measures suggest that, from the age of 1 week to adulthood, receptive fields shrink on average by about a factor of 3, a value comparable to that seen for similar measures in LGN cells (see Fig. 12.4). The four lower graphs in Figure 12.5 show the development of four indices of receptive field selectivity. These show that, with remarkable consistency, the spatial structure of V1 receptive fields remains constant during development. None of the parameters that measure receptive field structure—selectivity for spatial frequency and orientation, selectivity for direction of movement, or strength of neuronal surround suppression—varies at all with age. In some other respects, V1 neuronal properties are immature in infants. For example, peak response magnitudes and sensitivity to rapid stimulus change are substantially less in 1-week-old animals than in adults; however, the visual effects of these changes are, to some degree, ameliorated by the curious fact that responses in 1-week-old animals are substantially more reliable than in adults (Rust et al., 2002).

The simplest picture that emerges from these data is that the receptive fields of visual cortex neurons gradually reduce in size during development, without changing any of their

other spatial properties. The degree to which they do this seems to be identical to the rate at which the receptive fields of LGN cells change size and the spacing between foveal cones decreases, but this is substantially slower than the rate at which behavioral changes take place. Figure 12.6A compares the evolution of several spatial properties during development. The graph plots visual acuity (from Fig. 12.2A), along with the development of spatial resolution of LGN and V1 cells and with the development of the cone mosaic as indicated by the Nyquist frequency. Changes in behavioral acuity are more extensive than changes in any of the neural properties plotted, and all these neural properties seem to develop in step, as evidenced by their parallel progressions across the plot.

The comparison shown in Figure 12.6A suggests that the changes in V1 spatial properties simply follow changes at the periphery. One explanation, articulated by Wilson (1988), is illustrated in Figure 12.6B (see also Brown et al., 1987; Peterzell et al., 1993; and Peterzell and Teller, 1996). Cortical receptive fields can be considered to be a map of connections directly back to the mosaic of cones whose signals drive them. As noted earlier, cones in infant retina are spaced widely (*top left*), and the receptive fields of cortical neurons (given in cross-section, *middle*) are correspondingly broad. This corresponds to a selectivity for relatively low spatial

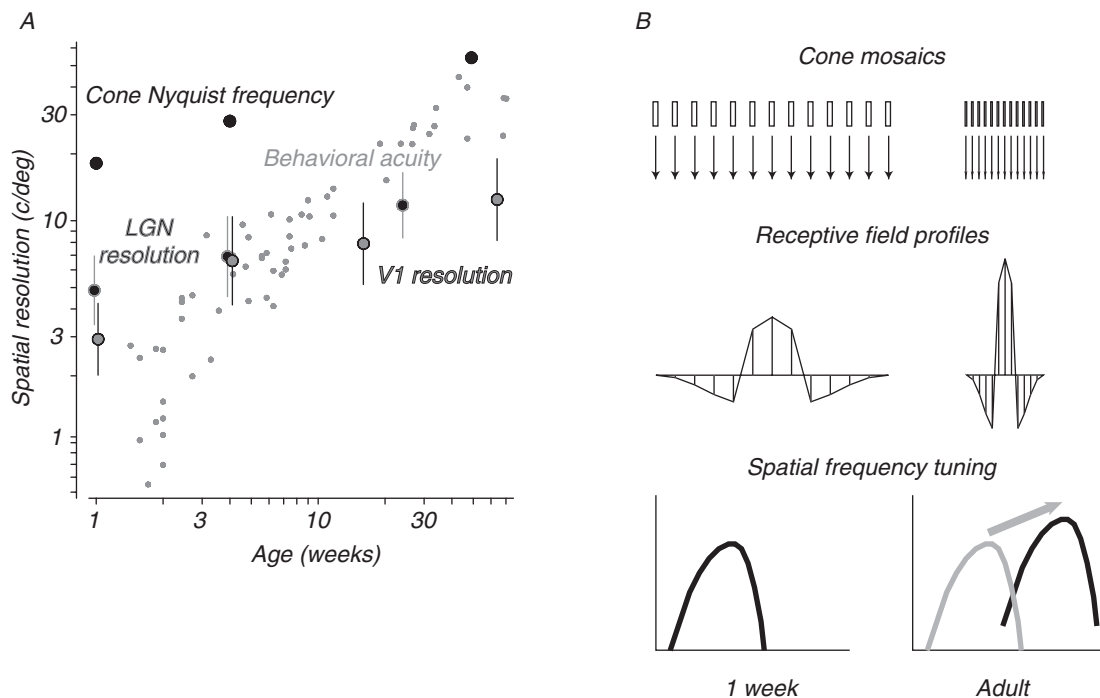

FIGURE 12.6. Relative development of different elements of spatial vision. *A*, The development of grating acuity (from Fig. 12.2A) is compared to three measures of neural development: Nyquist frequency (taken from the peak values of the cone density distributions in Fig. 12.3A); the spatial resolution of neurons in the

LGN (average of P and M cells, from Fig. 12.4); and the spatial resolution of neurons in V1 (from Fig. 12.5). *B*, A conceptual account of how cortical receptive field development would result from migration of cones; see text for details.

frequencies (*bottom*). Let us suppose that cortical receptive fields—as defined by their connections to cones—are unchanged during development. Now as the cones migrate toward the center of the fovea and become more tightly packed (*top right*), cortical receptive fields shrink in proportion (*middle right*), and neurons consequently develop a preference for higher spatial frequencies without changing the shape of their tuning curves (*bottom right*). Because of the changes in cone outer segment morphology (discussed earlier), the sensitivity of individual cones increases slightly during development, leading to a slight increase in contrast sensitivity, which, in turn, leads to the slight upward shift in the tuning curve (*bottom right*). Our finding that the resolution of V1 and LGN cells change at a rate similar to the change in peak density of cone photoreceptors, combined with the complete stability of neuronal selectivity for orientation and spatial frequency during development (see Fig. 12.5), suggests that cortical receptive field properties passively follow the retina as it develops. We earlier developed the argument that retinal changes are too small and happen too early in development to explain behavioral development; it follows, then, that postnatal changes at the level of the visual cortex also fail to account for the normal course of behavioral development.

The results of direct investigation of neonatal monkey cortex argue against the notion that visual experience is strongly instructive and instead support the idea that normal visual experience is simply permissive to normal visual development. The other important piece of the puzzle is to identify what specific changes take place in the face of abnormal visual experience.

Abnormal visual experience and amblyopia

It seems paradoxical that V1 receptive field development passively follows peripheral organization, which is not influenced by visual experience in primates (Blakemore and Vital-Durand, 1986b; Hendrickson et al., 1987; Levitt et al., 2001; Movshon et al., 1987), whereas decades of evidence has accumulated for experience-dependent plasticity in V1. Most studies of the effect of visual experience on development in primates have used monocular or binocular deprivation to manipulate visual experience (Baker et al., 1974; Blakemore, 1990; Blakemore and Vital-Durand, 1986b; Horton, 1984; LeVay et al., 1980; von Noorden and Crawford, 1978; Wiesel, 1982; Wiesel and Hubel, 1974). This kind of deprivation typically devastates spatial vision, reducing contrast sensitivity and resolution so severely that in some cases blindness results (Harwerth et al., 1983; von Noorden, 1973; von Noorden et al., 1970). The most obvious consequence of monocular deprivation is a dramatic loss of influence of the deprived eye over cells in the visual cortex, evident physiologically and anatomically, even

when the deprivation lasts for as short a period as 1 week. Physiologically, cortical binocularity is lost, and most neurons can be influenced only through the nondeprived eye. Anatomically, there is a nearly complete takeover of deprived eye territory by the nondeprived eye.

The obvious correlation between the loss of cortical influence by the deprived eye and the loss of vision has been interpreted to mean that visual function is determined by the number of cortical neurons influenced by a given eye; changes in this balance during development lead to changes in vision. None of these studies has quantified the spatial, temporal, or contrast response properties of deprived cortex, as there are few responsive cells to study. It may be that experience-dependent plasticity in primate V1 is restricted to the balance of inputs from the two eyes, and does not affect the spatial properties of individual neurons. But data on the effects of binocular deprivation suggest that cortical receptive field properties can be altered by experience (Blakemore, 1990). We wanted to establish whether cortical receptive field properties could be influenced by abnormal visual experience that was less radical than complete form deprivation, and we have therefore studied visual behavior and cortical organization in animals raised in a way that creates more modest and experimentally tractable visual deficits.

Visual disorders that occur in early childhood, such as strabismus (crossed eyes) and anisometropia (monocular defocus), are associated with *amblyopia*, literally meaning “blunted” vision. Visual acuity and contrast sensitivity in the amblyopic eyes of monkeys and humans are reduced, but not nearly so severely as they are following visual deprivation (Blakemore and Vital-Durand, 1981; Harwerth et al., 1983; Kiorpes, 1992b, 1996, 2001; Kiorpes et al., 1987; Kiorpes et al., 1993; Kiorpes and Movshon, 1996; Levi and Carkeet, 1993; Smith et al., 1985). Figure 12.7*A* shows the development of spatial resolution in each eye of a population of strabismic monkeys (Kiorpes, 1992b) and compares it to the development of resolution in normal monkeys tested monocularly. Resolution in the fellow (nondeviating) eyes develops normally, but resolution development in the strabismic eyes lags. Figure 12.7*B* illustrates losses in contrast sensitivity for three monkeys, each made experimentally amblyopic by a different technique. Normally, contrast sensitivity is similar for both eyes of an individual (*upper left panel, T7*). The other three panels show contrast sensitivity for each eye in monkeys in which the development of amblyopia followed experimentally produced strabismus, blur created by extended wear of a defocusing contact lens (anisometropia), or blur created by chronic instillation of atropine. Contrast sensitivity functions for the amblyopic eyes, regardless of the origin of amblyopia, are shifted to lower sensitivity and lower spatial frequencies. If we compare the functions obtained from amblyopic eyes with functions from young normal animals (Fig. 12.2*B*). There is

FIGURE 12.7. Spatial vision in amblyopic monkeys. *A*, Spatial resolution data obtained longitudinally from a set of six strabismic infant macaques (data from Kiorpes, 1992b). Data taken monocularly from each eye of the strabismic animals (triangles) are compared with monocular data taken from normal animals (circles; compare to Fig. 12.2*A*). The measure of spatial resolution was grating acuity, the highest spatial frequency at which a grating could be distinguished reliably from a uniform field of the same luminance. Animals younger than 16 weeks were tested using a forced-choice, preferential looking technique. Older animals were tested using a standard two-choice operant discrimination task. *B*, Monocular spatial contrast sensitivity functions for each eye of four macaque monkeys (one normal and three amblyopic), measured using operant techniques (data from Kiorpes et al., 1987, 1998).

a distinct similarity; this similarity is also evident when other visual functions are measured (Kiorpes, 1992b; Levi and Carkeet, 1993).

To explore the neuronal correlates of amblyopia, we analyzed the responses of V1 neurons in amblyopic monkeys (Kiorpes et al., 1998; Movshon et al., 1987). We studied selectivity for orientation, spatial frequency, drift rate, and contrast response properties of neurons driven by each eye, as well as binocular organization. In all types of amblyopic monkeys, there was a disruption of the binocular organization of V1 neurons. Figure 12.8*A* presents V1 eye dominance distributions from normal monkeys and from four groups of monkeys with amblyopia. Monocularly deprived monkeys were found to show the most marked loss of input from the amblyopic eye. The other three groups of amblyopic monkeys each showed substantial losses in binocular neurons, but in none of these groups was there a complete loss of cortical input from the amblyopic eye. Because all the animals in these groups had behaviorally documented amblyopia, this finding indicates that a loss of neurons influenced by the amblyopic eye is not sufficient to account for amblyopia. Thus it is important to evaluate the quality of the visual signals carried by the neurons driven by each eye.

In strabismic and anisometropic amblyopia, the spatial organization of receptive fields driven by the amblyopic eye is degraded. The distributions of preferred spatial frequency and spatial resolution are shifted to lower spatial frequencies relative to those for cells driven by the fellow eye. However, there is no consistent elevation in contrast threshold for neurons driven by the amblyopic eye. The combined results of two studies (Kiorpes et al., 1998; Movshon et al., 1987) are shown in Figure 12.8*B*, which summarizes and compares the behavioral and physiological findings for contrast sensitivity and peak spatial frequency in amblyopia. In each panel, the measures plotted are the interocular ratios of spatial frequency and contrast sensitivity. For behavior, these values are taken from the peaks of the contrast sensitivity functions (e.g., Fig. 12.7*B*). For physiology, the values are the geometric means of the values measured for populations of neurons driven by each eye. A comparison of the upper two panels shows that the range of behavioral deficits is large, whereas the range of physiological deficits is relatively smaller. Nonetheless, both measures show correlated losses in peak contrast sensitivity and peak spatial frequency. The same data are reorganized in the two lower panels to make a direct comparison of behavioral and physiological losses in peak spatial frequency and peak contrast sensitivity. There is a strong correlation between behavioral and physiological loss for peak spatial frequency ($r = 0.60$), although the physiological deficit is consistently smaller than the behavioral one. The relationship for contrast sensitivity is weaker ($r = 0.37$), and does not achieve statistical

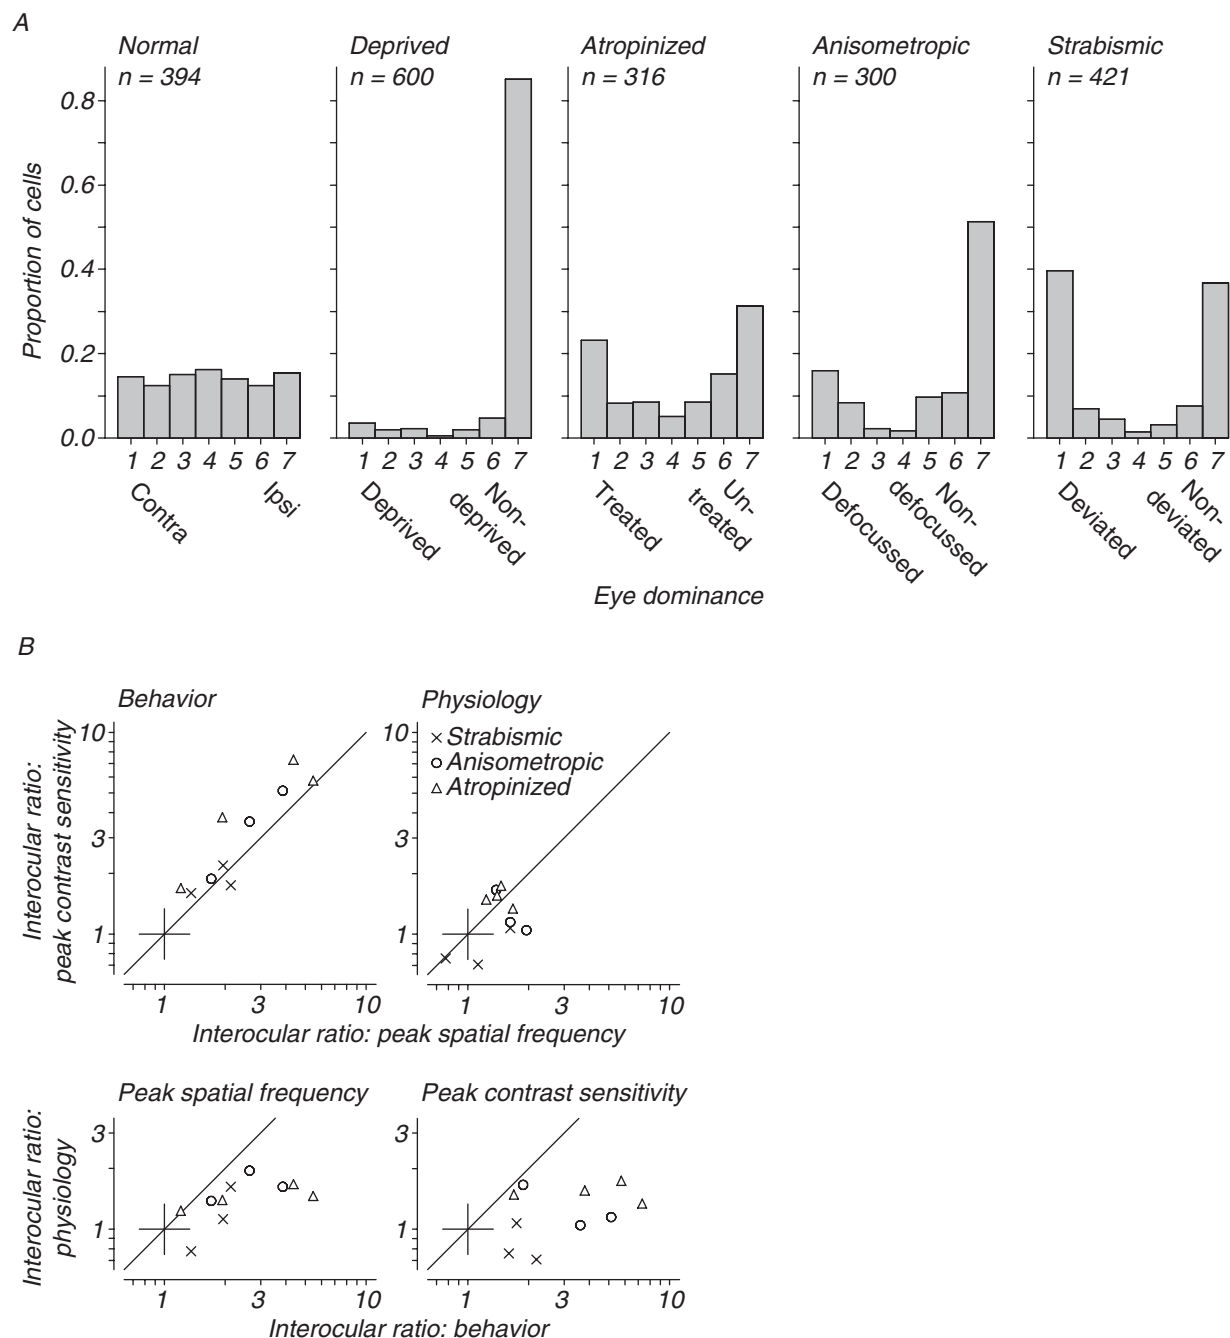

FIGURE 12.8. Physiological measurements of spatial vision in amblyopes. *A*, Distributions of cortical eye dominance obtained from five populations of macaque monkeys. The eye dominance scale is that of Hubel and Wiesel (1962), but only for the normal animals is the eye assignment based on group 1 being contralateral and group 7 being ipsilateral. The distributions for the other four groups are keyed so that the amblyopic eye corresponds to group 1 in all cases. The data for normal subjects and for the three right-hand groups of amblyopes are from Kiorpes et al. (1998) and Movshon et al. (1987). The data for the monocularly deprived

animals are from LeVay et al. (1980). *B*, Comparisons of physiological and behavioral data for 10 amblyopic monkeys studied by Kiorpes et al. (1998) and Movshon et al. (1987). Each axis represents the ratio of the indicated performance value between the amblyopic and fellow eye. For behavioral measures, the values compared are the peak spatial frequency and the peak contrast sensitivity from data like those shown in Fig. 12.7*B*. For physiological measures, the values compared are the geometric means of measured values for populations of cells tested monocularly through the amblyopic and fellow eyes.

significance. There was also no consistent effect of amblyopia on overall visual responsiveness, orientation tuning, or temporal tuning.

Thus, neuronal correlates of amblyopia are evident in the spatial properties of cells in V1, but the observed deficits do not fully explain the spatial losses in amblyopia—that is, the physiological losses are relatively small compared to the behavioral ones. A qualitative account of the visual loss in amblyopia might be constructed by combining the losses in spatial sensitivity with the alterations in eye dominance and binocularity (Fig. 12.8A), but we are aware of no quantitative model that supports this conjecture.

It is notable that, just as vision in an amblyopic eye resembles the vision of a younger normal eye, so, too, do the properties of cortical neurons driven by the amblyopic eye resemble the properties of neurons driven by a younger normal eye. However, this similarity is unlikely to reflect similar mechanisms in the two cases. We have already argued that the properties of developing cortical neurons are largely determined by the development of the foveal cone mosaic, but there is no reason to believe that retinal development is abnormal in amblyopic animals. LGN cell responses are quantitatively very similar in normal and amblyopic eyes (Blakemore and Vital-Durand, 1986b; Levitt et al., 2001). The disruption of cortical receptive fields in amblyopia must, therefore, result from changes in intracortical or intercortical circuits and not from degraded peripheral inputs. The changes observed are consistent with a broadening and blurring of the structure of cortical receptive fields, reminiscent of the far more extensive changes reported to result from complete binocular form deprivation (Blakemore, 1990). Like our data on V1 development, these results seem to favor a permissive view of the role of the environment in development, but with the added feature that not only visual experience, but *the right kind* of visual experience is required for normal development. In the animals raised with blurred vision in one eye, our experiments can be seen as a selective case of visual deprivation in which cells preferring the highest spatial frequencies are the most penalized by the experience of continuously blurred vision. Perhaps it is only natural that these cells would be the ones most affected, or even lost, resulting in distributions of preferred frequency that are shifted in the way that we have observed (Kiorpes et al., 1998; Movshon et al., 1987). But this account is incomplete—it does not suggest an explanation for the effects of strabismus, which does not cause image blur or the consequent loss of high spatial frequency stimulation.

It seems significant that the relationship between cortical signals and behavioral responses is consistent across development and amblyopia, even if the relationship is quantita-

tively imperfect. It is therefore natural to wonder about the course of development and the effects of visual experience in cortical areas outside V1.

Extrastriate cortex

We have until now considered the development of and effects of abnormal visual experience on the structure and function of the visual pathway, up to and including the primary visual cortex, V1. But in primates, there is a very extensive collection of cortical areas outside V1, which in aggregate involve about three times as much cortical tissue as V1 (Felleman and Van Essen, 1991). The functional properties of neurons in these areas and their relationship to behavior are a very active focus of study (see, for example, Chapter 34, Ventral and Dorsal Cortical Processing Streams; Chapter 78; Chapter 81; and Chapter 103), yet little attention has been paid to the way that they change during development or after abnormal visual experience. The visual responsiveness of extrastriate areas has been documented using 2-deoxyglucose autoradiography (Bachevalier et al., 1991; Distler et al., 1996). These measurements show that higher cortical areas are relatively delayed in their development compared to V1, and moreover that the development of the ventral “form” areas occurs over a longer time course than the development of dorsal “motion” areas. This general distinction is confirmed by the observation that neurons in inferotemporal visual areas do not appear to be visually responsive until about 6 months of age in macaques, whereas neurons in the dorsal area MT are responsive in much younger monkeys (Rodman et al., 1993). Anatomical experiments suggest that the normal connections of extrastriate cortical areas are probably present around the time of birth, and are organized approximately as in adults (e.g., Barone et al., 1996; Coogan and Van Essen, 1996), although some refinement certainly continues postnatally (e.g., Barone et al., 1995). Indeed, there is some evidence that higher-order areas have exuberant corticocortical connections that are later lost (Rodman and Consuelos, 1994; Webster et al., 1995). Although normal connections are present in infancy, synaptogenesis continues throughout the cortex for many weeks after birth (Rakic et al., 1986), and immunocytochemical studies reveal substantial changes in the distribution of various chemical markers during the first months of life (e.g., Conde et al., 1996; Hendrickson et al., 1991).

Behavioral data on the development of complex visual functions and the influence of amblyopia suggest that functions dependent on the action of extrastriate areas may develop more slowly than simpler acuity and contrast detection tasks in both monkeys and humans. For example, contour integration ability develops over a protracted

time course in comparison to simple grating acuity (Kiorpes et al., 2000a, 2001; Kovacs et al., 1999). Contour integration ability is also susceptible to disruption in amblyopia (Chandna et al., 2001; Hess et al., 1997; Kovacs et al., 2000; Kozma et al., 2000).

These findings lead to our concluding conjecture that a complete picture of the factors that limit visual development and vision after abnormal experience will not be obtained until we have an account of extrastriate cortical development. There is modest evidence that the binocularity and response properties of neurons in V4 are affected in amblyopia (Movshon et al., 1987), and we have argued that changes in binocular organization in area MT following strabismus show that an independent mechanism of cortical binocular plasticity operates during development in this area (Kiorpes et al., 1996). Also, disruption of binocular organization has recently been reported in several extrastriate cortical areas in amblyopic cats (Schroder et al., 2002).

Our analysis of the relationship between visual neuronal function and visual behavior in normal and abnormal development suggests that neuronal properties up to V1 offer only an incomplete account. Neither the changes in V1 neuronal properties during development nor the effects of amblyopia on those properties are quantitatively concordant with the behavioral changes we observe. If the answer does not lie at or before the level of the primary visual cortex, it seems clear that it must lie beyond.

Acknowledgments

The research from our laboratories described in this chapter was supported by grants from the National Institutes of Health (EY 2017 to JAM, EY 5864 to LK, and RR00166 to the Washington Regional Primate Research Center). We are grateful to Michael Gorman, Jasmine Allen Siegel, Laura Albanese, Jeanine Dimitri, and Suzanne Fenstermaker for their assistance, and to our many students and colleagues for their invaluable contributions to this work.

13 Development of Spatial Selectivity and Response Timing in Humans

ANTHONY M. NORCIA

THE VISUAL SYSTEM of the human, like other altricial species, undergoes an extensive period of postnatal development. Development is both quantitative (e.g., visual performance improves substantially with age) and qualitative (e.g., the visual system of the neonate displays a number of attributes that are absent in the adult). This chapter selectively reviews major aspects of quantitative and qualitative change. The emphasis is on functions that are thought to be the province of the early stages of the visual pathway, where the neural image is formed and primitive features of visual objects are first extracted. Large areas of activity in the field of infant visual development, such as object permanence, attention, and the recognition of objects and faces, are not covered. As with most reviews of human visual development, this review starts with a consideration of methodological issues unique to the field.

Research methods

Methodological considerations are of paramount importance in studies of human visual development. Because the behavioral repertoire is so limited (and constantly changing with development) and because infant observers cannot be instructed, specialized behavioral techniques have been developed (Dobson, 1990; Hainline, 1993; Hamer and Mayer, 1994). Electrophysiological measures, such as the visual evoked potential (VEP) require no overt behavioral responses other than fixation and accommodation. Because the VEP is generated in visual cortex, it is ideally suited for studying the early elements of the visual pathway, the development of which is the focus of this review.

The VEP is a far-field potential that is time- or phase-locked to the visual stimulus. It is this synchronization of the response to the stimulus that allows the investigator to design filters that can select out the visually driven activity from the background electroencephalographic (EEG) and other sources of biological and industrial noise. VEPs were first detected in the early 1950s by averaging the EEG record over fixed time intervals that were precisely aligned with the stimulus onset. The logic of averaging is that all activity that is not synchronized with the stimulus onset is random; thus, the average of these random signals will tend to zero in the

limit of an infinitely large number of averaged records. The time-locked activity, by contrast, is not diminished by the averaging process. As the number of records in the average increases, the time-locked activity represents an ever-increasing proportion of the variance in the record.

THE STEADY-STATE VEP When the stimulus is presented at periodic time intervals, the VEP can also be isolated using spectral analysis procedures. Periodic inputs (stimuli) lead to periodic outputs (responses), and the location of these responses in the spectrum is under the control of the investigator. This prior knowledge of what frequencies in the EEG are relevant (phase-locked at a frequency related to the input frequency) and which are irrelevant (non-phase-locked or of the wrong frequency) makes it possible to design frequency-specific filters that are highly effective in separating the signal from the noise.

Figure 13.1A shows an example of a typical steady-state VEP (SSVEP) spectrum obtained in response to a low spatial frequency grating that was reversed in contrast at 7.25 Hz (14.5 pattern reversals per second). This spectrum is compared to that obtained with the subject viewing a blank screen (lower spectrum in Fig. 13.1A). The SSVEP is composed of several response peaks that occur at exact integer multiples of the stimulus frequency. In the case of the pattern reversal stimulus, the response is symmetrical for each reversal of the pattern, and the spectrum comprises even harmonics (2F, 4F, 6F . . . where F is the stimulus frequency). Because the stimulus is periodic, the response waveform is also periodic, as illustrated in Figure 13.1B. The waveform is not sinusoidal and has two large positive and negative peaks corresponding to the frequency doubling of the response that is apparent in the spectrum.

The SSVEP differs critically from the EEG in that the phase of the SSVEP is constant over repeated presentations, whereas that of the EEG is random. This is illustrated in Figure 13.1C, which plots the SSVEP in polar coordinates. The components of the SSVEP response are complex numbers; that is, the response has both an amplitude and a phase value. The phase of the response is nonzero owing to the presence of neural delays and integration processes. The fact that the response phases from individual trials

cluster around a value of 180° in the figure (*filled symbols*) indicates that the response is synchronized with the stimulus. A phase angle of 180° is consistent with relative delays with respect to the stimulus of 34.5, 103.5, 148.0 . . . , ms for the 14.5-Hz response frequency. This ambiguity is due to phase being a modulo 2π variable. The phase of the EEG is random (see Figure 13.1C, *open symbols*). If one averages the x values (real part) and the y values (imaginary part) and computes the magnitude of the resulting vector, the SSVEP has an amplitude that is not consistent with zero, given the error, but the EEG is consistent with zero (see

larger and smaller filled and open symbols in Figure 13.1C, respectively).

THE SWEPT-PARAMETER VEP Spectral analysis of the SSVEP often results in signal-to-noise ratios that are sufficiently high to detect the response and to measure its amplitude and phase using relatively short data records; as the stimulus value is systematically varied (Regan, 1977). This technique, known as the swept-parameter or sweep VEP, is useful for measuring sensory thresholds—based extrapolation of VEP response functions (Campbell and Maffei, 1970).

It is a general property of sensory systems that evoked response amplitude increases as a function of stimulus intensity over a range of stimulus values. Figure 13.2 shows examples of response functions obtained in experiments where either the spatial frequency (*left panel*) or contrast (*right panel*) of a grating pattern was systematically varied over presentations lasting 10 seconds. In each case, the spectrum analysis was carried out at a series of 1-second intervals in order to map out the shape of the spatial frequency tuning or contrast response functions. Repeated measurements of the response functions were averaged as in Figure 13.1 (*bottom*), with all repetitions from the first second of the sweep being averaged together, all repetitions from the second being averaged together, and so on.

The SSVEP response is a roughly linear function of log-contrast (see Figure 13.2, *right panel*), suggesting that a contrast threshold can be estimated by extrapolation of this function to zero amplitude. This threshold extrapolation technique yields estimates of contrast threshold that are generally within a factor of 2 or 3 of adult psychophysical contrast thresholds (Campbell and Kulikowski, 1971; Cannon,

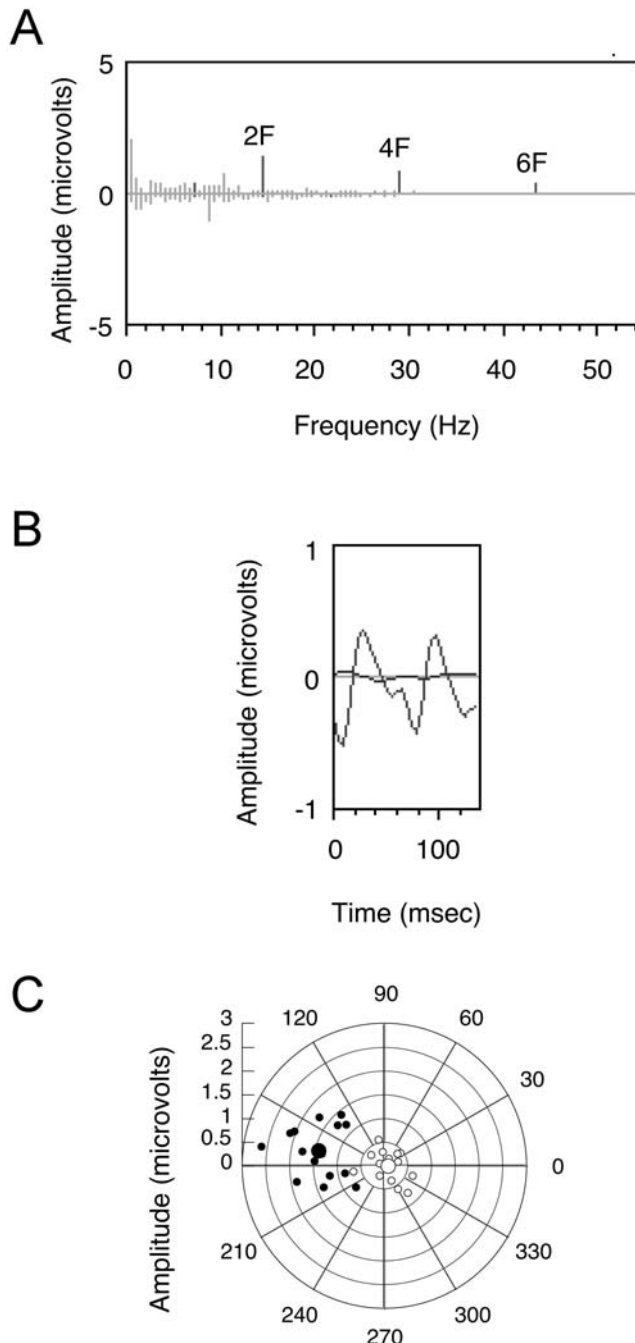

FIGURE 13.1. *A*, Spectra for steady-state VEP (data plotted above the x axis) and background EEG (data plotted below the x axis). The spectrum of the 7.25-Hz pattern reversal response comprises narrow peaks at frequencies that are even multiples of the stimulus frequency (e.g., $2F = 14.5$, $4F = 29$, $6F = 43.5$ Hz). The response (signal) is larger than the EEG (noise) at each of these frequencies in the spontaneous EEG and at nearby frequencies in the record obtained during visual stimulation. *B*, Time averages for the steady-state VEP shown in *A* and for the spontaneous EEG. The time average is periodic, with a base period equal to twice the stimulus period of 138 msec. The averaged response to a blank screen is also shown, indicating the experimental noise level (line near zero). *C*, Amplitude and phase of the steady-state VEP for each of 16 10-second trials composing the averages for stimulus-present (*filled symbols*) and EEG (*open symbols*) conditions previously shown in figure parts *A* and *B*. The VEP responses from individual trials cluster around a phase of 175° , indicating that they are synchronized with the visual stimulus. The spontaneous EEG shows a random phase relationship, with the resulting vector average (*open large dot*) being only a fraction of a microvolt.

FIGURE 13.2. Spatial frequency (*left panel*) and contrast (*right panel*) sweep records. VEP amplitude (*upper solid curves*) is plotted as a function of linear spatial frequency (*left*) or log stimulus contrast (*right*). Threshold was estimated by an extrapolation to zero amplitude based on a linear regression that used the amplitude values between the dotted cursors. In this example, the estimated grating resolution was 7.6 c/deg (*left panel*), and the contrast threshold was 0.8% (*right panel*). The open squares plot the amplitude recorded simultaneously at a slightly different frequency in the EEG where there was no visual activity. The lower panels plot the response phase, which shows an upward trend as spatial frequency increases (phase lag or increasing delay) and a downward trend on the contrast function as contrast increases (phase lead or decreasing delay). In each case, the phase behavior is indicative of an increase in speed of the response as the stimulus becomes more visible.

1983; Norcia et al., 1990b). The observation that voltage is a linear function of log contrast near threshold suggests that voltage will be a linear function of spatial frequency, given that the contrast sensitivity function is linear on semi-log coordinates (Campbell and Green, 1965). Thus, the same regression procedures can be applied to acuity estimation from the spatial frequency tuning function (see Figure 13.2, *left panel*).

Development of photoreceptor responses

Visual sensitivity is mediated by three cone types (short-wavelength-sensitive [SWS], mid-wavelength-sensitive [MWS], and long-wavelength-sensitive [LWS] cones) and by rods. The outputs of the cones are combined in subsequent stages of processing to support both chromatic and achromatic detection and discrimination.

Photoreceptor components are first present in the human fetal retina by 14 to 15 weeks' gestation, when the precursors of cone inner segments are visible (Narayanan and Wadhwa, 1998). By 18 to 19 weeks' gestation, the photoreceptor inner segments are arranged in a mosaic pattern with large cone inner segments (presumed to be SWS cones) being surrounded by several small cone inner segments (prospective red/green cones; Narayanan and Wadhwa, 1998). Rod inner segments are also identifiable at this age. The cone inner segments then elongate considerably between 19 and 25 weeks. At 24 to 25 weeks' gestation, the rod outer segments begin to emerge, ahead of the outer segments of the cones (Narayanan and Wadhwa, 1998).

Consistent with the emergence of photopigment in the outer segments, visual responses are first recordable at around 24 weeks in the VEP (Kos-Pietro et al., 1997; Taylor et al., 1987).

Each photoreceptor class has a characteristic spectral sensitivity; thus, measurements of spectral sensitivity and receptor isolation conditions have been used to determine when each class of photoreceptor becomes functional. Spectral sensitivity measurements with the scotopic VEP indicate that rods are functioning at 4 weeks of age (Werner, 1982). Similarly, the SWS cones show an adult spectral sensitivity by 4 weeks of age (Volbrecht and Werner, 1987). Photopic spectral sensitivity, measured with the VEP, is similar to that of the adult in 8-week-olds, suggesting that LWS cones are functional by this age (Bieber et al., 1995; Dobson, 1976). Knoblauch et al. (1998) found VEP responses to MWS- and LWS-cone isolating stimuli as early as 4 weeks of age, and Bieber et al. (1998) found adult-like action spectra for both MWS- and LWS-cone classes in 8- to 12-week-olds. Thus, all major photoreceptor classes are known to be functional by no later than 4 weeks of age.

Although all major photoreceptor classes are functional early in infancy, foveal cones are dramatically immature relative to more peripheral cones (Hendrickson and Drucker, 1992; Hendrickson and Yuodelis, 1984). At birth, foveal cones lack outer segments, whereas those in the parafovea are 30% to 50% of adult length. In the midperiphery cone, outer segments are 50% longer than they are in the parafovea, making them relatively adult-like. Despite the relative immaturity of the central retina, throughout development, visual acuity appears to be highest in the central visual field, compared to the peripheral field (Allen et al., 1996; Spinelli et al., 1983).

Spatiotemporal contrast sensitivity development

Perception of the visual world requires that the visual system must transduce light incident on the retina into neural signals. At the earliest stages, neural responses are dependent on the number of absorbed quanta. At the level of the inner plexiform layer, responses are recoded in terms of contrast, that is, spatial and temporal variations in light intensity. Spatiotemporal contrast forms the basis of all subsequent form processing, and contrast sensitivity forms a fundamental limit on what information is made available to visual cognition.

There is a long tradition, based on the theory of linear systems, of using sinusoidal gratings to measure contrast sensitivity (Campbell and Robson, 1968). In this framework, thresholds are measured as a function of spatial frequency (e.g., the number of grating cycles per degree of visual angle). Figure 13.3 shows the development of contrast sensitivity in human infants during the first 8 months of

FIGURE 13.3. Development of contrast sensitivity for 6-Hz reversing gratings. Between 4 weeks (*open squares*) and 9 weeks (*open circles*), the contrast sensitivity function shifts upward by a factor of approximately 5 to 6. Between 9 and 33 weeks (*filled circles*), the function shifts rightward, with little increase in maximum sensitivity at low spatial frequencies. Between 33 weeks and adulthood (*x's*), further increases in resolution occur (rightward shift), along with a small increase in overall sensitivity (upward shift).

life (data from Norcia et al., 1990b). In the figure, sensitivity was measured using the swept-parameter technique for gratings that were contrast-reversed at 6 Hz. Thresholds were measured at several spatial frequencies in each infant, with the result being a series of *contrast sensitivity functions*.

The contrast sensitivity function for this temporal frequency has a simple form at all ages: an exponential decline in sensitivity (Norcia et al., 1990b). At 4 weeks of age, peak contrast sensitivity is about a factor of 5 to 6 lower than that of adults. Between 6 and 9 weeks of age, sensitivity at all spatial frequencies increases by a factor of about 3. Between 10 weeks and 33 weeks, sensitivity at low spatial frequencies is constant, but there is a progressive increase in sensitivity at high spatial frequencies.

Contrast sensitivity depends on both spatial and temporal frequency. Relatively little is known about the full range of spatiotemporal contrast sensitivity, as it is difficult in infant studies to obtain the large number of thresholds needed to map the complete spatiotemporal surface. Sensitivity at low spatial frequency and high temporal frequency has been assessed by Apkarian (1993), who measured the critical flicker frequency for the VEP in infants aged birth to 1 year of age and in adults. She found that temporal sensitivity increased to near adult levels by 20 to 30 weeks of age. Gordon and McCulloch (1999) have found that the temporal tuning of responses to low *spatial* frequency targets flickering at 12 Hz is adult-like in 5-, 8-, and 11-year-old children, but that the spatial tuning of responses to high

spatial frequency gratings flickering at 6 Hz is still immature at 5 and 8 years of age. Similarly, psychophysical temporal contrast sensitivity has been found to be mature by the age of 4 years, but grating acuity continues to improve until about the age of 6 years (Ellemberg et al., 1999; see also the section that follows, Development of Resolution Acuity).

Chromatic contrast sensitivity (sensitivity for stimuli that vary in color but not in mean luminance) develops roughly in parallel to achromatic contrast sensitivity during the first 6 months of life (Allen et al., 1993; Kelly et al., 1997; Morrone et al., 1993). However, the waveform of the chromatic VEP continues to develop well after that of the achromatic VEP (see the section "Development of Response Timing" that follows).

NOISE AS A LIMITING FACTOR IN CONTRAST SENSITIVITY DEVELOPMENT The data shown in Figure 13.3 suggest that there are two processes underlying the development of contrast sensitivity. One operates early in development, controlling sensitivity at all spatial frequencies, and a second process operates after 10 weeks of age, primarily affecting higher spatial frequencies.

Contrast sensitivity is limited by several physical processes, including scatter in the optical media of the eye, the efficiency by which photons are captured by the photoreceptors, the size of the eye, and photoreceptor density (Banks and Bennett, 1988; Wilson, 1993). Sensitivity is also limited by noise in the visual pathway.

An estimate of the amount of neural noise can be obtained by measuring contrast thresholds in the presence of varying amounts of spatiotemporal white noise (Pelli, 1990). Using this approach, one determines the maximum amount of noise that can be added to the *stimulus* without affecting the observer's contrast sensitivity. The idea here is that if neural noise is limiting performance, the visual system will be insensitive to noisy variations in the stimulus that produce responses that are, on average, smaller than the so-called *intrinsic noise* of the visual system. Thus, the goal is to determine the amount of stimulus noise that is *equivalent* to the intrinsic noise by observing the tolerance of contrast threshold to imposed noise. The technique assumes that the imposed stimulus noise (which is spatiotemporally random) approximates the internal noise of the visual system.

Figure 13.4A shows an example of a grating presented either with or without noise. Figure 13.4B shows contrast response functions measured either in the presence of noise (*open circles*) or without noise (*filled circles*). Thresholds were estimated by extrapolating the contrast response function to zero amplitude. Thresholds are higher in the presence of noise, and the contrast response function is shifted rightward. Figure 13.4C plots contrast threshold as a function

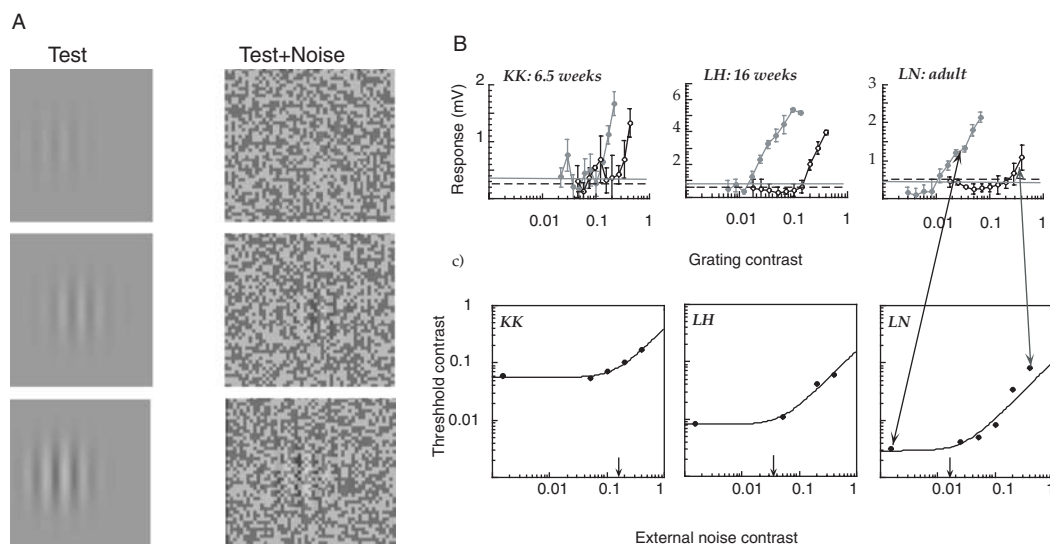

FIGURE 13.4. Equivalent noise paradigm. *A*, Schematic illustration of stimuli used to measure equivalent noise. Contrast response functions were measured from gratings of increasing contrast without noise (*Test*) and then again in the presence of spatiotemporal noise of a fixed level (*Test + Noise*). *B*, Contrast response functions measured without noise (*filled circles*) and in the presence of noise (*open circles*). Added noise raises contrast threshold and shifts the response function rightward. *C*, Contrast thresholds

(vertical axis) as a function of added noise contrast (*x* axis). The solid curve is the fit to an additive model of internal and external noise summation. Equivalent noise, estimated as the point where contrast threshold is elevated by a factor of 1.4, is higher in infants than adults. Note, however, that infant and adult thresholds are similar at high noise levels. (Adapted from Skoczenski and Norcia, 1998.)

of the contrast of the imposed masking noise. As masking noise contrast increases, there is eventually a point at which contrast threshold increases. A consistent estimate of the point at which contrast threshold is elevated by 1.4 (equivalent noise, N_{eq}) was obtained by fitting a two-parameter model (*solid curve*). The equivalent noise contrast is that amount of stimulus contrast that elevates threshold by the same amount as the internal noise.

As noted in the discussion of Figure 13.3, contrast sensitivity increases rapidly before 10 weeks of age, reaching an asymptote that is about a factor of 2 to 3 lower than adults at between 10 and 30 weeks. Equivalent noise declines with a similar profile (Skoczenski and Norcia, 1998). Figure 13.5 shows that, throughout development, the relationship between contrast sensitivity and equivalent noise has a slope very near 1, suggesting that intrinsic noise is a critical limitation on contrast sensitivity at all ages (Skoczenski and Norcia, 1998).

As soon as the noise masker elevates threshold, the entire contrast response function is shifted rightward (see contrast response functions in Fig. 13.4). This rightward shift is the signature of a nonlinear process known as *contrast gain control*. Gain control mechanisms shift the dynamic range of the visual response in a way that depends on the prevailing contrast values in the image. Gain control allows the response of neurons with limited dynamic range to avoid saturation at high contrast, provided the stimulus context is also high contrast. The topic of contrast gain control is discussed

FIGURE 13.5. Relationship between contrast sensitivity and equivalent noise over development. Contrast sensitivity and equivalent noise covary in a 1:1 relationship throughout development. Age is not explicitly plotted, but the high sensitivity points are contributed by progressively older observers. (From Skoczenski and Norcia, 1998.)

further in the section on Orientation-specific Pattern Masking.

Development of resolution acuity

The second major change in the spatial contrast sensitivity function is the marked improvement in sensitivity at high spatial frequencies. The rightward limit of the contrast

sensitivity function indicates the highest resolvable spatial frequency (grating acuity). Several laboratories have measured grating acuity with the swept-parameter technique. In these studies, the spatial frequency of a high contrast grating was systematically varied, and acuity was measured by extrapolating the VEP amplitude versus spatial frequency function to zero amplitude.

Figure 13.6 plots measurements of grating acuity from six studies (Allen et al., 1996; Auestad et al., 1997; Birch et al., 1998; Norcia and Tyler, 1985; Norcia et al., 1990b; Sokol et al., 1992). In each study, grating acuity was found to develop from around 5 c/deg at 1 month to around 15 to 20 c/deg by 8 months. Adult grating acuity is higher, by about a factor of 2, than that attained by 8 months.

Between 4 and 9 weeks of age, the increase in grating acuity visible in Figure 13.3 can be accounted for by an overall increase in contrast sensitivity, presumably brought about by a decrease in intrinsic noise in early processing stages, such as the retina. After that point, resolution increases, without a correlated increase in peak contrast sensitivity. Increases in resolution could be attributable to a number of factors that change over development, including decreasing intercone spacing, increasing photon capture secondary to maturation of the outer segments, and decreasing receptive field size in the lateral geniculate nucleus (LGN) and visual cortex (Hawken et al., 1997; Jacobs and Blakemore, 1988). Optical quality of the eye and eye size contribute little to this improvement (Banks and Bennett, 1988).

FIGURE 13.6. Development of sweep VEP grating acuity for 5- to 10-Hz pattern reversal stimuli. Acuity growth functions are similar across studies, with acuity increasing from 4 to 6 cycles per degree in 1-month-olds to around 15 to 20 cycles per degree around 8 months of age. (Data replotted from Norcia and Tyler, 1985 [filled circles]; Norcia et al., 1990b [open circles]; Allen et al., 1996 [half-filled squares]; Sokol et al., 1992 [triangles]; Auestad et al., 1997 [open squares]; Birch et al., 1998 [filled squares]). (Redrawn from Norcia and Manny, 2003.)

Development of orientation selectivity

The perception of objects requires more than just the registration of spatiotemporal variations in contrast. The first step along the path to object recognition is taken in primary visual cortex where neurons first begin to display selectivity for the orientation and direction of motion of image elements. Orientation selectivity, of at least a primitive form, appears to develop without the need for visual experience in both cats and monkeys (Albus and Wolf, 1984; Blakemore and Van Sluyters, 1975; Blasdel et al., 1995; Braastad and Heggelund, 1985; Chino et al., 1997; LeVay et al., 1980; Sherk and Stryker, 1976; Wiesel and Hubel, 1974). Human infants can discriminate the orientation of static lines within the first week after birth (Atkinson et al., 1988; Slater and Kirby, 1998). The detection of changing orientation in dynamic patterns has not been measurable at birth, but can be measured both behaviorally (Atkinson et al., 1988) and by VEP (Braddick et al., 1986) by 6 to 7 weeks of age. Hood et al. (1992) found that 1-month-old infants could discriminate orientation changes at 3 Hz, but not at 8 Hz, suggesting the presence of a postnatal maturation period of unknown extent for orientation-selective mechanisms. Manny (1992) used the VEP method of Braddick et al. (1986) to measure orientation tuning in 3-month-old infants. She found that orientation-tuning bandwidths were within a factor of 2 of those of adults. Chino et al. (1997) have found that orientation tuning of V1 cells in the macaque is present in newborn animals and becomes adult-like by 4 weeks of age (see also Chapter 12, Neural Limitations on Visual Development in Primates). It is generally considered that 1 week of monkey life is equivalent to 1 month of life in humans (Boothe et al., 1985); thus, these two measurements of basic orientation selectivity are in substantial agreement.

DEVELOPMENT OF ORIENTATION-SPECIFIC PATTERN MASKING

The visual system is rarely confronted with isolated lines or edges. Rather, objects appear in the midst of cluttered backgrounds and behind occluding surfaces and contours. The detectability of an oriented pattern is degraded by the presence of similar patterns presented to the same location, a phenomenon known as pattern masking. In adults, patterns of the same orientation are much more effective as maskers than are patterns of different orientation.

In Figure 13.4, examples were shown of the masking effect of two-dimensional white noise on the contrast response function. The masker had the effect of raising the threshold, with a concomitant rightward shift of the contrast response function. The author and coworkers repeated these experiments using one-dimensional, rather than two-dimensional, noise maskers in order to study the development of orientation-selective pattern masking (Skoczenski

et al., 1999). Schematic examples of the stimuli are shown in Figure 13.7A. Note that the grating is more visible in the presence of the cross-oriented masker than in the presence of a masker of the same orientation (*cf* Campbell and Kulikowski, 1966).

In 11-month-olds and adults, a noise masker of the same orientation as the test grating was found to elevate threshold by a factor of about 6, whereas an orthogonally oriented masker elevated threshold by much less (a factor of about 3) (see Fig. 13.7B, *right panel*). Remarkably, in 3-month-old infants, both maskers were equally effective; that is, threshold was elevated by a factor of 3 by same- and cross-oriented maskers (see Fig. 13.7B). Orientation-selective pattern masking was first seen by 8 months of age and was adult-like at 11 months.

The lack of orientation-specific masking could be attributable to a lack of orientation-selective mechanisms capable of responding to the 5-Hz contrast-reversing grating. In order to test this hypothesis, the author and colleagues used a technique developed by Regan and Regan (1987) for measuring orientation bandwidths in the VEP. With this technique, the test and mask gratings are modulated at slightly different temporal frequencies. The responses to the test and mask grating thus appear in different bins in the spectrum, and the influence of one stimulus on the other can be measured even though the patterns are presented simultaneously. Regan and Regan (1987) showed that the spectrum of the response to two gratings of the same orientation but of different temporal frequency contained several response components, in addition to the harmonics of the two input gratings. These responses occurred at frequencies that were combinations of the two input frequencies, that is, the sum and difference of the two input frequencies. Figure 13.8 shows an example from Candy et al. (2001). In the top left panel, the response to a single grating counterphase modulated at 3.3 Hz is shown. The response is composed of a series of spectral lines at even harmonics of the input frequency (6.6, 13.2, 19.8 Hz, etc.). When a second grating, modulated at 8.3 Hz, is superimposed, two things happen: the amplitude of the response to the first stimulus is reduced, and strong responses are seen at 5 Hz and 11.8 Hz (Fig. 13.8, *top right*). The 5-Hz response occurs at the difference between the two input frequencies, and the 11.8-Hz response occurs at the “sum frequency.” These additional components at the sum and difference frequency are due to the two inputs having both passed through a nonlinear processing stage. In the present context, this presumably arises from a combination of threshold and network nonlinearities (for a discussion of possible mechanisms, see Candy et al., 2001). Regan and Regan (1987) showed that these combination frequencies could be used to measure VEP orientation-tuning functions.

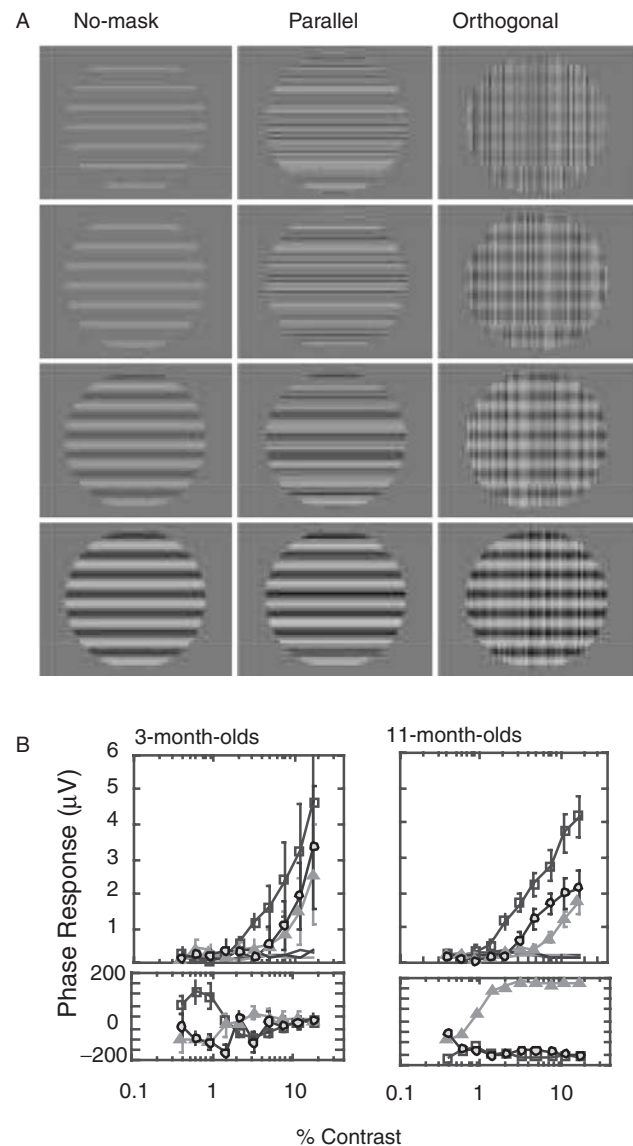

FIGURE 13.7. Orientation-specific masking paradigm utilizing one-dimensional spatiotemporal noise maskers. *A*, VEP contrast response functions were measured without noise (*No mask*) and in the presence of one-dimensional spatiotemporal noise that was at the same orientation as that of the test grating (*Parallel*) or at an orthogonal orientation (*Orthogonal*). Note that the grating is more visible when the masking is oriented orthogonally. *B*, Masked and unmasked contrast response functions for 3- and 11-month-olds. Parallel and orthogonal maskers shift the contrast response rightward by the same amount at 3 months; however, at 11 months, the parallel masker shifts the response function further to the right (rightmost curve plotted as triangles) than does the orthogonal masker (middle curve plotted as circles).

Theoretically, if infants lacked oriented cortical cells, they should generate just as much activity at the combination frequencies for cross-oriented targets as they did for similarly oriented targets. This is not the case, as can be seen in the bottom panel of Figure 13.8, which plots the amplitude of the sum term for two infants (14 and 20 weeks of age) and an adult. In this experiment, the contrast of a masking grating was fixed throughout the trial at a highly suprathreshold value. The contrast of the test grating was swept from below threshold to well above it. The results from three conditions are shown: the swept test, presented alone (*open squares*); the test presented with an orthogonal masker (*triangles*); and the test presented with a masker of the same orientation as the test (*circles*). There is no response at the combination frequency when only one of the inputs is presented or when an orthogonally oriented masker is presented, but there is a robust response when the target and mask share the same orientation. This signature of orientation selectivity was present even in younger infants in whom the pattern-masking effect was nonselective.

Young infants clearly have orientation selectivity, but contrast-gain control, although present, does not show the adult pattern of orientation selectivity. Young infants appear to

possess a gain control mechanism that is activated equally by all orientations, whereas adults show additional masking if the patterns share the same orientation. Gain control in the immature state could rely on equal pooling of inhibition across orientation columns in visual cortex (see, for example, Heeger, 1992). Alternatively, gain control comprise both intracortical and presynaptic mechanisms (Freeman et al., 2002). Intracortical inhibition may be shared preferentially among like orientations, whereas synaptic depression acting on the geniculocortical input would be nonspecific owing to the lack of orientation tuning in the LGN. According to this view, the neonatal visual system may lack intracortical masking processes that are orientation specific, but possess the presynaptic depression mechanism that is nonspecific with respect to orientation.

Development of position sensitivity

Pattern discrimination requires that the visual system not only be able to encode the orientation of features in an image, but also their relative positions. The adult visual system is extremely sensitive to positional offsets between nearby features, such as pairs of lines. Positional acuity, also

FIGURE 13.8. Demonstration of orientation selectivity in infants using nonlinear response components in a grating-on-grating masking paradigm. *Top panel*, The left panel shows the response of an adult to a single grating contrast reversing at 3.3 Hz (f_1). The response consists of several even harmonic components (e.g., $2f_1$; 6.6 Hz, $4f_1$; 13.2 Hz, etc.). The right panel shows the response spectrum obtained when a second grating of the same orientation (reversing at 8.3 Hz; f_2) is added to the 3.3-Hz grating. The response spectrum now contains prominent activity at the sum (f_2

+ f_1 ; 11.6 Hz) and difference ($f_2 - f_1$; 5.0 Hz) frequencies. Response amplitude at the harmonics of the 3.3-Hz grating are reduced and components related to the 8.3-Hz masker are also visible at frequencies equal to $2f_2$ and $4f_2$. *Bottom panel*, Contrast response functions for the nonlinear sum term. This term is large for parallel test and mask orientations (*open squares*), but is absent with orthogonal maskers or for the test presented alone (*gray curves*). The sum term thus indicates the presence of orientation selectivity in both infants and adults. (Redrawn from Candy et al., 2001.)

known as Vernier acuity, is finer than the spacing of the cone lattice that forms the limiting factor for grating acuity in the adult (Westheimer and McKee, 1977).

Positional sensitivity can be inferred from the VEP by showing that the response is dependent on the relative position or configuration of the stimulus. A demonstration of position sensitivity in infants is illustrated in Figure 13.9, which plots data from Skoczenski and Norcia (1999). Responses were measured using stimuli composed of a series of oscillating grating panels that were sandwiched between static grating panels. The motion of the oscillating panels was constant and equal to one-fourth of a period of the grating making up the oscillating pattern. The author compared the responses to the oscillating pattern when the static pattern was positioned symmetrically with respect to the two extremes of the motion (symmetric misalignment/misalignment), and when the static pattern was shifted by 90° of spatial phase, which yielded a stimulus that alternated between a simple grating and a grating with offsets (alignment/misalignment). If all that is being detected is the motion of the moving panels, the two stimulus configurations should produce the same response because the amount of motion is the same. However, the response to the alignment/misalignment condition has a large first harmonic component that is not present in the symmetric misalignment/misalignment condition. Zemon and Ratliff (1984) performed the original experiments in adults, upon which the author's experiment is based. Their study revealed that the first harmonic was actually a non-linear term owing to an interaction between the moving elements (frequency of 3 Hz, in this case) and the static elements (frequency of 0 Hz), yielding a sum/difference frequency component of 3 Hz. Grose-Fifer et al. (1994) showed that this nonlinear interaction was present in infants,

but that it had a very different temporal tuning than in adults.

The response at the first harmonic in the offset grating task is a marker of position sensitivity that persists down to very small offsets equal to the psychophysical threshold for discriminated left/right shifts of the moving elements relative to the static elements (Norcia et al., 1999). In their experiment, vernier offset size was swept over a range of values spanning the psychophysical discrimination threshold, and VEP thresholds were estimated by extrapolating the VEP amplitude versus displacement function to zero amplitude.

Vernier acuity, measured with the swept-parameter VEP, shows a long developmental sequence in humans, with adult values first being reached between 10 and 14 years of age (Skoczenski and Norcia, 2002; see also Fig. 13.10). Vernier thresholds were 20 to 40 times lower than adult levels in the youngest infant tested. By the second semester, thresholds were between 1 and 2 arc min, or a factor of 4 to 8 below those of the adults (0.25 minutes or 15 arc sec). It is only after the age of 6 years that VEP Vernier acuity exceeds grating acuity.

Development of direction selectivity and sensitivity

The detection of motion involves the determination of speed and direction. Directionally appropriate eye movements can be seen at term or even before term (Dubowitz et al., 1980; Hainline, 1993). However, it is unclear whether these early ocular following responses are controlled by cortical or subcortical pathways. Direction selectivity has been demonstrated behaviorally using forced-choice preferential looking (FPL) and looking-time habituation methods by 6 to 8 weeks of age (Wattam-Bell, 1996a; Wattam-Bell, 1996b). In these studies, 6- to 8-week-old infants demonstrated a

FIGURE 13.9. Demonstration of position sensitivity in infants. Response spectra are plotted from two infants for two stimulus conditions: alignment/misalignment (*top*) and misalignment/misalignment (*bottom*). The two conditions are identical in the amount of motion present, but differ in the relative positioning of the static

reference bars and the moving bars. The alignment/misalignment response contains a prominent response component at the stimulus frequency (3 Hz; *gray box*) that is absent from the misalignment/misalignment response. (Replotted from Skoczenski and Norcia, 1999, Fig.2.)

FIGURE 13.10. Development of Vernier acuity. Filled symbols plot VEP measurements (Skoczenski and Norcia, 2002). Behavioral data from Carkeet et al., 1997 (*open circles*) and Zanker et al., 1992 (*open squares*) are plotted for comparison. Vernier acuity reaches adult levels only in later childhood. (Reprinted from Norcia and Manny, 2003.)

behavioral discrimination between random-dot displays containing uniform motion versus displays in which alternate panels moved in opposite directions. Younger infants did not demonstrate this discrimination. VEP responses specifically associated with changes of direction have been recorded by 10 weeks of age (Wattam-Bell, 1991). Sensitivity to change of direction first emerged for lower stimulus velocities (5 versus 20°/second).

The sensitivity of directionally selective mechanisms can be measured with oscillating patterns similar to those used to measure Vernier acuity (Hamer and Norcia, 1994). Thresholds for oscillatory motion in the adult VEP are around 20 to 30 arc sec, similar in magnitude to vernier offset thresholds. Figure 13.11 shows oscillatory motion thresholds measured using the swept parameter VEP (Hamer and Norcia, 1994), compared to vernier offset thresholds taken from the study by Skoczenski and Norcia, 1999. Both functions show similar improvement over the first 6 months of life. Vernier thresholds in older infants are slightly lower than those for motion, but relative to the adult values of 15 versus 26 arc sec, the two functions show a similar degree of immaturity.

DEVELOPMENTAL MOTION ASYMMETRY One of the most striking immaturities in normally developing infants is an asymmetry of responsiveness to visual motion that can only be detected under monocular viewing conditions. This response asymmetry is manifested both in ocular following responses (optokinetic nystagmus [OKN]) and in the VEP. In the case of OKN, smooth ocular following is robust for motions that are nasally directed in the visual field (left to right motion in the left eye, right to left in the right eye), but is weak or primarily saccadic for motions that are temporal in direction (Naegele and Held, 1982). A similarly organized

FIGURE 13.11. Full-field motion thresholds (*filled circles*; Hamer and Norcia, 1994) compared to vernier offset thresholds (*open circles*; Skoczenski and Norcia, 1999) in infants. Both thresholds are around 500 arcsec in the youngest infants. Thresholds mature to between 70 and 150 arcsec by the end of the first year. At this age, each threshold is worse, by about a factor of 5, than that in adults.

bias in responsiveness is also apparent in the monocular VEP to oscillatory motion (Birch et al., 2000; Hamer and Norcia, 1994; Jampolsky et al., 1994; Mason et al., 2001; Norcia et al., 1991). In normal adults, the monocular response to oscillatory motion is equal for the two directions of motion, and the VEP response is composed of even harmonics of the input temporal frequency. In normally developing infants, one finds a large first harmonic component that is 180° temporally out of phase between the two eyes (Fig. 13.12, *left*). The presence of a first harmonic component is consistent with the response being larger in one direction of motion than the other. The 180° phase shift between the eyes is consistent with a response bias organized in a nasalward/temporalward direction, although whether the stronger direction is nasalward versus temporalward cannot be determined directly from the steady-state response. Mason et al. (2001) found that 90 displacements of bar gratings elicited a larger monocular response when the motion was temporally directed (e.g., left-to-right motion in the right eye), opposite the dominant direction of the molecular OKN asymmetry.

The monocular VEP direction asymmetry persists down to the oscillatory motion threshold (Hamer and Norcia, 1994), indicating that the thresholds presented in Figure 13.11 are those of direction-selective mechanisms. The VEP motion asymmetry is thus an additional marker for the presence of cortical directional selectivity (Norcia et al., 1991). Birch et al. (2000) have found that this marker is absent in infants younger than 1 month of age, but it can be recorded in those as young as 6 weeks of age at 6 Hz 1 c/deg.

The degree of motion asymmetry, and thus, the degree of immaturity, can be quantified by calculating the proportion of the response at the first harmonic relative to the sum of

the response at the first and second harmonics (Jampolsky et al., 1994; Norcia et al., 1995). At moderate temporal frequencies (6 Hz) and low spatial frequencies (1 c/deg), a symmetric response is achieved by 5 to 6 months of age (Birch et al., 2000; Jampolsky et al., 1994; Mason et al., 2001; Norcia et al., 1995; see Fig. 13.12, *left*). The age at which a symmetric motion response is achieved depends on both spatial and temporal frequency (Norcia et al., 1990a). Figure 13.13 shows data obtained at four different spatiotemporal frequencies (the combinations of 1 and 3 c/deg and 6- and 10-Hz oscillation frequency). At each spatiotemporal combination, the first harmonic shows a decline with age and the second harmonic shows an increase with age. If one considers the age at which the two curves cross (the point where first and second harmonics are of equal amplitude), one observes that this criterion value is reached first for the 6-Hz and 1 c/deg condition (14 weeks), next at 6 Hz and 3 c/deg (27 weeks), then at 10 Hz and 1 c/deg (57 weeks), and finally, at 78 weeks for the 10-Hz and 3 c/deg condition. Brown et al. (1998) found that infant monkeys achieved adult levels of symmetry at 6 Hz and 0.25 c/deg by 6 weeks of age, which is similar to the case in humans, given the 4:1 correction for equivalent developmental ages that has been applied in other contexts (Boothe et al., 1985).

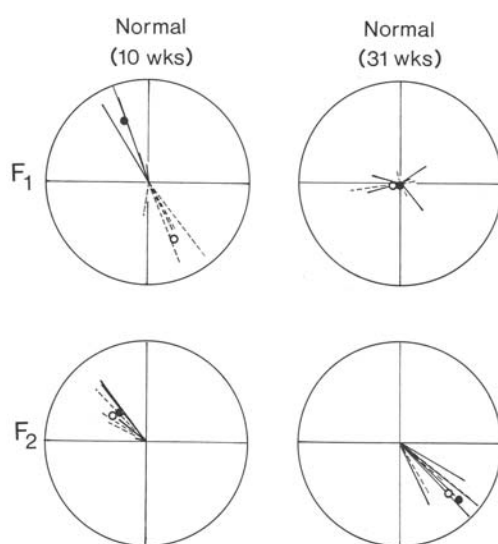

FIGURE 13.12. Developmental immaturity of the response to monocular oscillatory motion. VEP responses to a 6-Hz, 1 c/degree grating are shown in polar form for 6 Hz (first harmonic, *top panels*) and 12 Hz (second harmonic, *bottom panels*). Each vector represents the response amplitude and phase for a single 10-second trial. Filled and open symbols plot the vector average response. In the younger infant (*left panels*), the first harmonic response (F_1) is large relative to the second harmonic (F_2) and is 180° out of phase in the two eyes. The first harmonic response is absent in the older infant. (Reprinted from Norcia and Manny, 2003.)

The maturation of the oscillatory motion response depends on normal binocular interaction during a period of time that is similar to that over which the normal response matures (Birch et al., 2000; Norcia et al., 1995; Norcia et al., 1991). Individuals with constant strabismus present during the first 6 months of life have motion responses that retain the infantile motion asymmetry, a condition that persists well after the age that normal infant responses become symmetrical (Birch et al., 2000; Fawcett and Birch, 2000; Jampolsky et al., 1994). A similar response asymmetry is present in monkeys that develop strabismus during the first months of life (Tychsen and Boothe, 1996). Surgical correction of the strabismus results in a reduction of the magnitude of the motion asymmetry if the eyes are aligned prior to the age of about 2 years (Norcia et al., 1995). The amount of recovery is greatest at spatiotemporal frequencies that mature first.

Development of binocularity

The fact that humans have two laterally placed eyes, each with a slightly different view of the world, allows the brain to calculate object distances from the disparities in the retinal images, a process known as *stereopsis*. The different views afforded by the two eyes also poses a challenge, that is, the brain must select a unique visual direction for each object in the visual field, a process known as *fusion*. There has been considerable interest in determining the developmental sequences for fusion and stereopsis, especially since these functions are disrupted in strabismus (eye misalignment), a condition that occurs commonly in infancy and early childhood.

The most direct approach for determining the onset of sensory fusion in human infants has been to record a “cyclopean” VEP using one of two different stimuli. The first approach presents a uniform field or pattern to each eye that are modulated at different temporal frequencies in the two eyes (e.g., 8 Hz—for the right eye, 6 Hz—for the left eye). A cortical response, recorded at either the sum (14 Hz) or the difference frequency (2 Hz, also termed the beat frequency), indicates the presence of binocular neurons that integrate and respond to input from both eyes. Using this approach, France and Ver Hoeve (1994) reported that a binocular response was present in most normal infants by 2 months of age. The two-frequency approach has also been used by Brown et al. (1999) to study the development of fusion and rivalry. In that study, beat frequency response was recordable only for stimuli that had the same orientation in the two eyes.

The second approach for exploring the integration of information from the two eyes employs dynamic random-dot correlograms. Correlograms consist of a field of random dots presented dichoptically to the two eyes. Correlograms alternate between two different phases, a correlated and anticorrelated phase. In the correlated phase, the dot patterns are identical

FIGURE 13.13. Development of symmetrical monocular motion VEP response as a function of spatial and temporal frequency. Infants were presented with high-contrast (80%) oscillating gratings (90° phase shifts) at four spatiotemporal frequencies (6 Hz, 1 c/deg; 6 Hz, 3 c/deg; 10 Hz, 1 c/deg; and 10 Hz, 3 c/deg). Response amplitudes for each harmonic were normalized by dividing by the mean response amplitude measured across all responses for each combination of eye (left and right), harmonic (first and second), and

recording channels (Oz vs. O1 and Oz vs. O2). The age at which the first and second harmonics are equal (crossing point) was used as an estimate of age to maturity for each spatiotemporal condition. Maturity on this measure is first reached for 6 Hz, 1 c/deg (18 weeks), and development extends to almost 78 weeks at 10 Hz, 3 c/degree. Development continues beyond these midpoint estimates and extends at least into the third year at 10 Hz, 3 c/deg. Rel., relative

in the two eyes. In the anticorrelated phase, a dark dot in the pattern presented to one eye corresponds to a bright dot in the pattern presented to the fellow eye and vice versa. The cortical response to the alternation between the two phases is recorded. The “cyclopean VEP” response to these correlated/anticorrelated stimuli has been interpreted as being indicative of fusion without stereopsis as horizontal disparities are not induced by the stimuli. Using this approach, the onset of sensory fusion has been reported to occur typically at between 3 and 5 months of age (Braddick et al., 1980; Petrig et al., 1981), but possibly as early as 5 weeks of age (Skarf et al., 1993). Responses to random-dot patterns with disparity also emerge at about the same age (Birch and Petrig, 1996; Braddick et al., 1980; Petrig et al., 1981; Skarf et al., 1993). Stereo-acuity development through adulthood has been reviewed in Norcia and Manny (2003).

Development of response timing

Visual response latency is very much delayed in infants relative to adults. The most well-studied example of this general process is the maturation of the latency of the first positive peak (P100) of the pattern reversal response (Kos-Pietro et al., 1997; McCulloch and Skarf, 1991; Sokol and Jones, 1979). Figure 13.14 plots the latency of the first positive peak as a function of age and spatial frequency. The latency of the first positive peak rapidly declines to near adult levels by approximately 5 months of age for low spatial frequency targets. Longer maturational sequences are seen when finer scale patterns are used (Kos-Pietro et al., 1997; McCulloch and Skarf, 1991), and small latency decreases continue during childhood and adolescence (Allison et al., 1983; Zemon et al., 1997).

The latency of the evoked response is controlled by the neural integration time required in the retina, the conduction

FIGURE 13.14. Latency of the P100 component of the transient pattern reversal response as a function of age. Response latency declines rapidly between birth and 6 months of age for a range of check-sizes between 120 and 7.5 arcmin. The decline in latency is more rapid for the larger check-sizes. (Data from McCulloch and Skarf, 1991, as replotted in Norcia and Manny, 2003.)

velocity through the retinogeniculate pathway, and finally, cortical integration time. Fiorentini and Trimarchi (1992) compared latencies of simultaneously recorded pattern electroretinogram (ERG) and VEP responses. In adults, there was a 50-msec difference in latency between retinal and cortical responses. This difference was 125 msec at 5 weeks of age, indicating that much of the change in delay of VEP latency that occurs during the first 5 months is attributable to changes in postretinal mechanisms, most likely in the cortex itself.

Visual responses are faster for stimuli that are well above threshold than for stimuli that are near threshold (Kubova et al., 1995; Parker et al., 1982). Contrast sensitivity develops rapidly over the same time frame that latency is decreasing; thus, some of the apparent speeding of the cortical response could be due to increasing contrast sensitivity. If one compares response phase at a constant factor above threshold,

FIGURE 13.15. Development of chromatic VEP waveforms for 2- to 26-year-old observers recorded in response to purely chromatic stimuli modulated about white along the LWS/MWS cone excitation axis. In young observers, the response consists of a positive/negative complex. The negativity at 250 msec, seen in the youngest observers, is absent in adults. Starting at around 5 years of age, an earlier negativity, at approximately 150 msec, emerges and is retained into adulthood. (Reprinted from Madrid and Crognale, 2000, Fig. 2.)

this sensitivity difference can be factored out. In Figure 13.7, response phase for 3-month-old infants at 10% physical contrast is about 0° . At 8 to 11 months, contrast threshold is improved by a factor of 2, and the phase of the response at 5% contrast (a comparable multiple of threshold) has advanced by 100° . This speed-up is independent of stimulus visibility and is equivalent to 25 msec of delay at the response frequency of 11 Hz.

In contrast to the relatively precocious development of low-spatial-frequency achromatic mechanisms, low-spatial-frequency chromatic mechanisms show continued development through late adolescence (Madrid and Crognale, 2000). Figure 13.15 shows response waveforms for 2- to 26-year-old observers recorded in response to purely chromatic stimuli modulated about white along the LWS/MWS cone excitation axis. In young observers, the response consists of a positive/negative complex. The negativity at 250 msec, seen in the youngest observers, is absent in adults. Starting around the age of 5 years, an earlier negativity at approximately 150 msec emerges, and this persists into adulthood. A similarly protracted developmental sequence has been observed for stimuli that preferentially excite the SWS cone pathway.

Summary

Depending on what visual function is measured, adult-like performance can be seen at as early as 8 to 10 weeks of age (low-spatial-frequency contrast sensitivity) or as late as 10 to

14 years (Vernier acuity, chromatic VEP waveforms; for a more complete listing of late-maturing functions, see also Norcia and Manny, 2003). These different developmental sequences presumably reflect fundamental limitations at different levels of the visual system. Studies of nonhuman primates (see Chapter 12, Neural Limitations on Visual Development in Primates) have provided suggestions about limiting factors in the retina and primary visual cortex that may affect the processing of simple stimuli, such as gratings. Our understanding of the developing retina and visual cortex, particularly the extrastriate cortex, is far from complete. It is hoped that future advances in electrophysiological, behavioral, and imaging techniques will help fill in these large gaps in knowledge.

14 The Effects of Selected Forms of Early Visual Deprivation on Perception

DONALD E. MITCHELL

STUDIES OF THE PERCEPTUAL effects of early selected visual deprivation have had at least three motives. Arguably, the primary motive has been to identify the functional consequences of the cortical changes induced by early, selected, visual deprivation imposed within defined critical periods in an animal's early life, and *en passant*, to help shed light on the relationship between the physiological properties of neurons within area 17 and perception. A related motive has been to provide data pertinent to the debate over the complex and, indeed, sometimes paradoxical issue (e.g., Pettigrew, 1978) of how and why periods of abnormal visual experience exert such dramatic effects on certain aspects of cortical physiology for a long time after adult characteristics are present. Finally, the third motive behind a subset of studies has been to arrive at an understanding of the origins of certain common developmental disorders affecting human vision. Of particular interest have been the three major forms of amblyopia, one associated with the presence of strabismus (strabismic amblyopia), one with anisometropia (anisometropic amblyopia), and the last with a severe peripheral impediment to form vision in one eye (stimulus-deprivation amblyopia).

Over time, the inquiry into experiential influences on visual cortical neurons and perception has focused on a limited number of forms of visual deprivation. As a starting point, there were studies of the consequences of binocular visual deprivation. In these studies, animals were either deprived of all visual input as a result of being reared in total darkness, or else they were deprived of patterned visual input in the two eyes by means of bilateral eyelid suture. As a group, the remaining forms of deprivation involved selected visual input biased to one extreme of the range within which each of the major visual response characteristics of cortical neurons (ocular dominance, orientation selectivity, and directional selectivity) are distributed in the normal adult striate cortex. With respect to ocular dominance, two forms of selected visual deprivation have been used widely in an attempt to alter the distribution of cortical ocular dominance in area 17. These are monocular deprivation, whereby one eye is deprived of either patterned or all visual input, and manipulations, such as strabismus or alternating monocular deprivation, which involve an

attempt to reduce or eliminate simultaneous or concordant visual input to the two eyes. Attempts to manipulate the distribution of preferences of orientation or directionally selective neurons in area 17 have employed various procedures designed to reduce early visual input to a narrow range of the spectrum of contour orientations or directions of motion that would be encountered in the environment and represented in the visual cortex of normally reared animals. Studies of experiential influences on the development of the physiological representation of directional selectivity have employed an additional form of selected visual exposure—namely, stroboscopic rearing—that virtually eliminates direction-selective neurons in area 17.

The effects of these various forms of early selected visual exposure on perception are described for various species that have been studied extensively, namely, monkeys, cats, and, to a limited extent, rodents. Where possible, results are included for humans in whom the early visual input was either known to be, or could be inferred to have been, biased in a manner similar to that imposed experimentally on animals. However, to begin, it is first necessary to discuss the behavioral methods that have been employed in the context of the existence of critical periods for the various physiological effects of early visual deprivation.

THE BENEFITS AND SHORTCOMINGS OF COMMON BEHAVIORAL TESTING METHODS With respect to data collected on visually deprived animals, the behavioral testing procedures can be classified according to two main categories. Belonging to the first category are methods that require extensive training and that can be employed only for assessment of the perceptual capacities of mature animals, albeit with great precision. As such, they are useful for documenting the long-standing deficits that follow extended periods of deprivation. When employed in animals subjected to periods of selected visual deprivation that do not extend to the end of the critical period, the final perceptual deficit revealed by such methods may be reduced from that present immediately after the deprivation owing to partial recovery afterward.

The second category includes methods that require little or no training and can be employed on young animals.

Unlike the first category of methods that require animals to be trained to make unfamiliar motor responses, such as a nose or key press, these methods exploit the natural motor behaviors of young animals and require only that the behaviors be linked to particular visual stimuli. A prime example is forced-choice preferential looking (FPL), which exploits the natural tendency of infant primates and, to a lesser extent, kittens (Sireteanu, 1985) to prefer to look at certain visual stimuli over others. For instance, these animals often prefer contoured stimuli over homogeneous fields, and moving over stationary stimuli (Teller et al., 1974). For kittens, a technique based on a Lashley jumping stand that exploits the natural tendency for kittens to jump has been used to measure perceptual abilities in animals as young as 30 days of age (Mitchell et al., 1977; Mitchell et al., 1976; Murphy and Mitchell, 1987). In general, such methods permit longitudinal studies of the normal development of various perceptual abilities, as well as documentation of the immediate effects of periods of selected visual deprivation and the speed of the subsequent recovery. A disadvantage of some of these methods is that their use may be restricted to animals before a certain age.

THE MAGNITUDE OF THE VISUAL DEFICITS INDUCED BY DEPRIVATION IN DIFFERENT SPECIES Because visual thresholds can differ substantially across species, specification of the absolute magnitude of the postdeprivation thresholds may not allow for ease of comparison of the deficits. Consequently, in the case of spatial resolution, deficits are specified, according to common practice, in terms of octaves. An octave represents a factor of 2 difference from normal values; it is defined formally as the logarithm to the base 2 of the ratio of the measured resolution to normal values.

The effects of binocular visual deprivation

Study of the consequences of binocular visual deprivation has a long history, beginning with consideration of the documented findings from cases of “recovery from blindness” reported in the last 500 years. These cases represent individuals in whom visual input was restored by surgery after a long period of blindness, supposedly beginning near birth and caused by a peripheral obstruction to vision, such as bilateral cataracts. The findings fueled debate, beginning in the seventeenth century, over the issue of whether experience was necessary to see. The reader is referred to Morgan (1977) for summaries of the early reports and to Ackroyd et al. (1974), Fine et al. (2002), Valvo (1968), and Gregory and Wallace (1963), for descriptions of more recent cases. A particularly readable account of a case, which later formed the basis for the movie *At First Sight*, was published by the neurologist, Oliver Sacks (1993). In the fall of 2002, the

British Broadcasting Corporation devoted a television program (“the Man who Learnt to See”) to a case of a man, M.M., who had patterned visual input restored 43 years following severe binocular corneal scarring from a chemical explosion that he experienced when he was 3 years old. The rehabilitation of M.M. following surgery can be followed on his website: <http://www.senderogroup.com/perception.htm>. As summarized earlier (Mitchell and Timney, 1984), the findings from these cases can be difficult to interpret because of the frequent lack of quantitative measures of basic visual functions and the lack of precise information concerning the time of onset and course of progression of the visual deprivation. However, in situations in which the deprivation was known to be severe, to have begun early, and to have been prolonged, the visual rehabilitation was very slow (lasting more than a year), incomplete, and accompanied by periods of regression and/or emotional depression. Many of the obstacles to interpretation of binocular deprivation that characterized the early studies of humans are not present in animal studies because of the control over the timing and nature of the visual deprivation. In turn, the results from animal studies have informed the design of recent studies of humans with congenital binocular cataract, described later in this chapter (see also Fine et al., 2002).

With respect to controlled experiments conducted on animals, a distinction may need to be drawn between the consequences of rearing animals in complete darkness and of performing binocular eyelid suture. The latter permits both light and some patterned images on the retina, particularly in young kittens, monkeys, or ferrets (see Crawford and Marc, 1976; Krug et al., 2001; Loop and Sherman, 1977; Spear et al., 1978). Evidence that the two forms of binocular deprivation may not be equivalent can be found in the vast differences between the potential for recovery afterward. Considerable physiological recovery, including experientially dependent, selective development, is observed after dark rearing, but not after binocular eyelid suture (Cynader and Mitchell, 1980; Mower et al., 1981). Although there is no generally accepted explanation for the differences in recovery in these two conditions, it is possible that the different results may reflect differences in the degree of deprivation. Dark rearing eliminates all visually driven activity in the visual pathways, thereby allowing observation of the extent of development of a particular function that is made possible solely through the operation of intrinsic mechanisms of development alone. On the other hand, the limited form information that passes the eyelids of binocularly lid-sutured animals, which is presumably confined to low spatial frequencies, has the potential to allow some experientially guided patterning of cortical activity. In turn, the patterned cortical activity may lead to specification of cortical neurons, which may make them more resistant to

change in response to biased visual input imposed later. This explanation finds partial support in the observation that binocular lid-suturing fails to disturb development of orientation maps in area 17 of kittens during the first 3 weeks of life (Crair et al., 1998).

Although experimental studies have been conducted on animals, including chimpanzees (Riesen et al., 1951), for more than 50 years, the modern era of such studies, spurred by the results of electrophysiological investigations of visually deprived animals, can be traced from the mid-1960s. The results from these modern animal studies are summarized by species; this discussion is then followed by a description of the findings in humans after surgery for congenital binocular cataract.

CATS As might have been anticipated from prior electrophysiological investigations, the severity and permanence of the behavioral effects vary with the length of the deprivation. The deficits observed immediately after termination of deprivation and extending to 3 months or more are extremely profound. These animals appear blind, based on both omnibus qualitative tests of visuomotor function and on tests utilizing the jumping stand, being unable to distinguish between an open and a closed door except by use of tactile cues (Kaye et al., 1982; Timney et al., 1978). Although the deficits evident on gross tests of visuomotor behavior disappear quickly, precise quantitative tests of reaching behavior with the forepaw in kittens dark-reared until 6 months of age reveal small residual deficits in both reaction time and accuracy after 5 to 6 years of recovery (Fabre-Thorpe et al., 1990). In contrast to the fast recovery of gross visuomotor behavior, the recovery of visual acuity measured on the jumping stand is slow and becomes increasingly so as the deprivation lengthens (Mitchell, 1988a). This latter point is demonstrated in Figure 14.1, which shows the time required for 17 dark-reared animals to exhibit the first sign of vision on the jumping stand as a function of the period of deprivation. Although recovery is slow, the vision that is eventually attained can approach normal levels in animals subjected to periods of deprivation that terminate at or before 4 months of age. Animals that are visually deprived to 4 months of age appear blind on the jumping stand for 9 to 30 days, but achieve normal or near-normal levels of grating acuity after 4 months of visual exposure (Kaye et al., 1982; Mitchell, 1988a; Timney et al., 1978). However, as illustrated in Figure 14.2, animals reared in darkness for longer periods of time attain progressively lower final acuities, albeit considerably better than those achieved in the deprived eye of animals monocularly deprived for equivalent periods (see Fig. 14.6). The degree of visual acuity recovery observed following even longer periods of binocular deprivation is consistent with the substantial functional recovery of stimulus response properties of neurons in area

17 of animals that have been either dark-reared or binocularly deprived by bilateral eyelid suture until 11 to 15 months of age and then allowed 6 to 12 months of normal visual exposure (Cynade et al., 1976).

In addition to results obtained from dark-reared animals, Figure 14.2 displays data obtained using the same testing procedure from two laboratories (Mitchell, 1988a; Smith et al., 1980) on kittens reared from normal eyelid opening with bilateral lid suture. One animal (C79, Mitchell, 1988a) that acquired a pendular nystagmus never developed evidence of form vision. Moreover, both animals for which longitudinal measurements were recorded took approximately twice as long as kittens that had been dark-reared for the same time to show any signs of vision on the jumping stand. An additional comparison study of the extent of recovery of visual acuity following these two forms of binocular deprivation was conducted by Mower et al. (1982) on two binocularly lid-sutured kittens and three others that were dark-reared to 4 months of age. Only the mean data for the two groups of animals were provided, and these are depicted in Figure 14.2 by the triangle symbols. Of particular note was the lower mean acuity (2.67 versus 5.05 cycles/degree, or 0.92 octaves) attained by the animals that had been deprived by binocular lid suturing (open triangle symbols). Thus, like the differing physiological effects of these two forms of deprivation on the visual cortex (e.g., Mower et al., 1981), the long-standing deficits in visual acuity from the

FIGURE 14.1. The time (T) to recovery of the first signs of vision on the jumping stand (operationally defined as the ability to jump to a closed door, as opposed to an adjacent open door, by use of visual cues alone) in 17 kittens dark-reared from birth for the period (t) shown. The increase of T with t has been fitted by the following function: $T = 0.067t^{1.2}$. (Redrawn from Mitchell, 1988a.)

FIGURE 14.2. The grating acuity eventually attained by kittens binocularly deprived from birth is seen to decline with length of deprivation. The line shows the best exponential fit to the data from dark-reared animals (*filled symbols*). The open symbols represent data from three groups of animals that were binocularly deprived by eyelid suture (Mitchell, 1988a [*open circles*]; Mower et al., 1982 [*triangle*]; Smith et al., 1980 [*squares*]). The shaded region indicates the range of grating acuities for normal animals tested using the same procedure. Vision that is so poor as to enable only the ability to distinguish a closed from an open door on the jumping stand is depicted as OD.

latter form of binocular deprivation may be more substantial than those following equivalent periods of dark rearing.

Measurements of visual acuity probe the ability of binocularly deprived animals to see fine spatial detail (high spatial frequencies), but does not provide information on the visibility of course patterns (low or medium spatial frequencies). This missing information is supplied by measurements of contrast sensitivity functions, which have been obtained by only two groups using the behavioral technique of conditioned suppression (Blake and Di Gianfilippo, 1980; Lehmkuhle et al., 1982) on three dark-reared and two binocularly lid-sutured animals. The mean spatial contrast sensitivity functions reported by Lehmkuhle et al. (1982) for two animals dark-reared to 5 months and two other cats that were binocularly deprived by eyelid suture up until either 5 or 12 months of age are displayed in Figure 14.3A, together with the mean data for two normal cats. In addition, Figure 14.3B displays the results obtained by Blake and Di Gianfilippo (1980) on one animal that had been dark-reared until 6 months of age. The contrast sensitivity functions for the two forms of binocular deprivation are similar in shape, although there is a tendency for the sensitivities to be lower for the animals deprived by binocular lid suture. Overall, the data indicate a uniform reduction of sensitivity

for all spatial frequencies with respect to normal values. A point of special note that emerged from the investigation of Lehmkuhle et al. (1982), as well as from other data (Mitchell, 2002), is that the deficits that follow binocular deprivation are worse than those that follow ablation of area 17 in normal animals. This finding implies that the effects of deprivation extend to other visual areas besides area 17. Moreover, the greater losses, at both low and high spatial frequencies, than those observed after cortical lesions point to the fact that binocular deprivation affects both the X and the Y pathway (Stone, 1983), with possibly a larger influence on the latter pathway.

There is substantial evidence that dark rearing may have more pronounced effects on other perceptual capabilities than it does on spatial resolution. A substantial proportion of dark-reared cats, even when deprivation extends to 1 year of age, subsequently develops a convergent misalignment of the visual axes (Cynader et al., 1976; Cynader, 1979). It could be argued that the presence of an acquired strabismus may prevent the development of stereoscopic vision. Interestingly, tests of depth perception suggest that all dark-reared cats lack stereopsis, whether they acquire a strabismus or not (Kaye et al., 1982). Tests of depth perception in normal cats on a jumping stand, where the animal has to jump toward the closer of two stimuli viewed through the glass plate onto which the cat jumps, reveal that the threshold perceivable difference in depth between the two stimuli is smaller by a factor of about 8 when both eyes are open than when one eye is covered. This superiority has been attributed to the contribution of the binocular depth cue of stereopsis in the former situation (Mitchell et al., 1979). Animals that are dark-reared to 4 months of age, despite recovering normal or near-normal visual acuity, perform no better on the depth task binocularly than monocularly (Kaye et al., 1982), a result that suggests that they may not possess stereoscopic vision.

MONKEYS The early studies of dark-reared chimpanzees revealed severe degeneration of retinal ganglion cells after periods of deprivation lasting up to at least 16 months of age, thereby making it impossible to attribute the behavioral results to changes at the cortical level. By contrast, no abnormalities have been reported in the retinas of dark-reared monkeys (Chow, 1955, 1973), including the retinas of those employed (Hendrickson and Boothe, 1976) in one modern behavioral study (Regal et al., 1976). The animals of the latter study were not deprived from birth, but from 2 weeks of age, in order that they could be trained to self-feed. Three animals, dark-reared until 3 months and tested by preferential looking on one or two occasions after having spent 22 to 137 days in the light, exhibited grating acuities that were lower by between 1 and 2 octaves than those of age-matched control animals. The grating acuity deficits exhibited by two

FIGURE 14.3. *A*, The mean spatial contrast sensitivity functions for two normal cats (*filled circles*), two cats following ablation (*Lesion*) of area 17 (*filled diamonds*), two dark-reared (*DR*) cats (*open circles*), and two cats binocularly deprived by lid suture (*BLS*) (*open squares*).

B, Spatial contrast sensitivity function measured with counter-phased gratings (1.5 Hz) for a cat dark-reared to 6 months of age. (*A*, Data redrawn from Lehmkuhle et al., 1982. *B*, Redrawn from Blake and Di Gianfilippo, 1980.)

animals that were deprived until 6 months were no worse (0.6 to 1.5 octaves). By contrast, the latter animals appeared more impaired on several qualitative tests of visuomotor functions, such as visual placing and visual avoidance.

A more extensive study that included measurements of both spatial and temporal contrast sensitivity functions, as well as tests of stereopsis, was conducted later on five monkeys that were deprived for 2 to 16 weeks by bilateral eyelid suture beginning at 2 weeks of age (Harwerth et al., 1991). Only animals deprived for 7 weeks or more exhibited deficits in contrast sensitivity, and even these were restricted to spatial frequencies greater than 0.75 cycles/degree for two animals and 4 cycles/degree for another. By comparison, deficits in temporal contrast sensitivity for uniform field flicker were either nonexistent or else were very small, and did not vary in a systematic manner with temporal frequency. Whereas measurements of increment threshold spectral sensitivities revealed only minor variations from normal values, none of the binocularly deprived animals possessed stereopsis, including those with no contrast sensitivity loss. Although it could be argued that the small and variable losses in contrast sensitivity may be related to either the short period of deprivation or the prior 2-week period of normal vision, it is noteworthy that, like dark-reared cats, binocularly deprived monkeys appear to be stereoblind. Subsequent electrophysiological recordings from area 17 of these animals revealed a physiological explanation for this finding, namely a dramatic reduction in the proportion of cells that could be excited through either eye from a value of 76% (observed in normal animals) to 20% (observed in binocularly deprived cats) (Crawford et al., 1991). Nevertheless, confirmation that this population of cells lacks the ability to extract disparity and/or interocular phase information that relies on inhibitory inputs from the two eyes has yet to be made.

HUMANS Systematic explorations have been made of the visual abilities of humans following surgical intervention for congenital bilateral cataracts and restoration of a clear optical image to both eyes (Birch et al., 1998; Ellemberg et al., 1999; Mioche and Perenin, 1986; Tytla et al., 1988). Despite variation between studies in the length of deprivation prior to surgery and of the period of aphakia prior to full optical correction, there is considerable agreement on the major findings. As with binocularly eyelid-sutured monkeys, the spatial contrast sensitivities at low spatial frequencies (<2 cycles/degree) are within normal limits; however, beyond this range, the contrast sensitivities decline progressively from normal values with increasing spatial frequency. The grating acuity was reduced on average by 1.5 octaves (Ellemberg et al., 1999). As with binocularly deprived monkeys, temporal vision appears to be affected far less severely, with small deficits in uniform field flicker evident only at low temporal frequencies (5 to 10 Hz). Moreover, the deficits in spatial contrast sensitivity do not vary with the rate of temporal modulation of the grating pattern (Tytla et al., 1988).

The effects of monocular visual deprivation

Selected (monocular) visual deprivation is by far the most studied condition at all different levels of analysis, from its anatomical and physiological sequelae to its behavioral effects. Not only are the consequences of monocular deprivation profound and robust, but arguably, the key concept that has emerged from studies of experiential effects on development—namely, the idea that these effects occur only during certain critical periods—has been derived and subsequently refined by studies of this form of deprivation. A second important finding that has emerged from studies of the physiological effects of monocular deprivation is that

the effects in area 17 are far more profound than those that follow equivalent periods of binocular deprivation. This finding is the cornerstone of the hypothesis that the effects of monocular deprivation are a result of competitive interactions for synaptic space between the afferents from the two eyes. As with the physiological effects of monocular deprivation, the behavioral effects are far more profound than those that follow binocular deprivation in any form.

CATS The use of the jumping stand permits both an assessment of the immediate effects of various periods of deprivation on the vision of the deprived eye, as well as the time course and extent of any subsequent recovery following either restoration of normal visual input (referred to as binocular recovery) or imposition of a period of reverse deprivation (reverse occlusion) whereby the formerly non-deprived eye is closed during the recovery period. As might be anticipated from the physiological effects, the immediate effects of even short periods (6 days) of monocular deprivation, when imposed in the first 2 months of life (Mitchell et al., 2001), are profound. Animals subjected to monocular deprivation appear blind when first forced to use their deprived eye. However, after such short periods of deprivation, the vision of the deprived eye begins to recover within just a few hours. Studies of the rate and extent of the recovery of the vision of the deprived eye following periods of monocular deprivation imposed from the time of natural eye opening and terminated at different ages reveal two main trends (Mitchell, 1988a). First, as the length of deprivation increases, the period before signs of vision are exhibited by the deprived eye becomes progressively longer. Second, the vision that is recovered by this eye declines from levels close to normal, in terms of visual acuity, with very short periods of deprivation, to more severe deficits with only rudimentary light perception when deprivation extends to a year or more. These points are evident in the results shown in Figure 14.4, which plots the recovery of the vision of the deprived eye in three animals that were monocularly deprived from near birth until 42, 94, or 302 days of age and thereafter allowed binocular visual input (binocular recovery). Whereas the animal that was monocularly deprived for 6 weeks recovered sufficient form vision in the deprived eye within 5 days to permit measurements of visual acuity, the animals that were deprived for 94 and 302 days displayed no signs of pattern vision for 17 and 145 days, respectively. Moreover, in the animal that was monocularly deprived the longest, the deprived eye appeared completely blind for 2 months, and for an additional 2 months was capable of discriminating only between an open and a closed door on the jumping stand. In parallel with the progressive increase in the time for the first signs of form vision to emerge with increasing length of deprivation, there was a substantial decline in the level of visual acuity that was

eventually recovered by the deprived eye. For the animal deprived for 302 days, the deprived eye recovered an acuity of only 1.35 cycles/degree, a value 2.45 octaves below normal average values.

The generality of these two trends for both conditions of recovery are evident in the combined data from many animals, displayed in Figures 14.5 and 14.6. These figures show, respectively, a plot of the time interval for animals to exhibit the first sign of vision with the deprived eye and the final acuity achieved by the deprived eye as a function of the length of deprivation. The initial speed of recovery appears to be similar for both recovery conditions. For short periods of deprivation that extend to only 4 to 6 weeks of age, signs of vision emerge in the deprived eye within only 2 or 3 days. However, for deprivation lasting 12 to 18 months, a period of at least 4 months, and in some, as long as 12 months, elapses before animals begin to see. Although the initial speed of recovery of vision is similar for the two recovery conditions, for periods of deprivation of 4 months or less, animals that are reverse occluded (*filled symbols*) recover slightly better acuity than do those that have both eyes open during recovery (*open symbols*). With increasing length of deprivation, the vision that is eventually recovered declines regardless of the recovery condition. A proportion of animals that are deprived for a year or more never recover sufficient form vision to permit measurement of visual acuity; the remainder acquire only rudimentary form vision (visual acuity <1 cycle/degree).

Before passing to other matters, there are two caveats to consider with respect to the points made concerning the data displayed in Figures 14.5 and 14.6. First, close examination of the *initial* speed of improvement of vision in the deprived

FIGURE 14.4. The time course of vision recovery in the deprived eye of three kittens monocularly deprived to 42, 94, or 302 days of age, after which both eyes were open. The letter "B" denotes the situation in which the animal appears blind on the jumping stand. Throughout the period indicated by the horizontal line corresponding to zero on the ordinate for the animal deprived to 302 days, the animal was capable of discriminating a closed door from an open door on the jumping stand but could not pass a formal test of form vision. (Redrawn from Mitchell, 1988a.)

FIGURE 14.5. Recovery time increases with length of visual deprivation. The graph shows the time interval for the deprived eye to exhibit the first sign of vision as a function of the length of the period of monocular deprivation. Open and closed symbols depict data from animals in the situation of binocular recovery or reverse occlusion, respectively, throughout the recovery period. A single regression line has been drawn for the data from both conditions of recovery. (Redrawn from Mitchell, 1988a.)

eye of animals following very short periods (6 days) of monocular deprivation reveals that it is faster in animals that have both eyes open following deprivation than it is in those that are reverse occluded (Mitchell et al., 2001). This finding provides further evidence for the operation of cooperative associative mechanisms of recovery in the underlying neural substrate whereby the nondeprived eye serves as a guide or “teacher” for recovery of the deprived eye (Kind et al., 2002). Such mechanisms may mediate recovery in circumstances in which mechanisms based on binocular competition are ineffective. Second, the recovery that occurs during reverse occlusion and that is plotted in Figure 14.6 may not be maintained afterward when normal visual input is restored to the formerly nondeprived eye. The example of this phenomenon, shown in Figure 14.7, involves a kitten that had been monocularly deprived to 4 weeks of age. The kitten then underwent a 3-week period of reverse occlusion during which the vision of the initially deprived eye recovered from blindness to 3.4 cycles/degree (Mitchell et al., 1984b). However, shortly after opening the initially

FIGURE 14.6. Less vision is recovered as the period of deprivation lengthens. The visual acuity eventually attained by the deprived eye in 37 monocularly deprived kittens is presented as a function of the length of the prior period of monocular deprivation. Open and closed symbols depict data from animals in the situation of binocular recovery or reverse occlusion, respectively, throughout the recovery period. Visual function is denoted by letters, as follows: B, complete blindness; OD, the ability to discriminate an open from a closed door on the jumping stand; L, the ability to pass a formal luminance discrimination test on the jumping stand. The square symbols show equivalent data from six animals studied by Smith and Holdefer (1985). (Redrawn from Mitchell, 1988a.)

FIGURE 14.7. An example of a situation in which the vision recovered in the deprived eye during reverse occlusion was not retained afterward. The graph shows the changes in the grating acuity of the deprived eye (filled symbols) and nondeprived eye (open symbol) of monocularly deprived kittens during (shaded area) and after a 3-week period of reverse occlusion imposed at 4 weeks of age. The animal’s visual history is depicted in schematic fashion beneath the graph. The open arrows indicate the first day on which the animal could discriminate an open from a closed door on the jumping stand, whereas the bracket to the right indicates the range of acuity values recorded for normal animals. (Redrawn from Mitchell et al., 1984b.)

nondeprived eye, the vision of the initially deprived eye began to drop to low levels from which it never recovered. Meanwhile, the vision of the initially nondeprived eye improved gradually but never to normal levels. This finding has been explored thoroughly in a number of research articles, some of which address the obvious relevance to patching therapy for amblyopia (Mitchell, 1991; Mitchell et al., 1984a; Murphy and Mitchell, 1987).

Measurements of contrast sensitivity functions (CSFs) reveal that the losses of contrast sensitivity in the deprived eye are far more severe than the final deficits in grating acuity. The four examples from two studies (Lehmkuhle et al., 1982; Mitchell, 1988a), displayed in Figure 14.8, show results following either a short (6 to 8 weeks) or extended (8 to 16 months) period of deprivation. Even the animals subjected to a brief period of deprivation exhibited 10- to 20-fold differences in contrast sensitivities between the two eyes, compared to a difference of less than an octave in visual acuity. The cats deprived for the longest periods showed increased losses of contrast sensitivity (30-fold) at all spatial frequencies; moreover, the losses were approximately the same at all temporal frequencies (Lehmkuhle et al., 1982). As was also evident in the visual acuity data (compare Figs. 14.2 and 14.6), the long-standing deficits in contrast sensitivity following monocular deprivation were far greater than those that followed an equivalent period of binocular deprivation (Fig. 14.3).

MONKEYS In monkeys, monocular deprivation results in a more extensive range of visual deficits, as well as larger losses, than those reported in cats. Most significantly, monkeys that are monocularly deprived at 1 or 2 months of age for a period of 18 months exhibit reduced scotopic sensitivities (by as much as 3 to 4 log units), and also demonstrate changes involving both the shape and absolute sensitivity of their photopic spectral sensitivity functions (Harwerth et al., 1986). In contrast to the losses in contrast sensitivity and resolution, for which the critical period extended to 25 months, the deficits in scotopic and photopic sensitivity have quite short critical periods extending to only 3 and 6 months of age, respectively.

The earliest studies of the effects on spatial vision of monocular lid-suturing, imposed for a year or more in the first month of life, revealed that the animals were unable to demonstrate any pattern vision with their deprived eye, even after extended periods of reverse occlusion. Later research, which incorporated shorter periods of deprivation (2 to 4 weeks), revealed similar loss of pattern vision when imposed in the first month and severe, irreversible effects on visual acuity followed occlusion beginning in the first 9 weeks of postnatal life (von Noorden, 1973).

Extensive studies of spatial contrast sensitivity have explored not just the effects of the timing of the deprivation,

FIGURE 14.8. The graph shows contrast sensitivity functions for the nondeprived (*open symbols*) and deprived (*filled symbols*) eyes of four cats that were monocularly deprived from near birth to 6 weeks (A), 8 weeks (B), 8 months (C), or 16 months (D) of age. The open and closed arrows indicate the measured grating acuity of the nondeprived and deprived eye, respectively. (A and B, Data redrawn from Mitchell, 1988a. C and D, Data redrawn from Lehmkuhle et al., 1982.)

but also the outcomes from different variants of the deprivation itself, including eyelid suture, anisometropia produced by lenses, and chronic monocular cycloplegia (Boothe et al., 1982; Harwerth et al., 1983a; Kiorpes et al., 1987; Smith et al., 1985). The profound magnitude of the effects of eyelid suture on CSFs is shown in Figure 14.9 for three animals from the study of Harwerth et al. (1983a). Whereas the CSFs for the nondeprived eyes of all three animals were similar to those of normal animals, the CSFs for the deprived eyes revealed a profound loss of contrast sensitivity at all spatial frequencies. The extrapolated cut-off frequencies for the deprived eyes (approximately 0.3 cycles/degree) were worse than those for the fellow eye by a factor of 100 or more. Moreover, the CSFs for the deprived eyes were essentially the same for either long-term or short-term deprivation, and they remained unchanged despite 2 to 3 years of binocular experience. The similarity of the deficits observed in animals subjected to vastly different lengths of deprivation may result from an effective continuation of the deprivation beyond the time the eyelids are opened due to the development of form deprivation myopia (Daw, 1995) even after short periods of

FIGURE 14.9. The graph shows contrast sensitivity functions (CSFs) for the nondeprived (*open symbols*) and deprived (*filled symbols*) eyes of four monkeys that were monocularly deprived by eyelid suture from about 30 days of age to 22 months (A), 8 weeks (B), or 2 weeks (C). D, The CSFs are shown for a monkey reared from 1 to 8 months of age with chronic monocular cycloplegia. (Data redrawn from Harwerth et al., 1983a.)

eyelid suture. Temporal modulation functions for uniform field flicker reveal deficits in the deprived eye at all temporal frequencies, but these increase with frequency beyond the peak of the temporal CSF. Nevertheless, the deficits in temporal modulation sensitivity at all temporal frequencies are less severe than the spatial contrast sensitivity deficits (Harwerth et al., 1983b).

In contrast to the effects of monocular eyelid suture, the consequences of image blur resulting from chronic monocular cycloplegia are far less severe and show greater inter-animal variability (Harwerth et al., 1983a; Kiorpes et al., 1987). As illustrated by the representative animal shown in Figure 14.9D, no loss of contrast sensitivity may be observed at all at low spatial frequencies. A similar outcome was reported in animals reared with anisometropia induced by a $-10D$ lens worn in front of one eye for at least 60 days beginning at 30 days of age (Smith et al., 1985). Contrast sensitivities were reduced in the treated eye for spatial frequencies exceeding 1 cycle/degree. The cut-off frequencies for this eye were about 1 octave lower than those for the fellow eye. The deficits in contrast sensitivity lay in the midrange of values reported for humans with anisometropic amblyopia (Sen, 1980). In addition to the clinical relevance based on the magnitude of the deficit, the ratio of the contrast sensitivities between the two eyes did not vary with luminance, a finding common to human anisometropic, but not strabismic, amblyopes.

HUMANS There are a number of naturally occurring conditions arising at or near birth in humans that result in monocular degradation of form vision similar in nature and severity to that imposed experimentally in animals. The two most common of these conditions are congenital unilateral cataract and ptosis in which the upper eyelid partially or completely covers the pupil. Following restoration of sharp retinal images in later life by surgical interventions combined with appropriate optical correction of any refractive error, affected individuals manifest irreversible deficits in spatial vision that collectively define the clinical entity referred to as stimulus deprivation amblyopia (von Noorden and Maumenee, 1968). The severity of the deprivation and its similarity to that imposed experimentally in animals distinguishes it from amblyopia associated with strabismus and anisometropia. Despite lack of complete documentation of the extent of the deprivation in the perinatal months, as well as variability with respect to both the presence of any coexisting conditions, such as strabismus, and the type and duration of any subsequent treatment, there is general agreement on a number of points. In patients who receive aggressive treatment early, deficits in contrast sensitivity for static gratings may not be present at all for low spatial frequencies (<1 cycle/degree), but may increase with spatial frequency beyond this point. As the length of deprivation increases, the deficits extend to progressively lower spatial frequencies (Ellemberg et al., 2000; Tytla et al., 1988). For temporally modulated gratings, the deficits in contrast sensitivity are either greater for low temporal frequencies (Birch et al., 1998; Ellemberg et al., 2000; Tytla et al., 1988) or else show no dependence on temporal frequency at all (Hess et al., 1981).

When deprivation is long standing (lasting a year or more), a variety of very severe outcomes may result. Two groups have described patients with a complete loss of spatial (pattern) vision for either all spatial frequencies, or else spatial frequencies above 0.5 cycle/degree for certain temporal conditions. One group (Hess et al., 1981) described patients with no form vision for either static or temporally modulated gratings, leaving only the perception of flicker in the latter case. A patient described by the other group (Levi and Harwerth, 1980) had no pattern vision at all above 0.5 cycle/degree for gratings temporally modulated at 10 Hz but could resolve gratings over a wide range of spatial frequencies when they were not temporally modulated. One patient with a severe loss of contrast sensitivity was unable to discern flicker of temporally modulated gratings at any temporal frequency (Manny and Levi, 1982b). This patient, as well as one reported by Hess et al. (1981), exhibited deficits in temporal contrast sensitivity to uniform field flicker similar to those reported in monocularly deprived monkeys; that is, the deficits increased in magnitude with temporal frequency (Manny and Levi, 1982a). Because a pattern of increasing

losses at progressively higher temporal frequencies appear to be associated with the longest periods of deprivation, it has been suggested by Ellemberg et al. (2000) that these deficits may reflect retrograde changes at the level of the retina.

RODENTS Studies of the postnatal development of the visual cortex of rats (e.g., Fagiolini et al., 1994), mice (Drager, 1978; Gordon and Stryker, 1996), and hamsters (Emerson et al., 1982) have revealed experience-dependent changes that are qualitatively similar to those observed in cats and monkeys. However, as with the shifts of ocular dominance (Fagiolini et al., 1994; Gordon and Stryker, 1996), the behavioral effects of monocular deprivation are far less severe than those produced in higher mammals in which pattern vision in the deprived eye can be completely lost. In terms of the visual acuity of the deprived eye, the long-term consequences of periods of monocular deprivation imposed from near birth and extending through the presumed duration of the critical period are similar, but minimal, for all rodent species. For rats, behavioral measurements (Prusky et al., 2000) reveal a deficit of 0.58 octaves in the acuity of the deprived eye (0.65 versus 0.97 cycles/degree), a deficit smaller than that estimated (1.39 octaves) from evoked cortical potentials (Fagiolini et al., 1994). In hamsters and mice, behavioral measurements reveal deficits of 0.6 (Emerson et al., 1982) and 0.74 (Prusky and Douglas, 1998) octaves, respectively.

The effects of decorrelated binocular input

In addition to depriving one eye of patterned visual input, monocular deprivation also results in the two eyes receiving discordant visual input. However, there are forms of deprivation that dissociate the visual input to the two eyes without placing one eye at a chronic disadvantage. One such type of deprivation is artificial strabismus, a misalignment of the visual axes created either by surgical manipulation of one or more extraocular muscles or optically, by use of prisms. Another means to the same end is to rear the animal with alternating monocular occlusion so that the animal is never permitted to see with both eyes at the same time. Such deprivation can produce a near-complete breakdown of binocularity among neurons in area 17 in kittens to the extent that only a very small proportion of cells can be excited by either eye, with each eye retaining an equal representation overall (Daw, 1995; Mitchell, 1988b; Movshon and Kiorpes, 1990). In monkeys and, to some extent, in kittens, strabismus produced by surgical intervention results in a shift of ocular dominance among cortical neurons away from the deviating eye, as well as reduced vision in that eye (reviewed by Mitchell, 1988b; Movshon and Kiorpes, 1990). However, the ubiquitous finding of a reduction in the proportion of binocularly excitable cells associated with rearing conditions

that reduce the concordance of the visual input to the two eyes might have important implications for binocular vision in general and stereopsis in particular. Humans with stimulus deprivation amblyopia are stereoblind, and even when surgical interventions occur very early, it is rare for anything but rudimentary stereopsis to develop (Mitchell and MacKinnon, 2002). Moreover, humans with strabismus or other associated conditions that result in discordant visual input show impaired interocular transfer of visual aftereffects, a phenomenon dependent on the functional integrity of binocular neurons (Daw, 1995; Mitchell and Timney, 1984; Movshon and Kiorpes, 1990). The implications of the early rearing of animals with decorrelated early visual input have been explored in a number of animal studies, the results of which are presented in a later section without regard to species.

Two studies have documented the consequences for binocular depth perception of early alternating monocular occlusion in kittens. In both, the visual input to the two eyes was alternated on a daily basis up to either 6 months of age (Blake and Hirsch, 1975; unrestricted duration each day) or 3 months of age (Packwood and Gordon, 1975; 1 hour/day). The results for each study were consistent with a complete absence of stereopsis in adulthood. The study of Blake and Hirsch (1975) employed indirect tests for stereopsis based on comparison of binocular and monocular depth thresholds; the absence of superior performance of the former over the latter was interpreted as evidence of a lack of the uniquely binocular depth cue of stereopsis. The kittens had to detect whether the middle of three vertical rods was closer to them than the ones on either side. With both eyes open, a normal kitten could discriminate between differences in depth between the rods; these differences were one-tenth the size of those detectable when allowed to use only one eye. For cats reared with alternating monocular occlusion, the binocular and monocular thresholds were identical; moreover, they were no different than the monocular thresholds of normal cats. By contrast, Packwood and Gordon (1975) employed a shadow caster and red and green filters to provide anaglyphic presentation of three rods, of which the center one could be made to appear at a different depth on the basis of retinal disparity cues. Whereas normal cats, when subjected to relative retinal disparities of either 3 or 10 minutes of arc, could detect the middle rod as lying in a different depth plane than the flanking rods, the cats reared with alternating monocular occlusion responded at chance to all tested disparities. A study using similar methods, conducted by Kaye et al. (1982), indicated that stereopsis failed to develop in kittens in which strabismus was introduced by sectioning of an extraocular muscle.

Tests for the presence of global stereoscopic vision have been conducted in monkeys reared with discordant early

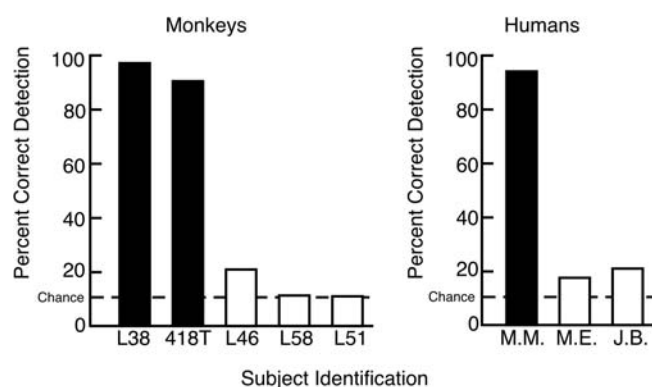

FIGURE 14.10. Performance data are shown for two normal monkeys (L38 and 418T, *filled bars*) and three monkeys reared with an optically induced strabismus (L46, L58, and L51, *open bars*). The animals were tested for global stereopsis with dynamic, random dot stereograms. Shown, for comparison, are the results obtained in a normal human (M.M.) and two humans (M.E. and J.B.; *open bars*) with a history of strabismus in early life. (Redrawn from Crawford et al., 1983.)

visual input using dynamic, random dot, stereographic displays. These displays revealed a cyclopean grating pattern in the presence of stereopsis (Crawford et al., 1983). In this study, three monkeys were reared from postnatal days 30 to 60 wearing helmets that contained two prisms (10 and 17 prism diopters) that dissociated the visual input to the two eyes in all positions of gaze (Crawford and von Noorden, 1980). As illustrated in Figure 14.10, all three of these monkeys (*open bars*) performed at chance on cyclopean detection of dynamic, random dot stereograms, whereas normal monkeys (*filled bars*) were 90% correct or better. The apparent stereoblindness of the helmet-wearing monkeys could not be attributed to amblyopia associated with optically induced strabismus, as measurements of CSF revealed either no deficit (L51) or extremely mild amblyopic deficits. (Also shown, for comparison, are comparable results from three humans performing the same task. One [M.M.] was normal, whereas the other two [M.E. and J.B.] had histories of disrupted early binocular input by strabismus.) Three years later, electrophysiological recordings from area 17 of these animals revealed that only 22% of the cells could be excited through either eye, as compared to 81% of the cells in normal control monkeys (Crawford et al., 1984).

Although tests of stereoscopic vision with more recent probes, such as those for linear and nonlinear stereopsis (Hess and Wilcox, 1994), may reveal some residual stereopsis in animals reared with discordant visual input, there is no doubt that such animals are stereoblind by most conventional assays. Moreover, such animals demonstrate other loss of binocular function, such as binocular summation of thresholds, whereby, for example, spatial contrast sensitivity measurements made binocularly are no better than those

made monocularly (Crawford et al., 1983). By contrast, binocular thresholds are superior by a factor of about 2 in normal animals.

The effect of selective exposure to particular contour orientations

Although both the robustness and interpretation of the physiological consequences of early exposure of animals to a restricted range of contour orientations are controversial (e.g., Mitchell and Timney, 1984; Movshon and Kiorpes, 1990; Movshon and Van Sluyters, 1981; but see also Sengpiel et al., 1999), the behavioral effects appear clear-cut. The earliest behavioral measurements were made in kittens reared in cylinders, like the animals of one of the pioneering physiological studies, so as to restrict the visual input to stripes of a single orientation (horizontal or vertical). Among these animals, measurements of grating acuity in adulthood revealed differences in the acuity for horizontal and vertical gratings of 0.26 to 0.87 octaves; the best acuity was always achieved for the orientation experienced as kittens in the cylinder (Muir and Mitchell, 1973, 1975). Later measurements (Blasdel et al., 1977), made in kittens that were restrained in order to lessen inappropriate visual stimulation through changes of head and body orientation with respect to the stripes, revealed deficits of similar direction and magnitude (0.49 to 0.73 octave).

In the context of the prevailing controversy that centered on the robustness of the physiological findings from selected exposure to restricted orientations, the small magnitude of the concurrent behavioral deficit did little to resolve matters. However, the rediscovery of “astigmatic” or meridional amblyopia in humans known to have received their initial optical correction of high astigmatism in late childhood reinforced the findings from the animal experiments. People with uncorrected astigmatism typically see contours of only one orientation clearly; other contours appear progressively more blurred with increasing departure from the favored orientation. Figure 14.11A illustrates the appearance of the target on the left to individuals with the two most common types of astigmatism who see only horizontal (*middle*) or vertical (*right*) contours sharply. Spurred by the initial “stripe-rearing” animal experiments, other researchers examined a large group of such astigmatic individuals. Their studies revealed that, even after full optical correction of refractive error, substantial differences (as much as an octave) existed in the acuity for gratings parallel to the principal meridians of the astigmatism, which are most commonly close to vertical and horizontal (Cobb and MacDonald, 1978; Freeman et al., 1972; Mitchell et al., 1973). Moreover, as illustrated in Figure 14.11B, for all subjects in whom the ratio of acuities for vertical and horizontal gratings lay outside the range observed among normal subjects, the best acuity always

FIGURE 14.11. *A*, Simulation of how the pattern on the left appears to astigmatic observers having the two most common forms of astigmatism in which either only horizontal (*middle*) or vertical (*right*) contours are sharply visualized. *B*, Histograms show the relationship between the meridional variations in acuity of 50 adult astigmatic eyes and 11 normal eyes (*open bars*) after complete optical correction of their refractive error and the visual experience of the uncorrected eye. Plotted on the abscissa is the vertical-to-horizontal grating acuity ratio, which has values of

>1.0 when vertical acuity is superior and <1.0 when the acuity for horizontal gratings is superior. Vertical and horizontal hatching depicts eyes for which vertical and horizontal contours, respectively, are seen most sharply by the uncorrected eye. For all astigmatic eyes for which the ratio of vertical to horizontal acuities exceeded the range of values observed in normal eyes, the grating orientation for which acuity was best was found to coincide with the contour orientation focused best by the uncorrected eye. (Redrawn from Mitchell et al., 1973.)

coincided with the orientation of contours least defocused by the *uncorrected* eye. This result is consistent with the idea that experience influences either the number or the tuning of orientation-specific cells in the human visual cortex, or both.

Measurements of CSFs for gratings parallel to the principal meridians of the astigmatism have revealed small deficits at even very low spatial frequencies, but which become larger with increasing spatial frequency (Freeman and Thibos, 1975; Mitchell and Wilkinson, 1974). The existence of deficits at very low spatial frequencies, as well as other considerations (Charman and Voisin, 1993; Gwiazda et al., 1986), point to a complex relationship between the presumed early optical error and the characteristics of meridional amblyopia.

Evidence that meridional amblyopia is a consequence of early astigmatism, and not promoted by another unknown factor that causes *both* astigmatism and the meridional variations in acuity, was provided by the demonstration of the development of meridional amblyopia in monkeys reared as infants with externally applied astigmatism (Boothe and Teller, 1982). Additional evidence of a link between astigmatism and the emergence of meridional amblyopia was provided by demonstrations of meridional amblyopia in four monkeys that developed astigmatism in one or both eyes. One of the animals was a normal control; for the other three animals, the astigmatism emerged in the nondeprived eye of animals that had been monocularly deprived from near birth (Harwerth et al., 1980; Harwerth et al., 1983c).

Two experiential manipulations have been shown to influence the development of directionally selective neurons in area 17. Of these, strobe rearing of kittens (rearing kittens in environments illuminated intermittently by very brief stroboscopic light flashes at 8 Hz) has been found to have particularly profound effects. Such intermittent illumination is known to destroy the appearance of smooth movement to humans. In kittens, strobe rearing virtually eliminates direction-selective neurons in areas 17 and 18 (Cynader and Chernenko, 1976; Kennedy and Orban, 1983; Pasternak et al., 1985), as well as in the lateral suprasylvian cortical visual area (Spear et al., 1985), with minimal or no effects on other stimulus response properties (Fig. 14.12A). Although the second manipulation—selective exposure to contours moving in only a single direction—can produce a substantial bias in the distribution of directionally selective neurons in area 17 (Daw, 1995), the consequences of this rearing procedure for motion perception have not yet been examined.

Accompanying the loss of directionally selective neurons associated with strobe rearing are substantial deficits in the perception of motion, as documented by Pasternak and colleagues (Pasternak et al., 1990; Pasternak and Leinen, 1986; Pasternak et al., 1985). These researchers have demonstrated that many aspects of pattern and temporal vision are normal in such animals, and that the small deficits that do exist may be attributable to the low luminance and limited total visual exposure associated with the brief duration (3 μ sec) of the strobe flashes during rearing. Thus, strobe-reared cats exhibit normal orientation discrimination thresholds, normal temporal frequency resolution (critical fusion frequency), and normal contrast sensitivities at low spatial frequencies (but slightly lower contrast sensitivities at higher spatial frequencies) (Pasternak and Leinen, 1986). Moreover, when exposed to stimuli of high contrast, the strobe-reared animals are able to discriminate, at performance levels comparable to those of normal cats, between stimuli moving in opposite directions over a wide range of stimulus speeds. However, severe abnormalities were noted in these animals in relation to tasks requiring comparison of contrast thresholds for detecting moving gratings versus discrimination of direction of motion. As illustrated in Figure 14.12B, normal cats could discriminate the direction of motion for drifting gratings of low spatial frequency at contrasts that were very close to detection threshold at all drift rates. However, strobe-reared cats, despite having only slightly lower detection thresholds than normal animals, required contrasts about 10 times higher in order to discriminate the direction of motion (Pasternak et al., 1985). These differences were even more pronounced for gratings of higher spatial frequency (Pasternak and Leinen, 1986).

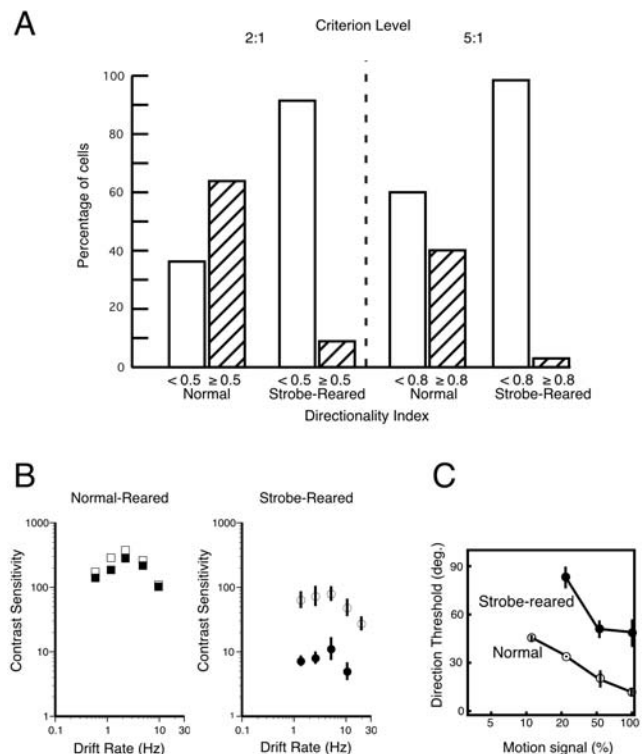

FIGURE 14.12. *A*, The directional selectivity of cells in area 17 is reduced in strobe-reared cats as compared to normal cats. The histograms show the percentage of cells classified as directional (hatched bars) or nondirectional (open bars) in normal ($N = 245$ cells) and strobe-reared ($N = 129$ cells) cats with respect to a directionality index. The index is defined as $1 - np/p$, where np is the response in the nonpreferred direction and p is the response in the preferred direction. The results are shown for two criterion levels with respect to p and np (2:1 or 5:1). *B*, Mean contrast sensitivity for two normal and three strobe-reared cats for the detection (open symbols) and discrimination (filled symbols) of the direction of motion of a 0.28-cycle/degree grating drifting at the rates shown on the abscissa. Normal animals could discriminate the direction of motion at or close to detection threshold. By contrast, in strobe-reared animals, direction discrimination required that the contrast be 10 times greater. *C*, Mean direction difference thresholds for dynamic, random dot displays were measured in two normal and three strobe-reared cats and presented as a function of the proportion of dots with the biased direction signal (% motion signal). The two extreme values for the motion signal represent displays in which dots move in random directions (0%) versus displays in which all the dots move in the same direction (100%). (*A* and *B*, Data redrawn from Pasternak et al., 1985. *C*, Data from Pasternak et al., 1990.)

Recent research has shown that strobe-reared cats also exhibit severe deficits in the ability to perceive global motion in dynamic, random dot displays consisting of multiple, localized, motion vectors (Pasternak et al., 1990). The most severe deficits (see Fig. 14.12C) are in the discrimination thresholds for differences in direction; these deficits are even large when all the dots in the display are directionally biased (see legend for Fig. 14.12).

Conclusions

The functional consequences of selected early visual deprivation can be extremely profound, as evidenced by the immediate effects of monocular deprivation. However, even the subtle deficits associated with other forms of deprivation, such as selected exposure to particular contour orientations, are robust, and as such, provide important data pertaining to the controversy surrounding the physiological effects of visual deprivation (Movshon and van Sluyters, 1981). The documented perceptual abnormalities associated with certain forms of selective deprivation have provided some insight into the relationship between properties of neurons and perception. However, to the extent that the effects of selected deprivation extend beyond area 17, definitive statements as to the relationship between the properties of neurons in area 17 and perception must be made with caution.

15 Toward a Future for Aging Eyes

R. A. WEALE

INTEREST IN THEORIES of aging has undergone a revival during the last three decades or so. This is due partly to the relevant experiments being conducted on a molecular level and partly to studies of nematodes that suggest that life spans of species, that is, a putative maximal number of years alive, need not be fixed. Uncomprehending journalists love to seize on such nuggets of undigested information and to speculate on human longevity, suggesting that life may be extended to 150 years or more. However, most researchers have been taught not to argue from one species to another, so when considering the eyes, the author considers it prudent to confine discussion to the human species, however great the temptation to do otherwise.

A question that keeps cropping up concerns the existence of one or more genes for longevity. It would appear to be universally true that evolution responds to biological pressures, and it is hard to see what pressure could be brought to bear on living organisms to prolong their lives well beyond their reproductive capacity. There is little doubt that there exist genes for promoting cellular repairs, and it is easy to understand that they could develop in efficiency if the survival of a species would demand this. However, this is a concept very different from one postulating the ad hoc existence of genes for longevity. Hence, where applicable, the hypotheses underlying the considerations in this chapter rest on cellular repair, not vital prolongation.

Bits and pieces of aging

One of the quantitative aspects of aging that has received relatively little attention concerns its epidemiology in general, and ocular problems in particular. A large number of human biological attributes show a linear decline. This is equally true for glycosides in the pigment epithelium (Cingle et al., 1996), for the depletion of cells in the trabecular meshwork (Grierson and Howes, 1987), and for the retinal microcirculation (Grunwald et al., 1993), as well as for a host of other properties relating to other parts of the body (Weale, 1993). It is to be expected that such declines ultimately lead to systemic failure and, consequently, to death, even in the absence of any obvious pathology. It is highly significant that, broadly speaking, properties depending on dividing cells exhibit a decline that appears to terminate in the neighborhood of a putative age of ~120 years (Weale, 1993). Currently, the age of +120 years seems to be the approximate

maximal human longevity attainable. The coincidence of these figures alone should suffice to put a damper on hopes for an early increase in human life expectancy.

Possible consequences of a linear decline in human biological functions are illustrated in Figure 15.1. The upper part shows the age-related decline in the lenticular concentration of glutathione (Harding, 1970), a scavenger of free radicals that helps to maintain the transparency of the lens and is, incidentally, of some oncological significance. The lower part contains a digest of studies of the prevalence of cataract (Weale, 1998b). It should be noted that the lower part is plotted on a log scale, correctly apposed to the zero level of the upper section, with the two age scales being in tandem. It is clear that the slopes of the lines aim toward the zero level of the declining glutathione data. This suggests a link between the two; that is, when glutathione is exhausted, lens transparency becomes unsustainable.

This concept has been generalized. The figure of ~120 years, cited earlier as the age for ultimate functional failure, is clearly statistical in nature, with many tens of properties distributed around it with a standard difference of more than two decades (Weale, 1993). On the assumption that system failure results from an accumulation of component failures, it has been shown that the cumulant of the distribution agrees well with mortality data for the longest lived member countries of the United Nations (Weale, 1997).

What is interesting is that the end points of the linear decline of properties of the eye, such as biochemical, vascular, and physiological attributes (e.g., lacrimation), are randomly distributed throughout the more general systemic data (Weale, 1998a). On the face of it, the eye has developed to serve a body lasting, under optimal conditions, 12 decades or so.

What are the exceptions to this sweeping statement, if any?

Presbyopia—a problem partially solved

It is generally understood that the failure to accommodate does not terminate at the age of 120 years, but at less than half this time span, which is why presbyopia has been referred to as a maverick of senescence (Pierscionek and Weale, 1995). It is likely that presbyopia raises a point that should never be overlooked in considerations of senescence:

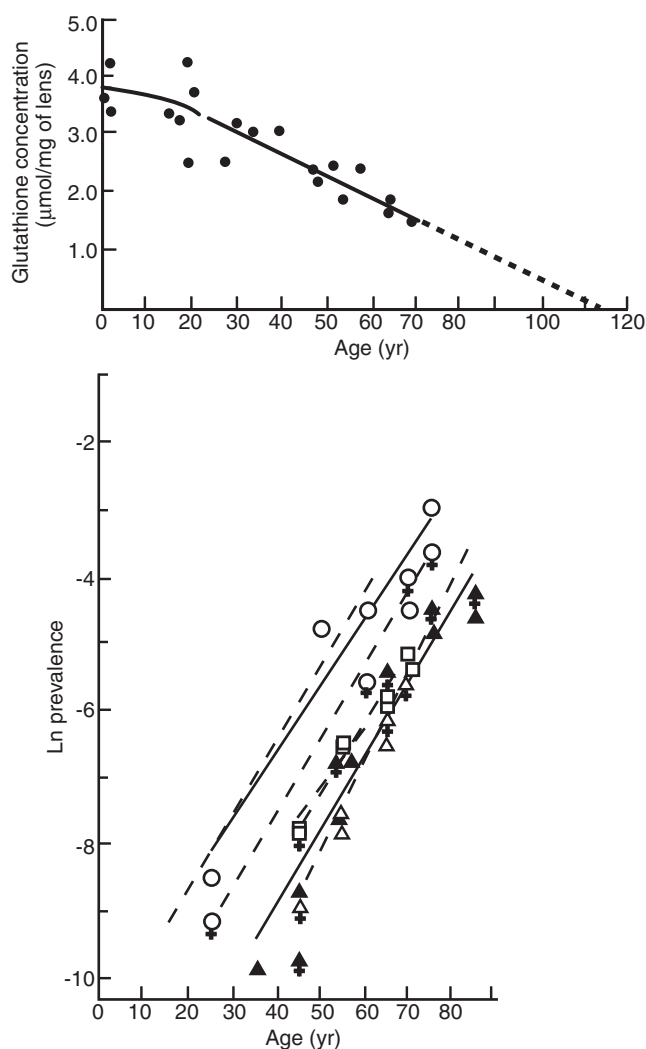

FIGURE 15.1. A suggestive relationship between the age-related decline in the concentration of lenticular glutathione (*top*) and the increase in the (log) prevalence of cataract (Weale, 1998b). The dotted part of the upper curve is a tentative extrapolation. The symbols denote Pima Indians (○ males; ○ females), European Israelis (△ males; ▲ females). Oriental Israelis (□ males; ■ females), and Oxford UK individuals (▲).

that is, any possible influence the environment may exert on aging rates. In other words, although a significant fraction of the aging rate is determined by one's genetic constitution, lifestyle, and external influences—which may include diet—have also been shown to play a role. In the case of presbyopia, climate appears to be a dominant determinant.

Table 15.1 shows how the age of onset of presbyopia (AP) varies with average annual ambient temperature (Rambo and Sangal, 1960). The cooler the climate, the later presbyopia is manifested. It may appear puzzling that humans, a homothermic species that preserves its body temperature, should exhibit such a phenomenon. However, the truth is that it is only the human core temperature that is kept constant. A shell, 1 cm in thickness and extending inward from

TABLE 15.1

*The variation of the age of onset of presbyopia (AP) with the average ambient annual temperature (T)**

Age at Onset of Presbyopia (Yr)	Average Ambient Temperature (F°)	Average Ambient Temperature (C°)
40	84	29
40.5	83	28
40.8	80	27
39.8	79	26
44.8	63	17
45.5	51	11
46	42	6

the surface of the dermis, averages body and environmental temperatures. The eye lens is obviously within that ambit; in addition, it is ill-equipped to benefit from the thermostatic provisions of the body because it has no blood supply: it is therefore exposed to the whims of climatic elements. More recent data suggest that, even at higher temperatures (e.g., in Eritrea or the Philippines), AP may occur at as early an age as the late 20s. Although the lens has been shown to contain heat-resisting protein, the mechanism whereby temperature acts on the rate of loss of accommodation has not been established.

Table 15.1 shows the onset, not the completion, of the symptomatic loss of accommodation, but it has been suggested that the early onset of an unnoticed, very early decline in accommodative amplitude is independent of temperature (Rambo and Sangal, 1960). In other words, the lines of decline for different climates may fan out from a fixed age so as to lead to onsets and terminal ages varying inversely with temperature.

The figures show that this effect does not explain the apparently maverick nature of presbyopia. To achieve success in this respect, it is necessary to try and account for presbyopia in biophysical terms, based on measurements of the properties of the lens.

The lens

A recent bibliography on relevant measurements is to be found in the analysis that attempts to resolve the difference between general systemic aging and the fast rush seen in presbyopia (Weale, 2000). There appear to be two keys to the problem. The first is the age-related variation of the mechanical and geometric properties of the lens. The mechanism of accommodation rests on the capsule molding the lens matrix that it contains; the moduli of elasticity and dimensions of both vary systematically with age. That of the capsule decreases with age (Fisher, 1969), whereas that of the matrix shows an increase. This is the physical counterpart of

why the lens is said to become harder with age (Glasser and Campbell, 1999).

It will be recalled that when a nearby object is fixated, the ciliary muscle is relaxed reflexively, as a result of which the suspensory ligaments of the lens that are attached to it have their tension reduced. Their remote ends being attached to the capsule, the tension therein is also reduced so that its overall surface contracts. This allows the matrix to bulge; that is, its two radii of curvature become smaller, and its optical power increases. The reverse process occurs when a distant object is fixated.

With regard to lenticular dimensions, which represent the second of the two keys to predicting the rate of loss of accommodative amplitude, the lens mass is known to increase with age, and as its specific density remains approximately constant, its volume rises. Although the increase in its sagittal diameter is well documented, there is some uncertainty about the transverse diameter (Strenk et al., 1999; Weale, 2001).

The problem to be solved consists in linking the changes just mentioned to the age-related loss in accommodative power. It may be noted that the decrease in Young's modulus of the capsule (Fisher, 1969) is accompanied by a decrease in the lenticular radii of curvature (Brown, 1974; Dubbelman and Van der Heijde, 2001). This is permanent and independent of whether or not there is any accommodation. Evidently, if the shape of the lens approaches its accommodated form owing to a senescent change in curvature, relaxation of zonular tension will have a smaller effect than is true in the younger, flatter lens. This, then, provides a qualitative explanation of why the accommodative decrement is affected by the reduction in capsular elasticity twice. Reflex changes in ciliary geometry are transmitted less efficiently because the capsule is losing its mechanical power and also because the shape of the lens matrix has moved in that direction owing to age.

The biophysical and optical changes attributable to age are encapsulated in equation 1, where the left represents the achievable change in power at a given age, and the right is made up of the following factors: ϵ , which is the ratio of the capsular elastic modulus to that of the lens matrix; σ , which is the stress applied to the zonule; and \mathcal{R} , which is the anterior radius of curvature. Figure 15.2 shows a comparison between $d\mathcal{F}$ (experimental data) (Brückner et al., 1987) and biophysical attributes of the eye lens, expressed as follows:

$$d\mathcal{F} = k \cdot \epsilon \cdot (1/\mathcal{R}) \cdot \sigma \quad (1)$$

In this equation, k is a calibrating constant. It may be noted that the rate of decline in capsular elasticity is within the compass of the rates of decline mentioned earlier as applying to the human system in general. The agreement between the optical and biophysical data provides tentative support

FIGURE 15.2. A comparison between observed data for the decline in accommodative amplitude and values predicted on the basis of underlying biophysical changes (Weale, 2000).

for the view that the maverick nature of presbyopia is due to at least two causal factors, namely, a geometric one and one involving mechanical properties of the lens.

A monkey of a ciliary muscle

In relation to the lens, a word or two may be addressed to a problem relating to the aging ciliary muscle itself. The variation in its cross-section as a function of age has been studied several times (Stieve, 1949). In essence, it was found that the muscle section tends to grow from childhood up to the fourth decade of life, presumably owing to work hypertrophy. As symptomatic presbyopia approaches, this muscle tends to change its shape, to shrink, and to become suffused with hyaloid material. In old age, it assumes a characteristically angular shape (i.e., its inner flank, which, in younger years is rounded and facing the lens, becomes almost angular, if not pointed).

The rate of presbyopia in rhesus monkeys is similar to that in humans when allowance is made for the differences in life expectancies among these species (Bito et al., 1982). However, there exists a significant difference between the age-related changes of the ciliary muscles in these two species (Lütjen-Drecoll, 2001). That is, the rhesus muscle fails to exhibit the above-mentioned angularity. It is tempting to suggest that its shape is typical, and that its human shape is anomalous. It will be appreciated that the angular shape approximates to a situation involving the muscle setting, as it were, in its accommodated form. If true, how could this come about?

Humans were not created to read, yet one of the important differences between the lifestyles of children and rhesus offspring, respectively, is that the former are made to read to such an extent as to promote myopia. Accommodation is

held to deform the eye, increasing the vitreous space, thus distancing the retina from the lens; if close work is carried out for at least 2 hours every day, permanent ocular changes result.

The comparison between the two types of ciliary muscle provides a suggestive, if tentative, example of the fact that senescence can also result from wear and tear. In this instance, it is self-inflicted as a result of the norms of civilization. If this explanation is valid, it does not augur well for the use of malleable lens implants in older patients who have undergone surgery for cataracts in the hope that they may be able to resume accommodating.

Errors and variations

The lens offers an insight into another interesting aspect of senescence, and this relates to the variability of some of its attributes. When population samples for some attribute are obtained, the data hardly ever coincide for a given age group. This can be due to a variety of reasons, even if one excludes faulty experimentation and systematic errors. Plotting the standard errors as a function of age is rarely done, but can be instructive. There are instances in which they are relatively constant, but in other cases, they increase systematically.

In the case of the lens, the age-related variation of standard deviations (std) appears to follow the same rule, no matter whether the elasticity of the lens is considered or some of the optical properties discussed later in this section; the slope of log std against log age is approximately unity or higher (Table 15.2). It can be shown that, if these attributes changed as a direct result of an accumulation of errors, the slope would be expected to be ~ 0.5 . The reason is that the underlying statistic would rest on the “random path” or “drunkard’s walk,” wherein the distance covered is proportional to the square root of the time taken to cover it.

It is clear from Table 15.2 that, overall, standard errors rise with age. If, for example, fluorescence is considered, the ratio of the error to the pertaining average value, the coefficient of variation, can be shown to remain remarkably constant. Lens absorbance does not rise linearly with age, as postulated by some authors (cf. Pokorny et al., 1987), but exponentially (Weale, 1988). This may go some way toward

explaining the high rate of increase in the standard deviation. The reason is that there is good evidence to suggest that more than one cause contributes to the senescence of the light transmission of the lens.

Broadly speaking, the lens becomes yellower and darker with age, even if there is no cataract in the making. This implies that less light of short wavelengths reaches the retina than of longer wavelengths. This affects the interpretation of aging processes in the spectral performance of the retina, which have been studied in considerable detail (Werner et al., 1990; Werner and Steele, 1988). As noted earlier, one of the peculiarities of the lens resides in the fact that it has no blood supply because its transparency needs to be maximized for an efficient functioning of the retina, yet it has to maintain some sort of metabolism to keep going. This leads to the nucleus—which is actually the lens babies are born with, the surrounding cortex accreting after birth—being effectively isolated. Its contents become degraded and yellow.

This, then, is a direct result of aging, although it cannot be viewed as part of a genetic program in the same sense as hair turning gray. This metabolic decay of the lens, however, is not the only factor to determine its appearance and function. The lens also acts as a photic calendar. The extent to which the tissue has been exposed to light is recorded in it, apparently indelibly, partly as additional yellowing, but revealed more systematically in studies of lenticular fluorescence.

The fluorescence of the lens is one of several unpleasant characteristics of this interesting organ. As yet, it remains undecided as to whether lenses of newborn infants, i.e., photically unexposed babies, exhibit any fluorescence. Such a determination would require irradiation of the pupil with violet or ultraviolet radiation and spectral analysis of any radiation emerging from the pupil. If there were any fluorescence, the emerging radiation would be expected to be of a long wavelength; in older eyes, it is typically green, with a peak wavelength of around 480 to ~ 530 nm. Such an experiment would be subject to an ethical barrier, but it would appear that no evidence on this point has been obtained from nonhuman lenses either. Backward extrapolations from accurate age-related measurements (Bleeker et al., 1986) suggest that the onset of fluorescence occurs a year or two after birth.

Of greater importance is the fact that measurements of lenticular fluorescence in widely differing geographical locations yield significantly different results. A comparison of data obtained in Atlanta and Oregon (Lerman, 1988) showed that the lenses of the inhabitants of sunny Atlanta fluoresced more than those of residents of rain-swept Oregon, Atlanta’s average annual solar illumination being some 30% higher. It can be shown that the extent of the southern lenticular fluorescence is correspondingly

TABLE 15.2

Slopes of log magnitude vs. log age for three properties of the lens starting at 10 years of age

Lens Properties	Slope
Fluorescence of the lens (Bleeker et al., 1986)	0.95
Lens absorbance at $\lambda = 460$ nm (Weale, 1982)	1.57
Lens matrix elasticity (Fisher, 1971)	1.28

~30% greater. The agreement may not be entirely coincidental.

There is a very close connection between the age-related absorbance and fluorescence of the lens. This is not surprising as both phenomena depend on the absorption of radiation. However, fluorescence involves the conversion of absorbed radiation of one wave-band into another, typically one with a lower wavelength. The mechanism effecting the conversion is assessed by the photoefficiency of the phenomenon, which is measured in terms of γ , the ratio of quanta emitted per quanta absorbed. At most, γ is a few percent, in stark contrast to the much higher photosensitivity of visual pigments. It is noteworthy that γ rises systematically with age, which is another way of saying that the aging lens becomes more sensitive to short wavelength light as age progresses. The tentative explanation for this phenomenon is that an unraveling of the spatial arrangement of lenticular crystallins occurs, which makes the chromophores increasingly accessible to the incident radiation. On this view, light does not directly harm the lens, but renders it more susceptible to injury from hazards—a better characterization of senescence than the ubiquitous one based on the calendar.

The preceding discussion has offered a sketch of the aging of the eye lens. It is important to keep in mind the various age-related changes as separate entities. Superficial arguments sometimes lead to the suggestion that a temporal sequence needs to be a causal one. Thus, it is said, the completion of presbyopia is accompanied by a noticeable yellowing of the lens. This, in turn, leads to light being scattered, which is ultimately followed by cataract development. However, we have seen that exposure to sunlight can enhance yellowing in younger age groups, that presbyopia differs in its progression in different climates, and that cataract can take different forms, only one of which has so far been linked reliably with solar radiation as a risk factor.

What a nerve!

At one time, it was thought that the rapid course of the loss of accommodative potency might be an exception to the suggestion that human biological functions decline at a rate of a little under 1% per year. However, it has now been established that, as rapidly as presbyopia develops—namely, twice as fast as other functional decrements on average—an additional phenomenon provides a possible explanation, and the condition is consistent with the theory.

There are certain attributes, however, that are not disposed of so easily, and that actually follow a law of their own. They relate to neural structures and the relevant nervous components and responses. All this was suggested explicitly relatively recently (Weale, 1993), but it had already been

surmised from a 30-year-old graph (Danon et al., 1981). The graph showed that the rate of the age-related decline of nerve conduction is one-third or one-quarter slower than that of the properties globally referred to earlier. Thus, whereas these other functional declines terminate hypothetically around the age of ~120 years, the speed of decline of nerve conduction would drop to zero only after nearly 400 years.

The difference between nervous and nonnervous senescence is neatly illustrated with reference to hearing loss. It is well known that there is a progressive, age-related loss of the perception of audible high frequencies, an observation that antedates the self-inflicted losses caused by industrial, disco, and other high-level noise stimuli. In contrast, low (bass) notes continue to be perceived in a relatively undiminished manner. Broadly speaking, the reason for this difference is that, with regard to high frequencies, senescence results from changes in peripheral organs, such as the continuous loss of hair cells, whereas low frequencies are conducted by bone and nerves, the attrition rate of which is incomparably lower.

The aforementioned comparison (Weale, 1993) of a large number of various biological functions has led to the tentative conclusion that tissues consisting of nondividing cells have a potentially longer life than those based on dividing cells. There is an *a priori* reason as to why nervous tissue might have to last for a comparatively longer time than tissues enjoying a rapid metabolic turnover. The prolonged existence of reflexes, innate and acquired, would be parlous if tissue renewal were taking place with the probability that the appropriate responses would have to be reacquired. What is true of such responses applies *a fortiori* to cerebral involvement: it is hard to imagine how memory could be maintained in the presence of a continuous turnover of the necessary component molecules.

The cellular dichotomy makes things rather difficult for the eye, as it is made up of, and functions with, an interesting combination of the two types of cells. We have already noted that the ocular data are distributed randomly among those for other human biological functions, but there is a preponderance of them among those functions with putative end points in excess of ~180 years (Table 15.3).

Clearly, there are standard deviations associated with these values, but overall, the end-point distribution for nondividing-cell tissue differs from that for dividing-cell tissue. Moreover, the former fails as a predictor of mortality, whereas the latter succeeds remarkably well (Weale, 1993). This difference suggests that attempts to tinker with the life span of a species—even when it comes to our own—may have to approach the problem step-by-step, rather than with a blunderbuss attack on genes presumed to control senescence. Such a view is reinforced by a consideration of some age-related disease processes.

Disease

Figure 15.1 showed that the log prevalence ($\log P$, there expressed as $\text{Ln}P$) of cataract is an approximately linear function of age (t), that is,

$$\text{Log}P - \log P_o = \alpha \cdot t \quad (2)$$

where P_o is the notional prevalence of the condition at birth, and α is a constant. This implies that the arithmetic function is an exponential:

$$P = P_o \cdot \exp(\alpha \cdot t) \quad (3)$$

Those readers who are mathematically inclined will realize that this is the integral of

$$dP/dt = \alpha \cdot P \quad (4)$$

which, in turn, implies that the rate of increase of the dependent variable at any time is proportional to the magnitude of the variable. It suggests, for example, that every seed that is produced gives rise to more than one seed in turn, or that this is how epidemics are propagated at their start.

Quite a few other conditions are described similarly; age-related maculopathy, a disease of the fovea and macula involving the loss of cones, is one of them. The most widely quoted example is mortality, even though this simple description is confined to a limited age span, rarely extending over the last 40 years or so of a sample population. Because Gompertz (1825) was the first to have used a version of equation 3, it is sometimes referred to as a Gompertz plot, and P_o and α as Gompertz constants.

There have been several attempts to increase the range of validity of equation 3, and these have been well summarized (Comfort, 1979). One involves the addition of an arbitrary constant, named after Makeham. Another, more interesting one, is attributable to Teissier (Comfort, 1979); it changes equations 2 and 3 by substituting for the time (t) the expression $t - t_0$ (where t_0 is a constant). Because, in survival data, this formulation implies a delay of the decline associated with aging, Teissier dubbed t_0 the "plateau of adult vigour." It so happens that he overlooked some important attributes of this formulation, which will now be addressed.

To begin, a reconsideration of equation 2 is in order. It contains two constants, namely P_o and α , which determine the intercept and slope of the straight line. Suppose now that

a given condition, such as the prevalence of age-related maculopathy, has been studied in different countries. Simplicity would lead one to expect that all the studies would produce values of P_o and α closely clustering around well-defined averages, characterizing the age variation of the prevalence of the disease.

The above-mentioned clustering would have to be not assumed, but demonstrated. A closer look at equation 2 leads to another possibility. One can assume that, although the constants are constant for any one population, they may in fact vary from one population to another. This is not as far-fetched as it might appear; there may be differences in the local genetic set-up, different prevailing risk factors, and so on. Thus, differentiating equation 2, one obtains

$$-d\log P_o = t \cdot d\alpha \quad (5)$$

which informs on how the slope α varies with the intercept P_o . Subsequent integration yields

$$-\log P_o = t \cdot \alpha + \text{const} \quad (6)$$

The value of the constant is determined by setting $\alpha = 0$, whence $-\log P_s = \text{const}$. This is the value of the intercept $\log P_o$ for the (hypothetical) situation in which a condition is unaffected by age. For example, it could represent a constant external hazard. Substitution in equation 6 yields

$$-\log P_o = t_s \cdot \alpha - \log P_s \quad (7)$$

where the constant t assumes the value t_s , that is, the age at which $\log P_o$ reaches the value $\log P_s$. Thus, substitution in equation 2 leads to a revised form of the Gompertz function, namely

$$\log P - \log P_s = \alpha \cdot (t - t_s) \quad (8)$$

This is akin to Teissier's expression, but with an important difference: P is not expressed as a multiple of P_o , but of P_s . Equation 8 predicts that, if the prevalence of a condition is measured in different circumstances, yielding different values of P_o and α , their plot should be rectilinear with an intercept at $\log P_s$. Moreover, it follows from equation 7 that the slope of this line is equal to t_s , that is, the number of years it takes from birth to reach a prevalence of P_s , defined as one for which the associated risk is independent of age.

Figure 15.3 provides remarkable support for the hypothesis here advanced. The data upon which it rests were obtained from various reliable studies (Bressler et al., 1989; Gibson et al., 1985; Klein and Klein, 1982; Martinez et al., 1982; Schachat et al., 1995; Vingerling et al., 1995).

The predicted rectilinearity is plainly confirmed. The value of $\log P_s$ (-0.09 , marked with an X) is lower than in any other corresponding condition, with a correspondingly large figure (102 years) for t_s .

Considering Teissier's concept of the "adult plateau of vigour," one can view this period as one that provides a measure of immunity. It can be shown that similar constants

FIGURE 15.3. Gompertz constants for six studies of the prevalence of age-related maculopathy.

can be determined for mortality data, for some types of mental conditions, for Parkinson's disease, and for cataract and glaucoma. What is so remarkable about the figure of 102 years is not its precise value, but that it is higher by far than any other determined up to this time. Analyses of mortality data, to quote one example, give the value for t_x as 60 to 70+ years in women and men.

What follows?

The earlier part of this chapter suggested that tissues consisting of dividing cells help researchers understand why, at present, the longest lived individuals may reach an age of ~120 years. It also set out the reasons why the eyes age in a manner consistent with general systemic aging (Weale, 1995). It was also stressed that nervous tissues do not fit this criterion, as their rate of decline is significantly slower than that of the dividing cells. So, in considering the age-related course of a disease that is apparently tied to neural components of the retina, one finds that, according to one system of measurement, the neural part of the eye shows remarkable resilience, greatly distressing though the condition is.

Hence, on the face of it, the arguments presented in this chapter appear to be consistent. What they highlight—if, indeed, they are valid—is the difficulties faced by those wishing to prolong our health span. Only fools prophesy, but it is important to remember that the 120-year organization is laid down early in life. Benefits for our health span are more likely to be obtained in the first instance by addressing risk factors: lifestyle seems to be the buzz word that has so far been linked principally to the 120-year system. What lifestyle control seems to be achieving—although regress is also observed—is an increase in people's life expectancy. It is likely that the senescence of neural components of the

visual system offer altogether a different problem, hardly though they appear to be.

III RETINAL MECHANISMS AND PROCESSES

16 Visual Transduction by Rod and Cone Photoreceptors

MARIE E. BURNS AND TREVOR D. LAMB

VISUAL PROCESSING begins with the conversion of light to an electrical signal in retinal photoreceptors. In this review we describe the current state of knowledge of this conversion process. First we summarize the remarkable performance of rod and cone photoreceptors and briefly describe their salient anatomical features. Then we present a brief overview of the transduction process before delving into the details. We divide transduction into activation and inactivation phases because there is a clear distinction between the molecular processes underlying the onset and recovery phases of the light response. Finally, we consider how the balance between activation and inactivation is achieved, and how these processes contribute to photoreceptor adaptation.

PERFORMANCE OF RODS VERSUS CONES Under most conditions, our vision is mediated by cones. Cones operate over an enormous range of intensities; indeed, at any level of illumination where we can make out color, our cones are providing useful signals. Cones also operate very rapidly, a factor that is likely to be of great importance to survival. In addition, our photopic (cone) visual system is extremely sensitive to small changes, being able to detect a contrast (Weber fraction, $\Delta I/I$) of $\sim 0.5\%$. Finally, cones give us color vision, which, among other benefits, helps to break camouflage, again providing a survival advantage.

In evolutionary terms, rods have arisen more recently than cones, and in the retina the specialized rod circuitry gives the appearance of having been superimposed on pre-existing cone circuitry. Despite their more recent origin, rods are numerically the dominant class of photoreceptor in the human eye by far, outnumbering the cones by about 20-fold over most of the retina. Yet, rods do not function over most of the intensity range that we normally experience (they are saturated); instead, they only function at exceedingly low intensities, corresponding to starlight or moonlight conditions. What is their role then, and why are they so numerous?

The answer seems to be that rods are specialized for the detection of individual photons of light (Hecht et al., 1942), and the subsequent circuitry of the scotopic visual system is designed to be able to detect just a few photon hits scattered over large areas (Barlow et al., 1971). This enables the visual system to operate in a “photon-counting” mode (Rose,

1948). The enormous number of rods is employed primarily to catch just about every photon that reaches the retina. Rods do not need to continue operating at intensities much above the level at which their responses to different photons begin overlapping appreciably because the primordial system (of cones) is sufficiently sensitive to operate at those levels.

As long ago as the 1930s, it was proposed that the physical limit to stimulus detection in the scotopic and photopic visual systems was set by the existence of an “equivalent background light” within the photoreceptors (Stiles and Crawford, 1932). Perhaps the greatest difference between rods and cones lies in the magnitude of this so-called dark light. In cones, the dark light corresponds to some hundreds of photon hits per cone per second, whereas for rods, the level is around four orders of magnitude lower, corresponding to just one photon hit per rod every 100 to 200 seconds (see Barlow, 1964). One of the great challenges in phototransduction is to understand how rhodopsin molecules in the rod outer segment are able to achieve such a great advantage over their counterparts in the cones.

It seems that this major advantage of rods over cones brings with it a great cost (Lamb, 1981): namely, the inability of the scotopic system to recover speedily after exposure to extremely intense “bleaching” illumination. This, it seems, may be an inevitable consequence of some sacrifice that has been made in order to achieve the incredibly low dark light that is needed to give the organism a survival advantage in conditions of near-darkness.

PHOTORECEPTOR STRUCTURE IN RELATION TO FUNCTION The ultrastructure of photoreceptors is remarkably similar across the animal kingdom. Photoreceptors consist of three primary functional domains: outer segment, inner segment, and synaptic ending. For the purposes of this chapter, we will focus our brief discussion on the general ultrastructural properties and functions of the outer and inner segments.

By far the most abundant protein in the outer segment is the light-capturing protein, rhodopsin. Historically, the term *rhodopsin* has been applied to the pigment found in those rods that use vitamin A₁ (such as mammalian rods), whereas the term porphyropsin has been applied to vitamin A₂-based rod pigments, and iodopsin to cone pigments. Here, however, we

will adopt the recent loose convention whereby the term rhodopsin will be generalized to refer to all visual pigments; the more explicit terms for rod or cone pigments will be applied only when necessary. Rhodopsin and many of the other components of the transduction cascade reside in (or at the surface of) the lipid material comprising the hundreds to thousands of membrane pairs that are stacked along the outer segment (Fig. 16.1). In cones, these sac-like structures are simply foldings of the plasma membrane, but in rods, the corresponding structures become completely pinched off from the plasma membrane, forming intracellular organelles called discs.

This topological difference between rods and cones represents a major anatomical disparity between the two types of cell, yet we do not at present understand its functional significance. One interesting possibility is that the enormous increase in stability of the rhodopsin molecule is aided in some way by the sealing-off of the discs; thus, perhaps it is advantageous to expose the amino-terminal region, not to the extracellular solution, but instead to the intradiscal medium. For cones, the greatly increased surface-to-volume ratio that is possible with patent sacs may be important, as this speeds the rate of change of intracellular ion concentrations mediated by plasma membrane fluxes; this is likely to be especially important for calcium ions, because calcium levels control negative feedback to the cascade (see “Calcium Feedback Regulation of Phototransduction”).

The lipids and proteins that comprise the discs and sacs eventually deteriorate, so that the photoreceptor needs to perform continual maintenance during its life span. Rods periodically shed old discs from the distal tip of the outer segment, and continually generate new foldings at the base of the outer segment, that in due course pinch off to form discs (reviewed in Young, 1976; see also Steinberg et al., 1980). Thus, rod outer segments are not of uniform age, but rather the newer components “move up” as they achieve seniority. A similar process of renewal and shedding occurs in cones; however, because the entire membrane is continuous, protein components of different age are distributed along the length of the outer segment.

Connecting the outer segment to the inner segment is the ciliary stalk, with a $9 + 2$ arrangement of microtubules and abundant actin filaments. All proteins destined for the outer segment (whether soluble or membrane bound) must pass through this narrow constriction. The mechanisms by which the proteins are transported and the discs are formed are not well understood.

The outermost portion of the inner segment contains a high density of mitochondria called the *ellipsoid*, which supplies adenosine triphosphate (ATP) via diffusion to the metabolically demanding outer segment. The high concentration of mitochondria in the ellipsoid also serves an optical purpose; this region has a high refractive index and helps to funnel photons into the outer segment, thereby increasing the probability that they will be absorbed. This phenomenon is

FIGURE 16.1. Anatomical features of rod and cone photoreceptors. The light-sensitive outer segment comprises a very large area of lipid membrane in which the photopigment molecules are densely packed. In cones, the pigment-containing membrane comprises the highly folded plasma membrane, which forms sacs. In rods, the rhodopsin-containing membrane becomes pinched off into discrete discs that are separated from the plasma membrane and from each other. In both cases, new membrane is synthesized at the base of the outer segment, just above the ciliary stalk, where new foldings are continually being formed. The inner segment contains the conventional cellular metabolic machinery. Organelles include the ellipsoid, which is packed with mitochondria, the myoid, endoplasmic reticulum, and the nucleus. At the base of the cell is the synaptic terminal that mediates communication with postsynaptic neurons. The path of the circulating electrical current is shown for the rod.

especially marked in cones, and gives rise to the Stiles–Crawford directional sensitivity effect. The inner segment also contains the endoplasmic reticulum, Golgi apparatus, and nucleus; thus, it performs a cell’s usual housekeeping chores, albeit with higher than average rates of protein synthesis and unusual membrane-trafficking demands. The plasma membrane of the inner segment contains potassium channels, which, in darkness, permit the efflux of potassium ions that balances the influx of cations into the outer segment, completing the loop that gives rise to the “dark current.”

OVERVIEW OF PHOTOTRANSDUCTION Phototransduction in rods and cones is mediated by closely related cascades, which are broadly similar in many respects to the transduction processes utilized in a variety of other G protein-coupled

signaling systems. A receptor protein is activated, causing activation of a G protein, which, in turn, activates a third protein, a so-called effector protein. This brings about a change in the cytoplasmic concentration of a second messenger substance, and thereby leads to modulation of ion channel opening in the plasma membrane. Thereafter, each of the active species must be turned off in order to permit recovery. Phototransduction is the essential first step in vision; thus, it is not surprising that defects in the phototransduction machinery are associated with a variety of blinding diseases in humans (reviewed in Dryja, 2000).

Phototransduction differs from chemoreceptive systems in that the receptor protein does not need to bind a chemical substance before activation can occur; instead, that chemical (a retinoid in the photoreceptor) is already prebound to the receptor. The absorption of light converts the retinoid from a powerful antagonist into a powerful agonist. Another difference from some other systems is that the response to stimulation is upside-down—that is, illumination leads to a reduction of a standing current and, hence, to hyperpolarization of the cell. Why vertebrate photoreceptors should have chosen this inverted response polarity is not entirely clear.

Activation of phototransduction

In this section, we will consider those steps that lead to activation of the light response, and we will postpone until the next section (“Inactivation of the Phototransduction Cascade”) those steps that contribute to inactivation (or recovery) of the light response. First we will outline each of

the molecular mechanisms known to underlie activation. Then we will examine the onset phase of the electrical response that is predicted from theoretical analysis of the activation steps, and we will compare that prediction with experimental results.

MOLECULAR MECHANISMS OF ACTIVATION The molecular reactions underlying the activation stages of vertebrate phototransduction are shown schematically in Figure 16.2 (modified from Lamb and Pugh, 1992, Fig. 1). Upon absorption of a photon of light, the rhodopsin molecule is transformed into an enzymatically active state (R^*) that catalyzes the activation of the G protein transducin (to G^*). Transducin, in turn, activates the effector protein phosphodiesterase (PDE) to PDE^* . The activated PDE hydrolyzes the diffusible messenger cyclic guanosine monophosphate (cGMP) so that the cytoplasmic concentration of cGMP decreases, leading to closure of cGMP-gated ion channels in the plasma membrane. Closure of these channels has the dual effect of generating the photoreceptor’s electrical response (by reducing the circulating current and hyperpolarizing the membrane voltage), and of causing a reduction in cytoplasmic calcium concentration. Each of these molecular steps will now be described.

ACTIVATION OF RHODOPSIN BY A PHOTON Absorption of a photon by the bent 11-*cis* retinal isomer within rhodopsin has a high probability (~ 0.67) of triggering the *cis* to *trans* isomerization of the retinoid. Apparently, the straighter all-trans isomer no longer fits neatly into the hydrophobic pocket so the rhodopsin molecule is strained internally,

FIGURE 16.2. Schematic representation of molecular reactions underlying activation. Following absorption of a photon ($h\nu$), the activated rhodopsin (R^*) repeatedly contacts molecules of the heterotrimeric G protein (G), catalyzing the exchange of GDP for GTP, producing the active form G^* ($= G\alpha - GTP$). Two G^* s bind to the two inhibitory γ subunits of the phosphodiesterase (PDE), thereby activating the corresponding α and β catalytic subunits,

forming PDE^{**} , which then catalyzes the hydrolysis of cGMP (cG). The consequent reduction in the cytoplasmic concentration of cGMP leads to closure of the cyclic nucleotide gated channels and blockage of the inward flux of Na^+ and Ca^{2+} , thereby reducing the circulating electrical current. The $Na^+/Ca^{2+}, K^+$ exchanger continues to pump Ca^{2+} out, so that the cytoplasmic Ca^{2+} concentration declines during illumination. (See color plate 5.)

undergoing a series of molecular rearrangements that lead to its activation (as R^*). The crystal structure of the ground state of rhodopsin was determined by Palczewski et al. (2000); what is now awaited is a determination of the crystal structure of R^* so that we can better understand the molecular nature of photoactivation. Although the precise structure of R^* is not yet known, many studies have contributed clues to the kinds of changes that must occur.

Historically, the molecular rearrangements underlying photoactivation have been studied spectrophotometrically because each intermediate has a different absorption spectrum, or color. Several transitions occur extremely rapidly, leading within $\sim 100\mu\text{s}$ to the formation of an intermediate named metarhodopsin I (or M_I). The next transition, to the form named metarhodopsin II (or M_{II}), is crucial to the photoresponse, as M_{II} is the form of the protein that is enzymatically active. The transition from M_I to M_{II} takes 1 to 10 ms (depending on temperature) and is thought to involve a substantial structural rearrangement of the protein (recently reviewed by Okada et al., 2001), thereby exposing the site for R^* interaction with the G protein. The conversion to M_{II} involves both a proton translocation and a proton uptake. The H^+ that had, until this stage, been protonating the Schiff base (linking the retinoid to Lys296) jumps across to the Glu113 residue that had been forming the negatively charged counterion that stabilized this configuration; in addition, another proton binds to Glu134 (Arnis and Hofmann, 1993).

CATALYTIC ACTIVATION OF THE G PROTEIN TRANSDUCIN As indicated in Figure 16.2, the molecular basis for activation of transducin is fundamentally the same as for any other G-protein cascade. Upon binding of the quiescent G protein to R^* , the $G\alpha$ subunit releases its bound molecule of guanosine diphosphate (GDP) and takes up a molecule of guanosine triphosphate (GTP) from the cytoplasm. The GTP-bound form of $G\alpha$ represents the active entity, denoted as G^* , which carries forward the activation signal. The activated rhodopsin, R^* , separates from the activated transducin and, unaltered by the interaction, is free to interact with additional molecules of the G protein, thereby catalyzing the activation of many G^* during its active lifetime. We denote the “gain” of this step by the parameter v_G , representing the rate of G^* activation by a single R^* .

Over the last few decades, estimates of the magnitude of v_G have varied widely. At room temperature, a number of biochemical experiments have reported values of $100 G^*s^{-1}$ or lower, whereas light-scattering approaches have yielded values exceeding $1000 G^*s^{-1}$ (e.g., Vuong et al., 1984), and theoretical analysis has suggested that the encounter rate between R^* and G is around $v_{enc} \approx 5000 s^{-1}$ (Lamb and Pugh, 1992). It is only recently that the different approaches have been reconciled, and it now seems clear that a rate of $v_G \approx 150 G^*s^{-1}$ at room temperature is consistent with biochemical, light-scattering, and electrophysiological measure-

ments (Leskov et al., 2000). We shall return to these rates after we have developed the theoretical framework in the section entitled “Predicted Form of the Onset Phase of the Light Response.”

R^* can only activate the G protein when the two molecules come into physical contact. This occurs via lateral diffusion of the molecules (within the membrane for the integral protein rhodopsin, and at the membrane’s cytoplasmic surface for transducin). On this basis, rapid lateral diffusion at the membrane has long been thought to be crucially important to activation. By studying rhodopsin hemizygote mice, Calvert et al. (2001) have provided evidence that the overall amplification of transduction, and hence the rate of G^* activation, depends strongly on membrane fluidity. Their results are consistent with the idea that numerous encounters between R^* and G are required (on average) before the two molecules are in the precise configuration required for binding. Hence, the activation rate (v_G) is indeed proportional to, although far lower than, the rate (v_{enc}) of molecular encounters. Thus, lateral diffusion is crucial to activation. Furthermore, as we discuss later, the results of Calvert et al. (2001) show that lateral diffusion is important not only to activation, but also to inactivation.

COUPLING OF G^* TO THE PDE Although the activated $G\alpha$ -GTP ($= G^*$) is weakly water-soluble, it probably only dissociates from the disc membrane on a relatively slow time scale, or at very high intensities. The usual means by which it encounters molecules of the effector protein PDE is again via lateral diffusion at the surface of the disc membrane.

The PDE is dimeric in structure, comprising a pair of closely homologous hydrolytic subunits (denoted α and β ; see Fig. 16.2). Each of the catalytic subunits binds a small γ subunit which, under resting conditions, inhibits the PDE, preventing hydrolysis of cGMP. When G^* encounters PDE γ , the two bind, thereby relieving the γ subunit’s inhibitory effect and permitting the hydrolysis of cGMP to proceed. Although there have been claims that G^* -PDE γ dissociates from the remainder of the PDE molecule, it is now generally thought more likely that the γ subunits remain closely associated with the $\alpha\beta$ hydrolytic units, ensuring that inhibition can rapidly be restored once G^* is inactivated. One detail that has not yet been clarified is whether or not there is cooperativity in the activation of PDE by G^* , that is, whether the singly activated form G^* -PDE (which we denote PDE*) has exactly half the activity of the doubly activated form G^* -PDE- G^* (denoted as PDE**), or whether the singly activated form might, for example, have much lower activity. However, this detail may be relatively unimportant, as the high density of G^* s in the neighborhood of an R^* is likely to favor the formation of the doubly activated form, PDE**.

How efficient is the coupling of G^* to PDE? Or, in other words, at some arbitrary time during activation, what pro-

portion of the G*s that have been produced will have been able to bind to PDEs? Put another way, what is the ratio of PDE* activation rate to G* activation rate ($c_{GE} = v_G/v_E$; see Fig. 16.3)? Stochastic simulations have shown that, even if G* were activated at the very high rate of several thousand per second set by encounters with R*, then a PDE subunit density of $250\mu\text{m}^{-2}$ (i.e., just 1 PDE subunit per 100 Rh) would be sufficient to achieve a coupling efficiency of 67% ($c_{GE} \approx 0.67$). At the much lower rate (v_G) that is now known to apply to G* activation, the coupling efficiency c_{GE} should be very close to unity. This is just what has been reported by Leskov et al. (2000), who found the mean rates of activation of G* and PDE* (v_G and v_E) both to be around 150s^{-1} in frog rods at room temperature.

Hence it appears that the coupling from activated transducin to activation of the PDE has an efficiency approaching unity (in terms of PDE* subunit activation, equivalent to 0.5 in terms of PDE** holomer activation). For our subsequent calculation of the overall gain of phototransduction, we will need a value for the rate of PDE* activation per R*; as noted earlier, this appears to be around $v_E \approx 150\text{ PDE}^*\text{s}^{-1}$ in amphibian rods.

HYDROLYSIS OF cGMP BY THE PDE The activated PDE** is a highly effective enzyme, and recent measurements indicate that it hydrolyzes cGMP at a rate close to the limit set by aqueous diffusion (Leskov et al., 2000). Its maximal catalytic rate has, for some years, been known to be around $k_{\text{cat}} \approx 4000\text{ cGMPs}^{-1}$, but what has only recently become clear is that its Michaelis constant is far lower than previously thought, at $K_m \approx 10\mu\text{M cGMP}$ (Leskov et al., 2000). Because the cytoplasmic concentration of cGMP is always lower than this value, the rate constant of cGMP hydrolysis is directly proportional to the ratio k_{cat}/K_m , a value that is far higher than previously realized.

This reaction, the hydrolysis by activated PDE of cGMP in the cytoplasm, represents the second amplifying step in phototransduction. In the theoretical analysis presented in the section on “Predicted Form of the Onset Phase of the Light Response,” the gain of the PDE step will be shown to be directly proportional to the parameter k_{cat}/K_m . As the gain achieved by rapid cGMP hydrolysis is cascaded with the first amplifying step—the R*-catalyzed formation of G* (and hence of PDE*)—the overall amplification during the activation phase of phototransduction can be extremely high.

CHANNEL OPENING/CLOSING BY cGMP In darkness, there is a resting concentration of cGMP of several micromolar, and this has the action of directly gating open cyclic nucleotide-gated ion channels in the plasma membrane. For reviews of the channel structure and gating, see Flynn et al. (2001). The decline in cGMP concentration leads to closure of the channels, and this has been shown to occur with a sub-millisecond delay (Karpen et al., 1988) as a combined

result of very rapid radial diffusion in the aqueous medium and extremely fast gating of channels by cGMP. The concentration dependence of channel opening is cooperative, with a Hill coefficient of $n_{\text{chan}} \approx 3$ and a dissociation constant around $K_{\text{chan}} \approx 20\mu\text{M cGMP}$ (although this value depends on calcium concentration; see the section entitled “Calcium Regulation of cGMP-gated Ion Channels: Calmodulin”). At the low cytoplasmic concentrations of cGMP that pertain both in darkness and in the light, the number of open channels can accurately be described as proportional to the cGMP concentration raised to the power n_{chan} , that is, as the cube of the cGMP concentration. This parameter n_{chan} can also be viewed as a gain factor (see the section that follows).

PREDICTED FORM OF THE ONSET PHASE OF THE LIGHT RESPONSE From analysis of the molecular scheme set out in Figure 16.2, and with knowledge of much of the information just presented, a mathematical formulation for the onset phase of the light response was developed by Lamb and Pugh (1992). In order to keep the analysis tractable, all inactivation reactions were ignored, restricting the window of validity to relatively short times after illumination. Several other simplifying assumptions were also made, but were shown not to compromise the validity of the solution under most circumstances. The predictions of the simplified analysis are presented graphically in Figure 16.3.

In response to a single photoisomerization, a single R* is created (after a short delay corresponding mainly to the M_I to M_{II} transition); because inactivation reactions are being ignored, it simply remains present (Fig. 16.3A). The presence of R* catalyzes the activation of G* at a constant rate, so that the quantity $G^*(t)$ ramps as a function of time, t , with a slope of $v_G \approx 150\text{ G}^*\text{s}^{-1}$. Because of the very efficient coupling to PDE, the quantity of activated PDE* subunits, $E^*(t)$, also ramps with time, with a similar slope of $v_E \approx 150\text{ E}^*\text{s}^{-1}$ (Fig. 16.3B).

Figure 16.3C illustrates the predicted time course for the decline of cGMP concentration, $c\text{GMP}(t)$, and for the decline of the fractional inward current, $F(t)$. As the rod photocurrent is relatively insensitive to changes in membrane voltage (Baylor and Nunn, 1986), $F(t)$ also represents the fractional circulating electrical current. Both $c\text{GMP}(t)$ and $F(t)$ decline with an accelerating time course owing to the continually increasing quantity of PDE*. If $E^*(t)$ indeed ramps with time, then it can be shown (Lamb and Pugh, 1992; Pugh and Lamb, 1993) that the electrical response should, to a good approximation, follow a delayed Gaussian time course:

$$F(t) = \exp \left\{ -\frac{1}{2} \Phi A (t - t_{\text{eff}})^2 \right\} \quad (1)$$

where Φ is the number of photoisomerizations (the flash intensity), A is a fixed parameter termed the amplification constant of transduction, and t_{eff} is an effective delay time

FIGURE 16.3. Predicted time course of activation when inactivation reactions are ignored. *A*, Following photoisomerization, a single R^* is activated. *B*, The quantities $G^*(t)$ and $E^*(t)$ of activated G protein and PDE increase linearly with time after R^* activation; in both cases, the slope is estimated to be around 150 s^{-1} per R^* (see section entitled “Estimated Rate of Activation of the PDE”). *C*, Activation of E^* causes the cGMP concentration to decline. Consequently, cGMP-gated channels close, and the fractional circulating current $F(t)$ declines according to equation 1 (in text). Responses in *C* are shown for a flash delivering $\Phi = 250$ photoisomerizations, with $A = 0.1\text{ s}^{-2}$.

that lumps together a number of very short delays in transduction.

Equation 1 is important because it provides what is essentially a single-parameter description of the onset phase of the light response; thus, apart from the short delay term (t_{eff}), there is only one parameter involved in describing the onset of the electrical response to any arbitrary flash intensity (Φ). All of the physical and biochemical parameters inherent in the scheme of Figure 16.2 have collapsed down into this single parameter, A . Furthermore, this overall amplification constant is specified by the theory as the product of the gains of the underlying stages:

$$A = v_E \beta_{\text{sub}} n_{\text{chan}} \quad (2)$$

where v_E is the rate of PDE* activation in response to a single photoisomerization, β_{sub} is a single PDE* subunit's rate constant for cGMP hydrolysis, and n_{chan} is the Hill coefficient of channel opening by cGMP. Finally, β_{sub} is given by

$$\beta_{\text{sub}} = \frac{\frac{1}{2} k_{\text{cat}} / K_m}{N_{\text{AV}} V_{\text{cyto}} B_{\text{cG}}} \quad (3)$$

where k_{cat}/K_m is the ratio of enzyme parameters for the PDE (described earlier), N_{AV} is Avagadro's number, V_{cyto} is the cytoplasmic volume of the outer segment, and B_{cG} is the cytoplasmic buffering power for cGMP. The factor of $1/2$ provides the conversion from a k_{cat} value for the holoenzyme PDE** to a β_{sub} value for a PDE* subunit.

In Figure 16.3C, the traces are drawn for a flash intensity of $\Phi = 250$ photoisomerizations, in conjunction with an amplification constant of $A = 0.1\text{ s}^{-2}$, typical of an amphibian rod. The theory predicts that, for any other flash intensity, the expected curve would have the same Gaussian shape as drawn, simply with a different time scaling. How does this prediction compare with experiment?

COMPARISON OF THEORY WITH EXPERIMENT In Figure 16.4, we compare the predictions of equation 1 with suction pipette responses from an amphibian rod (*A*) (data from Torre et al., 1986) and from a human rod (*B*) (data from Kraft et al., 1993). In each panel, a single value for the amplification constant A has been chosen, and curves are calculated for the set of measured flash intensities. Clearly, the onset phase of the response is reasonably well described over a wide range of flash intensities. The values of A were 0.065 s^{-2} for the salamander rod and 2 s^{-2} for the human rod. The smaller value of A for the amphibian rod arises primarily because of the much greater cytoplasmic volume of its outer segment (V_{cyto}), which, in the theory, appears in the denominator of equation 3.

For the salamander rod (Fig. 16.4A), the theory traces provide a good fit that extends to later times than one might reasonably expect for a model that ignores inactivation. The reason for the extended period of “good fit” in this cell is that it had been loaded with the calcium buffer BAPTA for the express purpose of slowing down the onset of inactivation reactions. In the same cell, prior to BAPTA incorporation, the experimental traces began deviating from theory by about 300 ms after the flashes (see Fig. 7 of Lamb and Pugh, 1992). As far as we are aware, equation 1 has always been capable of providing a good description of the onset phase of rod responses at suitably early times.

ESTIMATED RATE OF ACTIVATION OF THE PDE In an earlier section, entitled “Catalytic Activation of the G Protein Transducin,” we referred to disparities between different methods for estimating the rates v_G and v_E at which G^* and PDE* are activated in response to a single R^* . Recently, these discrepancies appear to have been reconciled by Leskov et al. (2000). Their biochemical measurements of v_G and v_E were broadly consistent with earlier measurements using comparable methods; both were found to be around 150 s^{-1} . However, in addition, they made new measurements of the PDE hydrolytic parameters and found the value of the Michaelis constant K_m to be far lower than previously

FIGURE 16.4. Comparison of experiment with predicted onset, for families of flash responses from a salamander rod (A) and a human rod (B), recorded using the suction pipette method. In both panels, the black traces show experiments, whereas the gray traces plot equation 1 (in text) using the calculated number of photoisomerizations, Φ , and a fixed value of the amplification constant A and effective delay time t_{eff} . A, Recordings from a salamander rod, following incorporation of the calcium buffer BAPTA, for flashes delivering from 9 to 2000 isomerizations. (Data from Fig. 2B of Torre et al., 1986.) Dark current, -29 pA ; amplification constant, $A = 0.065\text{ s}^{-2}$; delay time, $t_{\text{eff}} = 20\text{ ms}$. B, Recordings from a human rod for flashes delivering from 34 to 3800 isomerizations. (Data from Fig. 4 of Kraft et al., 1993.) Dark current, -13.5 pA ; amplification constant, $A = 2\text{ s}^{-2}$; delay time, $t_{\text{eff}} = 2.2\text{ ms}$. In both panels, the origin of time has been set to the middle of the flash stimulus, after allowance for the delay introduced by electronic filtering.

reported. Substitution of this value into equations 2 and 3 yielded estimates for v_E from electrophysiological measurements that were consistent with the biochemical values. Thus, with $k_{\text{cat}} = 4400\text{ s}^{-1}$, $K_m = 10\text{ }\mu\text{M}$, and $V_{\text{cyto}} = 0.85\text{ pl}$ for a toad rod outer segment, and assuming $B_{\text{CG}} = 1$ (no cGMP buffering), the parameter β_{sub} in equation 3 was calculated to be $\beta_{\text{sub}} = 4.3 \times 10^{-4}\text{ s}^{-1}$. Then, substituting an amplification constant of $A \approx 0.1\text{ s}^{-2}$ for a toad rod, and a Hill coefficient of $n_{\text{chan}} = 2$ in equation 2, the rate of PDE* subunit

activation was found to be $v_E \approx 120\text{ E}^*\text{ s}^{-1}$, which is in reasonable agreement with the biochemical estimate.

Finally, Leskov et al. (2000) suggested that the estimates from light scattering could also be brought into line if it were assumed that the signal measured by Vuong et al. (1984) originated from the binding of G^* to PDE, rather than from the release of G^* . Such a proposal for the origin of the light-scattering signal had, in fact, already been made by Kamps et al. (1985). If their explanation is correct, then the estimates of protein activation rates from biochemistry, light scattering, and electrophysiology all fall neatly into line with each other.

Inactivation of the phototransduction cascade

Rapid time resolution in the visual system is crucial for survival. However, the overall visual system cannot respond appreciably faster than its photoreceptors, and it is therefore important that the photoreceptor response be as brief as possible, consistent with the achievement of a sufficiently high amplification. Speed of response is most important at increased light intensities at which amplification can be sacrificed. At the very lowest intensities, when the visual system operates in a photon-counting mode and photon hits are few and far between, the speed of response is less critical.

What, then, determines how long the photoreceptor's response to a brief flash of light lingers? Is it determined passively, by the inherent rates of thermal degradation of activated cascade components? Recent results have shown the answer to this question to be a resounding no, with shut-off being an active process in both rods and cones. In this section, we will focus on what is currently known about rhodopsin inactivation in rods, mentioning relevant cone data when it is available.

MOLECULAR MECHANISMS OF RHODOPSIN INACTIVATION

Inactivation of the photopigment molecule is arguably the most important aspect of recovery owing to the high amplification achieved by R^* (see previous section). As long as rhodopsin maintains some level of catalytic activity, an amplified response persists, resembling the presence of steady light and contributing to desensitization and/or saturation of the cell.

At exceedingly low scotopic intensities, at which the visual system operates in its photon-counting mode, it can be argued that reproducibility of both the amplitude and the time course of the single-photon response is important, in order that the system should be better able to count the photons. However, this argument does not apply at higher scotopic intensities, or in the photopic range, where the shape of responses to individual photon hits is irrelevant; at these intensities, all that matters is the shape of the average response. The mechanisms that limit the duration of

rhodopsin's active lifetime, that contribute to its reproducibility under dark-adapted conditions, and that shorten the lifetime even further under light adaptation, are the subject of intense study.

Fast and slow mechanisms contribute to the shut-off of activated rhodopsin. First, R^* is phosphorylated; second, it is capped by the protein arrestin (e.g., Kühn and Wilden, 1987). These two steps rapidly lead to an enormous reduction in rhodopsin's catalytic activity, as described in the next subsections. Subsequent to these fast inactivation steps, the photoisomerized all-*trans* retinal is hydrolyzed from the opsin protein and, in due course, is replaced by 11-*cis* retinal, leading eventually to the total shut-off of catalytic activity. These slower steps, which contribute to dark adaptation and pigment regeneration, are beyond the scope of this review.

PHOSPHORYLATION AS A RAPID FIRST STEP IN SHUT-OFF The first step in shut-off—phosphorylation of rhodopsin's COOH-terminal residues—is performed by rhodopsin kinase (RK) (Kühn and Wilden, 1987), although other protein kinases, such as protein kinase C (e.g., Udovichenko et al., 1997), may play a role under some conditions. Phosphorylation of rhodopsin reduces its catalytic activity substantially (e.g., Wilden et al., 1986) and is essential for recovery of the photoresponse (Nakatani and Yau, 1988b; Sagoo and Lagnado, 1997; see also the section on “Comparison of Effects of Mutations of Inactivation Proteins”).

There are multiple potential sites for phosphorylation by RK in rhodopsin's COOH-terminal domain, six such sites in mice and seven in humans. However, mass spectroscopy of COOH-terminal peptides of rhodopsin following light exposure has suggested that rhodopsin is predominantly monophosphorylated after a flash (Ohguro et al., 1995), raising the interesting possibility that the large number of sites merely serve to increase the rate at which phosphorylation occurs. However, experiments on individual transgenic mouse rods have suggested that multiple phosphorylation is essential for rapid recovery of the single-photon response (Mendez et al., 2000; see also the section on “Comparison of Effects of Mutations of Inactivation Proteins”). Furthermore, mutant mouse rhodopsins containing fewer than three of the six potential phosphorylation sites were found to display first-order inactivation kinetics, suggesting that, under these conditions, a single, stochastic process is responsible for turning off unphosphorylated rhodopsin, and that it is rate-limiting for recovery. Similar behavior is also observed when phosphorylation of R^* is completely prevented (see section cited above). Stochastic shut-off of this kind is quite abnormal, as rhodopsin inactivation in WT rods is fairly reproducible (see the section entitled “Rhodopsin Shut-off: Reproducibility of the Single-

Photon Response”). This suggests that reproducible rhodopsin inactivation requires multiple phosphorylation of R^* (Mendez et al., 2000, Figs. 5 and 6).

ARRESTIN BINDING IS REQUIRED FOR COMPLETION OF THE RAPID PHASE OF R^* INACTIVATION Following phosphorylation, the protein arrestin binds with high affinity to phosphorhodopsin (Wilden et al., 1986). In mouse rods that do not express arrestin (*Arr*^{-/-}; Xu et al., 1997), the dim flash response rises to a peak amplitude comparable to that of normal rods, and begins to recover roughly halfway back to baseline levels (see Figs. 16.5 and 16.6). However, it then enters a period of extremely slow recovery, declining with a final time constant that is on the order of 40 seconds. The time course of the final decline of the response in the *Arr*^{-/-} rods is comparable to that for the disappearance of metarhodopsin II (Cone and Cobbs, 1969).

The failure of normal recovery in *Arr*^{-/-} rods suggests that the binding of arrestin is essential for the rapid quench of rhodopsin's activity, and that in the absence of arrestin, phosphorylated R^* must await hydrolysis of the retinoid. The fact that the failure of normal recovery occurs fairly late in the response suggests that significant rhodopsin activity normally persists throughout the duration of the single-photon response. Slowing the rate of guanosine triphosphate (GTP) hydrolysis by transducin (see the section entitled “Inactivation of the G Protein and the Effector (Transducin and PDE)”) also selectively slows the final recovery of the dim flash response (Sagoo and Lagnado, 1997; Chen et al., 2000). This raises the interesting and yet unanswered question of whether deactivation of rhodopsin or of transducin/PDE is rate-limiting for the recovery of the single-photon response.

Inactivation of cone pigments is also likely to involve phosphorylation and arrestin binding. Because recovery of the photoresponse occurs roughly 10 times faster in cones than in rods, one might expect these biochemical shut-off steps likewise to occur more quickly in cones. Consistent with this possibility was the discovery of a cone-specific isoform of opsin kinase (GRK7), which was first cloned from ground squirrel (Weiss et al., 1998), and has since been identified in other mammals as well. Whether or not this cone-specific isoform is specialized for more rapid inactivation of R^* is unclear, though, partially because of the apparent differences in expression of RK and cone opsin kinases in different species. For example, cones of dogs and pigs exclusively express cone opsin kinase (Weiss et al., 2001), whereas mouse and rat cones express only RK (Lyubarsky et al., 2000; Weiss et al., 2001), and primate cones appear to express both (Chen et al., 2001; Weiss et al., 2001).

A second cone-specific isoform of the regulatory machinery for transduction is cone arrestin (Craft et al., 1994). It

exhibits no detectable binding to light-activated or phosphorylated rod rhodopsin (Maeda et al., 2000), suggesting that it has fundamentally different biochemical properties from rod arrestin. Its role in recovery of the cone photoreceptor has yet to be determined.

RHODOPSIN SHUT-OFF: REPRODUCIBILITY OF THE SINGLE-PHOTON RESPONSE One electrophysiological approach that has been used to estimate the number of stages involved in R^* shut-off is an examination of the degree of reproducibility, or variability, in the shape of a rod's response to different single-photon hits. Rieke and Baylor (1998) and Whitlock and Lamb (1999) conducted experiments of this kind on toad rods and, despite recording apparently similar events, came to quite different conclusions. Rieke and Baylor reported that the single-photon events were highly reproducible in shape, concluding that 10 to 20 stages in R^* 's shut-off needed to be invoked in order to explain such a high degree of reproducibility.

In the same species, Whitlock and Lamb reported that the apparent variability in shut-off timing was twice as large as that found by Rieke and Baylor. They concluded that six or seven stages in R^* shut-off could explain the observed degree of kinetic variability. They went on to speculate that, if a powerful mechanism of calcium feedback were to modulate the R^* lifetime within the single-photon response, then the variability might even be explained by a single stage of shut-off. However, that possibility has now been excluded by the GCAPs (guanylate cyclase-activating proteins)-/- experiments of Burns et al. (2002), which have ruled out calcium feedback onto R^* lifetime within the single-photon response. Accordingly, the electrophysiology of single-photon response is consistent with an apparent number of stages involved in R^* shut-off of around six. Although this number corresponds neatly with the number of sites available for phosphorylation, the agreement may be no more than fortuitous.

INACTIVATION OF THE G PROTEIN AND THE EFFECTOR (TRANSDUCIN AND PDE) Despite the importance of R^* inactivation, that alone is not sufficient for rapid recovery of the electrical response to a flash. It is also important that G^* and PDE^* (the activated transducin and cGMP PDE) be turned off rapidly. As in most heterotrimeric G protein cascades, the rate-limiting step for turning off both the G protein and its effector is the hydrolysis of GTP, that is, the rate at which the GTP's terminal phosphate is cleaved by the $G\alpha$ subunit. For many years, it has been noted that the basal GTPase activity of purified transducin is exceedingly low, with a turnover time of minutes rather than seconds. Thus, it has long been anticipated that mechanisms for speeding the rate of GTP hydrolysis must exist in order to explain the rapid physiological shut-off.

In the last few years, an entirely new family of proteins, called RGS proteins (regulators of G protein signaling; reviewed in Ross and Wilkie, 2000), has been discovered. One member of this family, RGS9-1 (He et al., 1998), is expressed in rods and even more abundantly in cones (Cowan et al., 1998). In photoreceptors, RGS9-1 is obligatorily associated with an orphan G protein β subunit, $G\beta 5L$ (Makino et al., 1999). The resulting RGS9/ $G\beta 5L$ complex is essential for achieving normal rapid shut-off of the light response, both in rods (Chen et al., 2000; see Fig. 16.5) and in cones (Lyubarsky et al., 2001).

Under physiological conditions, it appears that RGS9/ $G\beta 5L$ only affects GTPase activity when G^* is bound to the PDE γ subunit, that is, while the PDE is in its active form, PDE^* (see the earlier section on "Coupling of G^* to the PDE"). It has been known for some time that the acceleration of GTPase activity is aided by $PDE\gamma$ (Arshavsky and Bownds, 1992; Antonny et al., 1993), but the mechanism by which both $PDE\gamma$ and RGS9/ $G\beta 5L$ might work together has been unclear. Recently, it has been found that $PDE\gamma$ increases the affinity of RGS9/ $G\beta 5L$ for $G\alpha$ (Skiba et al., 2000), thereby speeding the rate of GTP hydrolysis and the rate of recovery of the flash response in vivo. Thus, the inactivation of G^*/PDE^* utilizes an elegant method of self-regulation, whereby transducin is prevented from turning off before it has bound to and activated PDE.

The crystal structure of the complex between $G\alpha$ -GTP, $PDE\gamma$, and RGS9 has recently been presented by Slep et al. (2001). Details of the molecular mechanisms involved in the regulation of transducin's GTPase activity are reviewed by Cowan et al. (2001) and Arshavsky et al. (2002).

COMPARISON OF EFFECTS OF MUTATIONS OF INACTIVATION PROTEINS Collaborations between researchers in molecular biology, biochemistry, and physiology are revealing the many levels of regulation that actively turn off the phototransduction machinery, thus speeding recovery of the response to an increment in illumination. Although a great deal has been learned about mechanisms of response shut-off from conventional approaches over several decades, there has been a recent explosion in the application of transgenic approaches to photoreceptors, some of which we will illustrate here. One striking observation to have emerged from gene manipulations in mouse photoreceptors is that rods and cones appear to lack sophisticated compensatory mechanisms to oppose alterations in gene expression of many of the molecules of transduction. Thus, there have been few problems associated with significant changes in expression levels of proteins other than the one under examination. Instead, the most serious and consistent difficulty in creating these transgenic and knockout mice has been the degeneration of photoreceptors, especially in cells with prolonged responses that make them sensitive to steady backgrounds

(Makino et al., 1998). In addition, overexpression or underexpression of rhodopsin can cause degeneration (Li et al., 1996; Lem et al., 1999). These issues can usually be resolved either by careful titration of transgene expression levels (e.g., Mendez et al., 2000) or by rearing the animals in darkness (e.g., Xu et al., 1997).

As examples of the mutations that have been studied in mouse photoreceptors, we present in Figures 16.5 and 16.6 a composite set of responses from cells of different transgenic and knockout mice. In addition to wild-type responses, we illustrate five mutants: three involving disruption of rhodopsin inactivation and two involving the slowing of subsequent stages of recovery. Both figures plot responses to repeated presentations of a very dim flash. In Figure 16.5, the raw responses are shown on a slow time scale, whereas in Figure 16.6, the averaged responses are compared on a faster time scale. In the following descriptions, many of the features we discuss can be seen in these two figures.

R* inactivation Genetic perturbations of rhodopsin inactivation have yielded a wide range of phenotypes that reveal much about the inherent time course of rhodopsin inactivation in intact cells. Phosphorylation of rhodopsin can be prevented by several transgenic techniques: by deleting the entire COOH-terminal domain of rhodopsin (S334ter; Chen et al., 1995), by abolishing the expression of RK (Chen et al., 1999), or by mutating all of the carboxy-terminal serine and threonine residues to alanines (CSM [completely substituted mutant]; Mendez et al., 2000). Under each of these conditions, rhodopsin's activity, measured electrophysiologically, persists for several seconds, with the single-photon response reaching a plateau level of around double the normal amplitude, and then decaying abruptly back to baseline after a long stochastic interval of around 3 to 5 seconds (see Fig. 16.5). Because this interval is considerably shorter than the time course of hydrolysis of

all-*trans* retinal, it can be surmised that mammalian rods possess a backup mechanism that is capable of turning off unphosphorylated R*. Ironically, these large and long-lasting responses are occasionally observed in normal mammalian rods (e.g., Baylor et al., 1984). This suggests that, in normal rods, as many as 1% of all rhodopsin molecules are not capable of being phosphorylated.

The similarity of responses from RK-/-, S334ter, and CSM rods suggests that the sole defect in each case is a lack of rhodopsin phosphorylation, and that the binding of RK has little effect on R*'s catalytic activity. Furthermore,

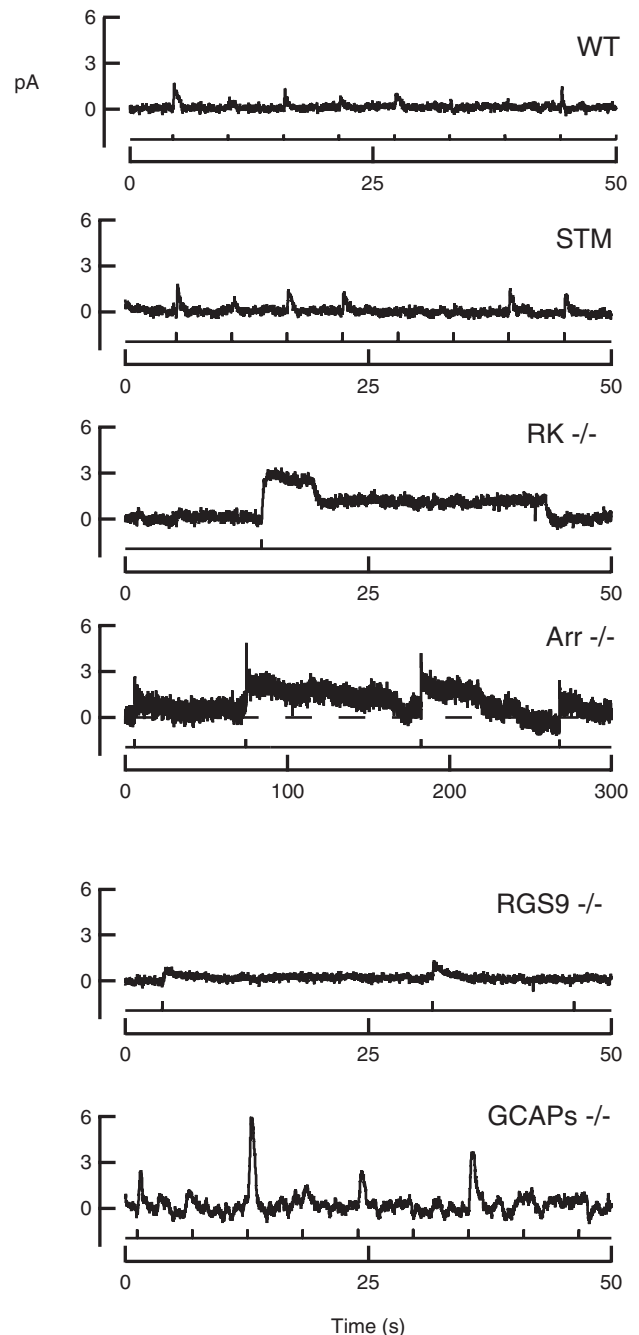

FIGURE 16.5. Dim flash responses recorded from mouse rods of different genotypes. Flashes were delivered at the times indicated by the flash monitor below each recording. Mouse rods expressing mutant rhodopsin with three of the six potential phosphorylation sites (Serine Triple Mutant, STM; Mendez et al., 2000) show responses that are qualitatively similar to wild-type (WT) responses, whereas responses from rods lacking RK (RK-/-; Chen et al., 1999) are prolonged steps of variable duration. Mouse rods lacking arrestin (Arr-/-; recording by AF Almuete in the Burns lab) initially recover, but require much longer times for final inactivation (Xu et al., 1997). Note the sixfold longer time base for the Arr-/- recording. Deficiencies in the rate of GTP hydrolysis (RGS9-/-; Chen et al., 1999) and calcium feedback to guanylate cyclase (GCAPs-/-; Burns et al., 2002) likewise yielded prolonged responses. Note the increased cellular dark noise and very large elementary response amplitude in the GCAPs-/- recording.

FIGURE 16.6. Form of the average single-photon response from transgenic and knockout mouse rods with perturbed inactivation. Abbreviations are the same as for Figure 16.5. Flashes occurred at $t = 0$.

in each of these examples, the mutant (or knockout) responses deviate from the control responses at roughly 100 msec after the flash, during the rising phase of the flash response. This suggests that, normally, phosphorylation begins to reduce rhodopsin's activity very soon after the R^* is formed.

Experiments on mouse rods that do not express arrestin ($Arr^{-/-}$) have likewise provided important clues regarding the *in vivo* time course of rhodopsin inactivation. First, $Arr^{-/-}$ responses do not differ greatly from wild-type responses until fairly late in the falling phase of the dim flash response (Xu et al., 1997; see also Fig. 16.6). The partial recovery (approximately halfway back to baseline) of the $Arr^{-/-}$ response suggests that phosphorylation alone is sufficient to reduce rhodopsin's catalytic activity by at least 75% (keeping in mind that R^* activity in the absence of all rapid inactivation, such as in the $RK^{-/-}$ rods, generates a response with a peak amplitude roughly twofold larger than normal). On this basis, one might view arrestin as contributing relatively little to inactivation. However, in the absence of arrestin, the final time constant of recovery is nearly 200-fold longer than normal, and roughly 10-fold longer on average than responses of rods that lack rhodopsin phosphorylation. Thus, although the magnitude of the effect of arrestin during the single-photon response is rather small, the implications for the overall function of the rod during prolonged light exposure are astounding.

Inactivation of G^*/PDE^* . Knockout and transgenic approaches have also proven useful for elucidating the mechanisms of G^*/PDE^* inactivation. Experiments on mouse rods expressing a mutant form of $PDE\gamma$ that binds poorly to G^* (W70A; Slepak et al., 1995) have shown that G^*/PDE

interactions are required for normal rates of GTP hydrolysis measured in *in vitro* assays, as well as for the normal amplification and recovery of the flash response (Tsang et al., 1998). An even greater effect on the rate of GTP hydrolysis has been observed in mouse rods expressing neither RGS9-1 nor $G\beta 5$ L ($RGS9^{-/-}$). Retinal homogenates of these mice have shown an impaired rate of GTP hydrolysis that could not be accelerated by the addition of exogenous $PDE\gamma$ (Chen et al., 2000), thereby confirming the notion that RGS9/ $G\beta 5$ L acts on the G^*/PDE^* complex.

CALCIUM-DEPENDENT FEEDBACK Finally, knockout mice have proven to be very effective at isolating the calcium-dependent negative feedback mechanisms. Although such mechanisms have been studied by more conventional physiological and biochemical approaches for decades, the abolition of one such mechanism (e.g., calcium regulation of guanylate cyclase by knocking out GCAPs) in intact cells allows the other calcium-dependent mechanisms to be studied unperturbed. The results and interpretations of these experiments will be described in the section that follows.

Calcium feedback regulation of phototransduction

It has been clear from many investigations conducted since the mid-1980s that the photoreceptor's response to light is accompanied by a decline in cytoplasmic calcium concentration (e.g., as reviewed by Koutalos and Yau, 1996). Here we begin by summarizing those findings.

In darkness, the flow of current into the photoreceptor outer segment is carried primarily by Na^+ ions, but a substantial proportion (~15% in rods) is carried by Ca^{2+} ions.

This steady influx of Ca^{2+} in darkness is balanced by an equal and opposite efflux, driven by the $\text{Na}^+/\text{Ca}^{2+}$, K^+ exchanger that resides in the plasma membrane along with the cyclic nucleotide gated channels. Different estimates have placed the dark resting concentration of free cytoplasmic Ca^{2+} in the range of 200 to 700 nM. During illumination, the outer segment ion channels close (see the section entitled “Channel Opening/Closing by cGMP”), reducing the influx of Ca^{2+} ions. As a result, the exchanger drives down the cytoplasmic Ca^{2+} concentration to a level that has been estimated to be in the range of 10 to 50 nM in saturating light. In amphibian rods, the decline is not especially fast, with an effective time constant of around 1 s. In cones, where the surface-to-volume ratio of the outer segment is much greater, the time course of decline is substantially faster.

It has been known for several decades that a lowered calcium concentration increases the rod's circulating dark current (Hagins and Yoshikami, 1974) and activates guanylate cyclase (Lolley and Racz, 1982), and that elevated calcium concentration enhances light-activated PDE activity (Torre et al., 1986). Furthermore, minimizing the light-induced decline in intracellular calcium by incorporation of calcium buffers or by “calcium clamp” protocols dramatically increases the flash sensitivity of dark-adapted photoreceptors and prevents the onset of normal light adaptation (Torre et al., 1986; Fain et al., 1989; Matthews et al., 1990). However, it has taken some years to unravel the relative importance of the individual molecular mechanisms that participate.

We now know that the decline in calcium concentration orchestrates at least three separate changes in the outer segment. These are often referred to as *negative feedback mechanisms* because any perturbation of the state of the system tends to be opposed. It is now clear that the most important of these feedback mechanisms is the calcium-dependent regulation of guanylate cyclase activity, mediated by GCAPs. In addition, there are also effects of calcium on the disc membrane cascade of reactions leading to PDE activation, probably mediated by the calcium-sensitive protein recoverin, and on the sensitivity of the plasma membrane ion channels to cGMP, mediated in rods by calmodulin. We will discuss each of these three processes in turn.

CALCIUM REGULATION OF GUANYLATE CYCLASE Evidence for calcium regulation of guanylate cyclase originated in the 1980s. Biochemical experiments showed that cyclase activity was regulated in a cooperative manner by a decline in calcium concentration (Pepe et al., 1986; Koch and Stryer, 1988), whereas electrophysiological experiments suggested that cyclase activity was elevated during recovery from saturating flashes (Hodgkin and Nunn, 1988). Today we know that the rapid restoration of circulating current after

a flash is, to a major extent, attributable to activation of guanylate cyclase by the lowered intracellular free calcium concentration.

Ca^{2+} regulation of guanylate cyclase activity is mediated by GCAPs, of which there are three retinal isoforms: GCAP1, GCAP2, and GCAP3. GCAPs belong to the calmodulin superfamily of EF-hand proteins, but contain only three functional Ca^{2+} binding sites (reviewed in Dizhoor and Hurley, 1999). Biochemical studies have shown that at low calcium concentrations, GCAPs activate guanylate cyclases, whereas at high calcium concentrations, the calcium-bound form of GCAPs inhibits guanylate cyclase activity (Dizhoor and Hurley, 1996; Rudnicka-Nawrot et al., 1998). The calcium concentration that has been reported to activate guanylate cyclases half-maximally ($K_{1/2}$) has varied widely depending on experimental conditions, with most reports clustering near ~200 nM (Dizhoor and Hurley, 1996). The activation by calcium is cooperative, and although an early in vitro experiment gave an estimate for the Hill coefficient of about 4 (Koch and Stryer, 1988), subsequent experiments have given values of about 2 (reviewed in Pugh et al., 1997).

Photoreceptors express not only multiple GCAPs, but also multiple isoforms of guanylate cyclase (GC1 and GC2; reviewed in Pugh et al., 1997). The reason for having multiple guanylate cyclases and GCAPs is not known, but presumably they serve distinct functions. GCAP1 activates primarily GC1, whereas GCAP2 and GCAP3 activate both GC1 and GC2 with similar potencies (Haeseleer et al., 1999). It has generally been thought that the calcium dependence of cyclase activation by the GCAPs is similar. However, expression of a GCAP2 transgene in mouse rods lacking endogenous GCAPs (only GCAP1 and GCAP2 occur in mouse rods) has been found to restore maximal calcium-dependent cyclase activity but not to restore normal flash response kinetics (Mendez et al., 2001). In contrast, expression of a GCAP1 transgene in GCAPs $^{-/-}$ rods did restore normal kinetics (Howes et al., 2002). This suggests that GCAP1 and GCAP2 may serve different temporal roles in rods.

Comparison of the steady-state responses of GCAPs $^{-/-}$ rods and wild-type rods suggests that, in a wild-type rod, a given relative change in the cGMP concentration produces an 11-fold larger relative change in the guanylate cyclase activity (Burns et al., 2002). Assuming that the Hill coefficient for channel activation is about 3, this suggests that the Hill coefficient for guanylate cyclase activation by calcium is about 4 in normal rods. However, most biochemical measurements of calcium dependence of guanylate cyclase activity have given a Hill coefficient of about 2 (reviewed in Dizhoor and Hurley, 1999). A satisfactory explanation for this large discrepancy remains to be elucidated.

The power with which calcium regulates guanylate cyclase activity perhaps helps to achieve the surprising speed with which feedback can occur. Experiments on intact GCAPs^{-/-} rods have shown that feedback to guanylate cyclases normally begins very quickly, within roughly 40 ms of the flash (Burns et al., 2002). The rapid feedback to guanylate cyclases causes the rising phase, as well as the amplitude, of the response to be severely attenuated, such that calcium feedback to guanylate cyclases decreases the dark-adapted flash sensitivity (Mendez et al., 2001). In addition, feedback speeds the restoration of the dark current, causing a more rapid recovery of the dim flash response.

Calcium feedback to guanylate cyclase not only reduces the amplitude of the signal (single-photon response) of rods, but also of the noise. In darkness, rods are noisy; spontaneous fluctuations in dark current arise primarily from spontaneous fluctuations in cGMP concentration stemming from thermal activation of rhodopsin and PDE (Baylor et al., 1980; Rieke and Baylor, 1996). Calcium feedback via GCAPs reduces these spontaneous fluctuations, reducing the standard deviation of the dark noise by roughly a factor of 6.3, while at the same time reducing the amplitude of the response by a factor of 4.5. Thus, calcium feedback in the dark-adapted rod serves at least two distinct purposes: (1) it speeds the recovery of the flash response, improving temporal responsiveness at the cost of sensitivity; and (2) it improves the signal-to-noise ratio of the cell by roughly 40%.

Perhaps not surprisingly, GCAPs^{-/-} rods do not adapt normally to steady lights (Mendez et al., 2001). The incremental flash sensitivity is markedly reduced at the brightest backgrounds, reflecting the importance of the steady-state feedback regulation of guanylate cyclase for range extension (see the section entitled "Calcium-dependent Mechanisms of Adaptation"). Thus, both the dynamic and steady-state changes in intracellular calcium have profound effects on guanylate cyclase activity and significant implications for rod function.

CALCIUM REGULATION OF THE DISC MEMBRANE CASCADE OF REACTIONS

Electrophysiology. Electrophysiological evidence for the calcium dependence of the disc membrane reactions that lead to activation of PDE came from experiments in which cGMP was infused into rods. The duration of the bright flash response was shown to be greatly extended under conditions in which Ca^{2+} was expected to have been elevated, even though guanylate cyclase activity had been overridden by the supply of exogenous cGMP (Torre et al., 1986). Prolongation of the flash response has also been seen in experiments in which recombinant recoverin was dialyzed into rods (Gray-Keller et al., 1993; Erickson et al., 1998).

Experiments lowering the Ca^{2+} concentration around the time of flash delivery (Hodgkin et al., 1986; Matthews, 1997) have revealed a shortened response duration and have suggested that the extent of light-dependent PDE activation is determined by the intracellular calcium concentration only near the time that the flash is delivered, presumably while R^* remains in existence. Finally, experiments on truncated salamander rods have suggested that lowered intracellular calcium can speed the quenching of rhodopsin's activity by phosphorylation, as the rate of rise of the flash response is sensitive to both calcium and ATP, but not GTP γ S (Sagoo and Lagnado, 1997).

Biochemical experiments. Biochemical evidence supporting the calcium-dependent regulation of light-dependent PDE activity was first derived from experiments on frog rods (Kawamura, 1992). These experiments demonstrated that rhodopsin phosphorylation was dependent on free calcium concentration and was mediated by the calcium-binding protein recoverin (S-modulin; Kawamura, 1993). The molecular target of recoverin was identified by cross-linking as RK (Sato and Kawamura, 1997). These observations have been extended by several research groups, leading to the hypothesis that recoverin calcium binds to RK in the dark, thereby inhibiting rhodopsin phosphorylation. During light exposure, when the calcium concentration decreases, recoverin unbinds its calcium and its affinity for RK is reduced, so that it no longer inhibits rhodopsin phosphorylation. One as yet unresolved caveat to this hypothesis is that some in vitro measurements have claimed that the extent of rhodopsin phosphorylation is unaffected by light adaptation and changes in intracellular calcium (Ohguro et al., 1995; Otto-Bruc et al., 1998).

CALCIUM REGULATION OF cGMP-GATED ION CHANNELS: CALMODULIN Light-evoked changes in intracellular calcium concentration cause a shift in the $K_{1/2}$ for activation of the cGMP-gated channels by cGMP (Hsu and Molday, 1993). In rod channels, this shift is thought to be mediated by the binding of calmodulin (Weitz et al., 1998) or a calmodulin-like protein (Gordon et al., 1995) to the β subunit of the rod channel (Chen et al., 1994) at high calcium concentrations. The decline in calcium that accompanies the steady-state response to light causes the modulator to dissociate from the channel, increasing the affinity of the channel for cGMP. The contribution of this mechanism to range extension in rods is thought to be rather modest (2- to 10-fold; Koutalos et al., 1995b; Sagoo and Lagnado, 1996; Nikonov et al., 2000;). A similar but more powerful mechanism also appears to operate for cone channels (Rebrik and Korenbrot, 1998; Rebrik et al., 2000; Muller et al., 2001).

In the next section, we will try to evaluate the relative roles of the molecular mechanisms that we have described above in the context of adaptation.

Mechanisms of photoreceptor light adaptation

Photoreceptors have the daunting task of reporting the time course of illumination across an intensity range of at least 10 orders of magnitude. The rod (scotopic) system operates primarily over the dimmest four orders of magnitude, whereas the cone (photopic) system covers the brightest seven, with mesopic vision (both rods and cones functioning) covering a couple of orders of magnitude in the midrange. In human vision, the lowest useful intensity corresponds to $\sim 10^{-2}$ photoisomerizations s^{-1} , whereas the rods have saturated at an intensity of $\sim 10^3$ photoisomerizations s^{-1} , and yet the cones never saturate under steady illumination (see discussion that follows, and Burkhardt, 1994).

Light adaptation causes two characteristic changes in the incremental light response of photoreceptors: it reduces the cell's sensitivity (measured as the peak amplitude per unit of flash intensity) and it speeds the kinetics of response recovery. The cellular events known to contribute to light adaptation encompass at least five categories: (1) response compression; (2) calcium-dependent mechanisms that act on a relatively short time scale; (3) elevated steady-state activity of the PDE, which acts by reducing cGMP's turnover time; (4) recently discovered large-scale movements of protein out of the outer segment; and (5) pigment bleaching. In the following sections we briefly describe the contributions of these phenomena to the overall light adaptation of photoreceptors; for more extensive coverage we refer the reader to several recent reviews (Pugh et al., 1999; Govardovskii et al., 2000; Fain et al., 2001).

An important clue to possible molecular mechanisms of light adaptation comes from the observation that, over a wide range of background intensities, the gain of the transduction process is unaltered by light adaptation (Nikonov et al., 2000). Accordingly, over this range of intensities, any modulation of the cascade of reactions leading up to PDE activation must operate only via effects on the *lifetimes* of active substances, rather than on the *gain* of any activation step, a concept that will be discussed in more detail later in this chapter.

RESPONSE COMPRESSION During steady illumination, the steady level of photoreceptor circulating current decreases, leaving less current available for suppression by additional photon absorptions. Hence, if sensitivity is measured (as it usually is) in terms of absolute, rather than relative, changes in circulating current, then during illumination the sensitivity is bound to decrease because of this effect. Although this effect clearly contributes to measurements of light adapta-

tion, it is difficult to view the phenomenon as an adaptation to background light; rather, it represents an unavoidable consequence of the way that phototransduction operates. In this context, it is worth noting that, in cones, such a drawback is not apparent in measurements of intracellular voltage in the eyecup preparation, where the steady-state hyperpolarization does not exceed half the maximum available range, even at exceedingly high steady intensities (Normann and Perlman, 1979; Burkhardt, 1994). Thus, for the intact cone system, the compressive effect never exceeds a factor of 2, and the cone is able to undergo voltage excursions of roughly equal magnitude for intensity increments and decrements on a background.

CALCIUM-DEPENDENT MECHANISMS OF ADAPTATION Calcium was clearly established as a messenger of light adaptation by the experiments of Nakatani and Yau (1988a) and Matthews et al. (1988). These and subsequent experiments showed that, in the absence of the normal light-induced change in cytoplasmic calcium concentration, the photoreceptor did not display the normal characteristic features of light adaptation. Instead, the photoreceptor simply exhibited response saturation with a much more abrupt decline of sensitivity as a function of increasing background intensity (reviewed in Fain et al., 2001).

These results have sometimes been misinterpreted to indicate that the decline in calcium concentration actually *causes* the decline in flash sensitivity during light adaptation, but nothing could be further from the truth. Instead, the decline in calcium concentration must be viewed as *rescuing* the photoreceptor from the far greater desensitization that would occur in the absence of its intervention, so that it thereby provides an extension of the range of operating intensities (Pugh et al., 1999). In considering the role of calcium, a distinction needs to be made between dynamic and steady-state effects (Pugh et al., 1999; Torre et al., 1986). The rapid transient drop in calcium concentration has been proposed to underlie the rapid recovery of the flash response to its baseline level (Torre et al., 1986), whereas the steady-state change is thought to account for light-adaptation behavior (Koutalos and Yau, 1996).

The role of calcium-dependent modulation of the disc-based reactions in photoreceptor light adaptation is not fully understood, despite our knowledge of the molecular mechanisms listed in a previous section ("Calcium Regulation of the Disc Membrane Cascade of Reactions"). It is clear that the calcium concentration at the time of flash delivery has an effect on the duration of the flash response (see section just cited). In addition, the so-called step-flash effect (whereby the recovery of a bright test flash is accelerated by the prior application of a background) is abolished when changes in calcium concentration are prevented (Fain et al., 1989). Furthermore, this effect also exists in mammalian

rods and is eliminated in rods that do not express recoverin (Dodd, 1998). Hence, the electrophysiological results are consistent with the notion that recoverin-mediated steady-state effects of calcium modulate the disc-based reactions and contribute significantly to overall light-adaptation behavior. Moreover, because of the invariance of the amplification constant of transduction with background intensity (Nikonov et al., 2000; see also the section entitled "Gain Reduction: A Matter of Intensities"), the steady-state effect of calcium must be on the lifetime of intermediate(s), rather than on gain. Finally, a small part of the rescue of sensitivity comes from calcium regulation of the ion channels, through the reduction in $K_{1/2}$ for channel opening by cGMP.

CONTRIBUTION OF ELEVATED STEADY-STATE PDE ACTIVITY Continuous illumination directly causes a steady-state increase in PDE activity, thus increasing the rate constant of cGMP hydrolysis (Hodgkin and Nunn, 1988; Kawamura and Murakami, 1986); this serves to reduce the effective lifetime of the cGMP molecule. Somewhat paradoxically, though, it was not realized until quite recently that this mechanism makes a major contribution to photoreceptor light-adaptation behavior (Nikonov et al., 2000; Pugh et al., 1999). Indeed, this phenomenon appears to represent the rod's most powerful mechanism for steady-state adjustment of sensitivity, and furthermore, it is calcium independent.

A useful way of thinking about this mechanism is to apply the so-called "bath tub" analogy (Pugh et al., 1999), whereby water flows into a bath from a tap and out via a plug hole. The size of the plug hole represents steady PDE activity, whereas the steady inflow through the tap represents steady cyclase activity; the depth of the water represents the cGMP level. In darkness, with a small plug hole and a slow trickle of water from the tap, any perturbation in the water level dies away only slowly. However, in moderate illumination, with a gigantic plug hole and the tap running rapidly, any perturbation comes to equilibrium much more rapidly. From such an analysis it can be shown that, for a given driving function (opening-up of a given additional plug hole), the response measured by the change in water level is both faster and smaller in the adapted state. For a further discussion of this concept, see Govardovskii et al. (2000) and Pugh and Lamb (2000).

GAIN REDUCTION: A MATTER OF INTENSITIES A simple mechanism that one could imagine for reducing flash sensitivity during light adaptation would be a reduction in amplification of the cascade, for example, by reducing the amplifying step between rhodopsin and transducin. Although some studies have suggested that there can be a reduction in rhodopsin-transducin gain during light adapta-

tion (Lagnado and Baylor, 1994; Jones, 1995; Gray-Keller and Detwiler, 1996), other studies have found no evidence for a change in amplification (Torre et al., 1986; Hood and Birch, 1993; Thomas and Lamb, 1999; Nikonov et al., 2000). In attempting to resolve this issue, it is important to restrict consideration to the very earliest times in the light response, before inactivation reactions come into play. Because both the reduction of rhodopsin's catalytic activity by phosphorylation (Chen et al., 1995; Chen et al., 1999; Sagoo and Lagnado, 1997) and calcium activation of guanylate cyclase (Burns et al., 2002) begin during the rising phase of the flash response, the window of relevant times is very short. Bearing in mind this temporal restriction, the most recent analyses have indicated that, for intensities eliciting up to 70% suppression of the circulating current in rods, the amplification of transduction is invariant with intensity (Nikonov et al., 2000, suction pipette; Sokolov et al., 2002, electroretinogram).

By contrast, brighter illumination, sufficient to hold the rods in saturation for a prolonged time, has been found to reduce the amplification (Kennedy et al., 2001; Sokolov et al., 2002). Furthermore, this reduction in gain is associated quantitatively with a large-scale redistribution of transducin within the rod, with a substantial fraction of both the α and $\beta\gamma$ subunits of transducin translocating from the outer segment to the inner segment (Sokolov et al., 2002). The gain reduction that results from the massive movement of transducin from the outer segment is a novel form of light adaptation. However, it is not yet clear whether the purpose of this mechanism is to rescue rods from saturation at higher light intensities than would otherwise be possible, or whether it might perhaps act as a means for minimizing unnecessary metabolism while the rod's photocurrent is saturated.

CONTRIBUTION OF PIGMENT BLEACHING TO LIGHT ADAPTATION The bleaching of photopigment makes a negligible contribution to light adaptation, except at the very highest intensities experienced by cones. In human rods, complete saturation occurs at around 10^3 photoisomerizations s^{-1} , which, with a pigment regeneration time constant on the order of 400 s, corresponds to a steady-state bleach level of 4×10^5 out of $\sim 10^8$ rhodopsin molecules, or less than 0.5%. Hence, rods are completely inoperative at light intensities that cause any appreciable level of bleaching.

Cones, on the other hand, are capable of functioning even when almost all of their pigment has been bleached (Burkhardt, 1994), and it has long been known psychophysically that the cone system does not show saturation under steady illumination of any intensity (Barlow, 1972). This seems to indicate that cones are much less susceptible than rods to the presence of bleaching products, although an additional contributory factor no doubt stems from the fact

that cone pigments exhibit much faster removal of all-trans retinoid and faster return to the native 11-cis form (Shichida et al., 1994). The physiological relevance of the cones' ability to function at very large bleaches is not clear, because large steady-state bleaches are so unpleasant to the observer that they are actively avoided wherever possible. In practice, it seems likely that the steady-state cone pigment bleaching level experienced by human observers seldom exceeds about 90%, contributing a factor of, at most, ~10-fold to reduced quantal catch, even though the cones are fully capable of functioning at much higher bleach levels.

COMPOSITE EFFECT OF ALL THE ADAPTATIONAL MECHANISMS Koutalos et al. (1995a, 1995b) undertook experiments to separate the steady-state effects of calcium feedback on guanylate cyclase, on the cascade leading to PDE activation, and on ion channel activation. They provided a compelling theoretical model of the contributions to light adaptation of these different calcium mechanisms. They reported that the cyclase-mediated effect was most important at relatively low intensities, whereas the effect on the PDE cascade became more important at higher intensities; the effect on the channels was modest at all intensities.

That description would appear to remain valid, with one modification. In view of the analysis of Nikonov et al. (2000) showing the role of steady PDE activation in desensitization, it seems likely that much of the effect that Koutalos et al. (1995b) attributed to calcium-dependent modulation of the cascade might instead arise from light-dependent activation of the cascade. Indeed, Nikonov et al. (2000) presented calculations of the extent to which light adaptation would be perturbed by "knocking out" different components of the calcium feedback system (their Fig. 14). That analysis confirmed the important role of the GCAP/cyclase effect at relatively low intensities, but also attributed a substantial component of desensitization to the light-induced cascade activation of PDE, over a range of intermediate intensities. Their analysis suggested relatively small effects for both the recoverin-mediated effect on the cascade and the modulation of channel sensitivity.

Summary and conclusions

Photoreceptors have a seemingly simple job description: to accurately relay to the rest of the visual system information regarding the timing and number of photon absorptions, and to do this across more than 10 log units of light intensity. Although nature has evolved two separate neural receptors and pathways to mediate vision across this enormous range of intensities, this has clearly not been enough. Rods and cones possess a multitude of specialized mechanisms: (1) mechanisms that serve both to amplify and to deactivate the response in a timely manner; (2) mechanisms that serve to

adapt the cell to light in both the short- and long-term; and finally, (3) mechanisms that serve to maintain these functional abilities, via pigment regeneration and other homeostatic mechanisms that lie beyond the scope of this chapter (e.g., disc shedding and renewal). Our current level of understanding is beginning to reveal our true ignorance regarding the engineering principles with which nature has achieved the generation of signals essential for the visual perceptions of the world around us.

17 How Retinal Circuits Optimize the Transfer of Visual Information

PETER STERLING

What it means to “understand” the retina

The retina is a thin sheet of *brain* tissue (100 to 250 μm thick) that grows out into the eye to provide neural processing for photoreceptor signals (Fig. 17.1). In cats and macaque monkeys, it weighs about 0.1 g and covers 800 mm^2 , about twice the area of a U.S. quarter (Packer et al., 1989). The retina includes both photoreceptors and the first two to four stages of neural processing. Its output projects centrally over many axons (1.6×10^5 in cats [Williams et al., 1993]; 1.3×10^6 in humans; and 1.8×10^6 in macaques [Potts et al., 1972]), and analysis of these information channels occupies about half of the cerebral cortex (van Essen et al., 1992; Baseler et al., 2002). Because the retina constitutes a significant fraction of the brain (roughly 0.3%), to “solve” it completely would be a significant achievement for neuroscience. This overview considers what a “solution” would entail and summarizes progress toward that goal.

First, we need the basic patterns of connection. The retina’s two synaptic layers span only 60 μm , and most lateral processes span only tens to hundreds of micrometers (versus millimeters to centimeters in cortex). Therefore it has proved technically straightforward to identify, trace, and quantify the neurons and many of their synaptic connections. This reveals the retina to comprise about 75 discrete neuron types connected in specific, highly stereotyped patterns. Second, we need the “neurochemical architecture”. Although information is far from complete, the main neurotransmitters and their receptor types have been identified with the key cell types and synapses. Third, we need the basic response of each cell type. Because the intact retina can be maintained *in vitro*, a cell’s light response can be recorded and the cell filled with dye to determine its morphology. This has permitted the neuroanatomical/neurochemical connections to be interpreted as functional “circuits” (Fig. 17.2).

Such circuits explain both intrinsic retinal mechanisms and also visual performance. For example, known circuits can explain reasonably well how a ganglion cell achieves its “center-surround” receptive field, and how one type of ganglion cell produces a linear, sustained response while a different type yields a nonlinear, transient response. Still other

circuits explain how at night a ganglion cell manages to fire 2 to 3 spikes to a single photon, while by day it fires a similar number of spikes to an increment of 10^5 photons. Finally, we know how different retinal circuits specialize for spatial acuity, motion, and opponent perception of hue (Calkins and Sterling, 1999; Wässle and Boycott, 1991).

CROSSING FROM “HOW” TO “WHY” Deep understanding of any brain region requires that we go beyond mechanism (*how*) to consider the computational purpose (*why*). For instance, why do we need a neural processor within the eye—since all other sense organs transmit spikes directly to the brain (Fig. 17.3)? And what explains the particularities of retinal design? For example, why are mammalian photoreceptors small, whereas in many cold-blooded species they are large? And why do photoreceptor and bipolar cells use presynaptic “ribbons,” since these are absent from the brain itself?

Many biologists dislike asking “why?” because it can be hard to prove that a given feature is truly adaptive, rather than merely decorative or a historical leftover of some evolutionary/developmental program (Gould and Lewontin, 1979). For an engineer, however, “why” is no problem. Every aspect of his design implies some specification of performance, constraints in cost (energy, materials, labor), and many compromises. If an engineer understands his design, he can explain *exactly why* his bridge was built a particular way (Glegg, 1969; Petroski, 1996). If he cannot explain this, stay off! So, the ability to answer “why” measures the depth of our comprehension.

Another test of comprehension is to ask whether circuit components *match optimally*, a condition termed “symmorphosis” (Diamond, 1992, 1993; Diamond and Hammond, 1992; Taylor and Weibel, 1981; Weibel, 2000). Where a neural system can be shown to satisfy the principle of symmorphosis across many levels (behavior \leftrightarrow circuit \leftrightarrow cells \leftrightarrow molecules), it can be chalked up as virtually understood. Many biologists do not care for this question either, reasoning that because evolution is ceaseless, how can we know whether a given feature has reached optimality?

But when a mechanism is shown to meet some physical limit, such as diffraction or diffusion, then natural selection

FIGURE 17.1. Radial section through monkey retina about 5 mm (~25°) from the fovea. The synaptic layers span only 60 μm. Cone and rod inner segments are easily distinguished from each other, as are their terminals in the outer plexiform layer. Pigmented cells of the choroid layer (Ch) convert vitamin A to its photoactive form and return it to the outer segments. Pigmented cells also phagocytose membrane discs that are shed daily from the outer segment

tips. OS, outer segment; IS, inner segment; ONL, outer nuclear layer; CT, cone terminal; RT, rod terminal; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer; B, bipolar cell; M, Müller cell; H, horizontal cell; A, amacrine cell; ME, Müller end feet; G_{ON} and G_{OFF}, ganglion cells. (Light micrograph by N. Vardi; modified from Sterling, 1998.)

FIGURE 17.2. The basic circuits that relay rod and cone signals through the retina to ganglion cells are known. Cone signals modulate ON and OFF cone bipolar cells (CB) that excite ON and OFF ganglion cells (GC). Rod signals modulate cone terminals via electrical synapse and relay single-photon signals via a private rod

bipolar cell (RB) that excites the AII amacrine cell. The AII is bifunctional, inhibiting the OFF ganglion cell with glycine and exciting the ON ganglion cell via electrical synapse to the ON bipolar terminal. IPL, inner plexiform layer. (Modified from Sterling, 1998.)

has clearly hit the wall. And where several physical constraints conflict, neural design must reflect their compromise. In short, where actual performance approaches “ideal” performance calculated from physical limits, there is a genuine opportunity to address the “why” of a design. Although for most brain regions this is a distant goal, for mammalian retina such questions can now be addressed, and they provide the framework for this overview.

Consider that in nature the visual system operates near threshold. This is easily forgotten living under artificially bright light and viewing mostly high-contrast images, such as newsprint or the computer screen. But go bird watching or hunting (heaven forbid!), and you are quickly reminded that our ancestors strained to see the finest detail at the lowest contrast in the poorest light. To maximize sensitivity their eyes were selected to make each stage—from the optical image to the ganglion cell spike train—as efficient

as possible. Thus each stage should approach the limits set by physical laws and by compromises required by the organism’s “niche.” Thus *every stage* is a potential “bottleneck,” and the purpose at each stage must be to staunch the loss of information up to the physical limit. This hypothesis sets a framework for interpreting the functional architecture.

The central idea of this chapter is that the retina evolved to maximally extract information from the natural spatiotemporal distribution of photons and to convey this information centrally, with minimal loss. Upon this broad goal there are functional constraints: cover a wide range of intensities (10^{10}); respond to very low contrasts ($\sim 1\%$); integrate for short times (~ 0.1 second); keep tissue thin (~ 0.2 mm); and maintain the metabolic rate no higher. There are also basic constraints on biological computation: signal amplitude and velocities are set by properties of biological membranes and

FIGURE 17.3. Only the visual sense requires neural processing at the site of transduction. The mammalian cone (*upper left*) requires lateral integration at its output (horizontal cells [H]), followed by 8 to 10 parallel circuits for a second stage (cone bipolar cells [CB]). Then, it requires more lateral integration (amacrine cells [A]) and finally, 10 to 20 parallel lines (four are shown; ganglion cells [G]) to carry action potentials to the brain. This chapter considers why photoreceptors require such extensive integration and so many parallel circuits before projecting centrally.

the speed of aqueous diffusion; accuracy and reliability of synaptic transmission are constrained by its quantal and Poisson nature. The retina's functional architecture reflects numerous compromises shaped by the interplay of these major factors as they contribute to the organism's overall success in its environment.

WHY NATURAL IMAGES NEED LOTS OF LIGHT Both prey and predators try to merge with the background, so in nature contrast for significant objects tends to be low. Consider the bighorn sheep among the cottonwoods (Fig. 17.4A). The retinal image is represented as peaks and troughs of intensity that differ from the local mean by only ~20%, and much fine structure exhibits far lower contrast, only a few percent (Fig. 17.4B). This range is common in nature (Laughlin, 1994; Srinivasan et al., 1982), and thus our visual threshold for a small stimulus, such as one spanning a single ganglion cell dendritic field, is ~3% contrast (Watson et al., 1983; Dhingra et al., 2003).

To create an optical image at low contrast requires many photons (Rose, 1973; Snyder et al., 1977). Because light is quantized, a small difference from the mean, say 1%, implies that the mean itself must contain at least 100 photons. But photons at each image point arrive randomly in time (Poisson distribution). So even when an image is perfectly still on the retina, the intensity at every point *varies* temporally, with a standard deviation equal to the square root of the mean. Because the minimum detectable contrast (Δn) must differ from the mean by at least one standard deviation, the ability to detect a contrast of 1% implies a mean of at least 10,000 photons:

$$\Delta n/n > \sqrt{n}/n = 100/10,000 = 1\%$$

This root-mean-square fluctuation (\sqrt{n}) is termed "photon noise."

One might think that daylight would provide plenty of photons to represent any scene. But this depends on the extent of photon integration: fine spatial detail implies limited spatial pooling and thus relatively large fluctuations from photon noise (Fig. 17.5A). This might be avoided by increasing temporal integration, but because mammals move swiftly, prolonged integration would blur the spatial image. Thus temporal integration is constrained to ~100 msec (Schneeweis and Schnapf, 1995). Although daylight contains enough photons/100 msec to cast a fine image on the cornea, the excess is not large, nor does it extend to even slightly dimmer situations, for example, when a cloud obscures the sun. The need for intense light to register fine detail at low contrast partly explains why athletes, bird watchers, and the like do not wear sunglasses (Sterling et al., 1992).

Mammalian photoreceptor mosaic

THE NEED FOR TWO TYPES OF DETECTOR The photoreceptor mosaic is optimized to cover the full range of environmental light intensities (10^{10}). This design specification requires two types of detector with different sensitivities, the rod and the cone (see Figs. 17.1, 17.5, and 17.6).¹ The rod serves under starlight where photons are so sparse that over 0.2 second (the rod integration time), they cause only ~1 photoisomerization (R^*)/10,000 rods. Consequently, under starlight and for 3 log units brighter, a rod must give a *binary* response, reporting over each integration time the

¹Of course, insects cover the same intensity range with a single type of photoreceptor, but they differ in many respects, including basic optical design, regeneration of rhodopsin, and use of an entirely different transduction cascade. When insect phototransduction is finally worked out, we may understand better how it manages to compress the full intensity range into a single cell type.

FIGURE 17.4. How narrow-field and wide-field ganglion cell arrays “filter” the transduced image of a natural scene. *A*, Photograph of a bighorn sheep among the cottonwoods. Spatial detail is represented as peaks and troughs of intensity around some mean level (arrowheads mark the area scanned in *B*). *B*, Photometer scan across the middle of the image. Much discernible structure, for example, fine branches, differs from the mean by only a few percent. Were this scene viewed by a cat at 10 meters, 1 pixel would correspond roughly to one cone, and the intensity axis would correspond roughly to the signal amplitude across the cone array. Dimensions and spacings of the narrow and wide receptive fields

are also indicated. *C*, Signal amplitude after filtering by narrow-field array. Subtraction by the surrounds of the shared signal component has reset the mean to zero: pooling by the centers has removed the noisy fluctuations. *D*, Signal amplitude after filtering by the wide-field cell array. Again, a zero mean, but the broad pooling and sparse sampling has removed all but the coarsest spatial detail—thereby clearing the wide-field cell dynamic range to efficiently encode motion. (Photograph by A. Pearlman; computations for *B* to *D* by R. Rao-Mirotznik and M. Eckert; modified from Sterling, 1998.)

occurrence of either 0 or 1 R^* . The rod continues to serve at dawn (or twilight) as photons arrive more densely, providing more than one R^* /integration time. The rod sums these linearly up to 20 R^* /integration time and then gradually saturates, with 100 R^* evoking a maximal photocurrent of ~ 20 pA. Under steady light, the rod adapts (reduces gain), and this allows it to continue signaling up to $\sim 1000 R^*$ /rod/integration time (Nakatani et al., 1991).

The cone serves under full daylight, beginning when photon density reaches ~ 100 photons/receptor/integration time. The cone actually absorbs and transduces single photons, but because its gain is 50-fold lower than the rod's, it requires 100 R^* for the signal to rise above the continuous dark noise. By 1000 R^* /integration time, when rods are nearly saturated, the cone responds strongly. The cone photocurrent saturates at ~ 30 pA (similar to the rod), but this occurs at much higher intensity (Burns and Lamb, 2003). Whether the mammalian cone in situ adapts by reducing gain or simply by saturating remains uncertain, but in any case, this detector serves intensities up to $10^6 R^*$ /cone/integration time (Pugh and Lamb, 1993; Schnapf et al., 1990). Consequently, whereas the rod signal is at first binary and then graded, but always corrupted by photon noise, the cone signal is always graded and far less noisy.

SUBDIVIDING THE RECEPTOR MOSAIC How should space in the receptor mosaic be apportioned? To maximize photon capture, receptors should completely fill the plane, and they *do*, occupying 90% and leaving an irreducible 10% to narrow intercellular channels required for exchange of ions and metabolites (Fig. 17.5). To maximize night vision, rods should fill the plane, but that would reduce daylight vision. Obviously there can be no single "optimal" solution, but only compromises that promote survival in a given niche. For example, the ground squirrel forages only in daylight and expresses only cones. However, most mammals cover the full intensity range and express both types of receptor. Their rods always far outnumber cones, and across species (from mouse to human), the ratio is surprisingly constant, about 20 rods per cone.

That this ratio genuinely represents a compromise can be appreciated from the many interesting exceptions that have been observed (Hughes, 1977). For one example, cones in the primate fovea completely fill the plane and exclude all rods (see Fig. 17.5). This enhances spatial resolution in daylight, but once light intensity falls below 100 photons/cone/integration time, the cost is utter blindness in this retinal region. To convince yourself, wait for color to disappear at dusk, indicating loss of cone function, then extend your arm and fix steadily on your thumb: it will disappear. This specialization for high spatial acuity requires various auxiliary modifications to the retina, mentioned in a later section.

What sets the basic ratio at 20 rods:1 cone? For the rod system, photons are so sparse that a ganglion cell may sum signals from more than 10,000 rods, yet still be dominated by photon noise. Therefore, the rod system madly competes for territory to catch every photon. But if rods managed to capture the last 5% of the mosaic, their signal-to-noise (S:N) ratio would improve only by $\sqrt{100/95}$, or 2.6%. Of course, there would be no daylight vision. So that is the trade: sacrifice 2.6% in sensitivity at night for the advantage of excellent photodetection by day.

For the cone system, photons are relatively plentiful, so the same ganglion summing signals from only 500 cones (each transducing, say, 1000 photons) will be responding to 500,000 photons. The S:N ratio calculated for photons ($500,000/\sqrt{500,000}$) is ~ 700 . Thus the cone-driven ganglion cell will hardly be affected by photon noise; instead its threshold is set by synaptic gain and neural noise (Dhingra et al., 2003; Freed, 2000a). Consequently for regions of the receptor mosaic where ganglion cells sum broadly, cones cannot improve vision by expanding territory, and thus they are well "satisfied" with 5%.

Where a particular species or retinal region requires higher spatial acuity, the cone territory *does* expand. Here, too, the physical constraints are known: (1) spatial acuity is set by ganglion cell sampling density because Nyquist's limit requires at least two samples for each spatial cycle (reviewed by Wässle and Boycott, 1991; Williams, 2003); (2) ganglion cell dendritic fields shrink and collect from fewer cones. Eventually, photon noise reduces the ganglion cell S:N ratio, and to preserve it cones must capture more territory. For example, in peripheral cat retina, where the dendritic field of a brisk-sustained ganglion cell sums 1000 cones, the rod:cone ratio is 100. However, in the central retina, where the brisk-sustained cell dendritic field shrinks to encompass only 30 cones, the rod:cone ratio is ~ 10 (Cohen and Sterling, 1992; Steinberg et al., 1973; Williams et al., 1993).

WHY THE OUTER SEGMENTS OF MAMMALIAN PHOTORECEPTORS ARE UNIFORM AND SMALL Dimensions of the rod outer segment are surprisingly uniform across mammals. Length is about 20 μm : 18 to 20 μm for cow and rabbit; and 25 μm for cat, Galago (nocturnal prosimian), macaque, and human (Nakatani et al., 1991; Tamura et al., 1991). Diameter is about 1.5 μm : 1 to 1.2 μm for cat (Steinberg et al., 1973; Williams et al., 1993), Galago, and owl monkey (all nocturnal); and 1.8 to 2 μm for rabbit, macaque, and human (Curcio et al., 1987, 1990; Packer et al., 1989). Diameter is somewhat smaller in central retina: cat, 1 μm central versus 1.6 μm peripheral; diurnal primate, 2 μm central versus 4 μm peripheral (Curcio et al., 1987; Packer et al., 1989). It is curious that rods should be smaller in nocturnal species. Possibly, adaptations that enhance photon

gathering in the nocturnal eye (such as a large pupil, reflective tapetum) tend to move the rod circuit away from its high gain, nonlinear regime (Field and Rieke, 2002; van Rossum and Smith, 1998). This switchover can be postponed to a higher environmental light intensity by reducing the rod collecting area.

The cone outer segment is also relatively small and invariant in volume. The shape can vary; for example, it narrows in primate fovea to enhance spatial sampling, and also lengthens (Fig. 17.6). But calculations based on Greeff's drawings suggest that across the human retina, cone outer segment volume is constant to within a factor of 2 (Fig. 17.6). In agreement, the outer segment volumes of isolated macaque cones, judged by their different inner segment diameters to represent all eccentricities, are small and constant: $30 \pm 10 \mu\text{m}$ (Schnapf et al., 1990).

In nonmammals the outer segments can be *much* larger (Fig. 17.7A). Thus, length can increase by orders of magnitude, reaching $60 \mu\text{m}$ in toad and $525 \mu\text{m}$ (!) in deepsea fish (Pugh and Lamb, 1993; Rodieck, 1973). Outer segments can also be much thicker. For example, the salamander outer segment, although only $25 \mu\text{m}$ long, is $11 \mu\text{m}$ in diameter. Thus, mammalian outer segments are reduced in volume by 30- to 80-fold.

This evolutionary "miniaturization" of the mammalian outer segment certainly reduces its efficiency of photon capture. For example, a photon penetrating a primate rod is 2.4-fold less likely to be captured than a photon in a toad rod. The reason is that the membrane discs bearing rhodopsin always stack as densely as possible, 36 discs/ μm (Fig. 17.7B). And the number of rhodopsin molecules per μm^2 of disc membrane is always 25,000 (Liebman et al., 1987). Therefore, as a photon traverses the outer segment, its probability of striking a rhodopsin depends on the number of discs. In this respect the mammalian outer segment is clearly suboptimal, which suggests a competing design constraint.

Recall that to match the mammalian motor system, photoreceptors must be *fast*. Whereas photocurrent in the large amphibian rod rises slowly, peaking at 1 to 2 seconds and with an overall integration time of 2 to 3 seconds, photocurrent in the small mammalian rod rises 10-fold

faster, peaking at 200 msec, with an overall integration time of ~ 300 msec (Baylor et al., 1979; Baylor et al., 1984; Kraft et al., 1993; Nakatani et al., 1991; Tamura et al., 1991). These times are essentially identical across mammals (Nakatani et al., 1991; Tamura et al., 1991), a striking contrast to insects whose different niches require large differences in speed and numerous adaptations to achieve them (Laughlin, 1994). Photocurrent in the mammalian cone rises equally rapidly, about 2 to 3 times faster (60 to 100 msec), but the integration time is shorter (50 msec) because the recovery of the photocurrent is faster and biphasic (Schnapf et al., 1990).

Why does speed require a small outer segment? The photocurrent generated by closing a cGMP-gated cation channel depends on reducing the intracellular concentration of cGMP (Burns and Lamb, 2003). Phosphodiesterase (PDE), the enzyme that hydrolyzes cGMP, is among the fastest enzymes; its catalytic rate approaches the physical limit set by how fast cGMP can reach it by aqueous diffusion (Liebman et al., 1987; Leskov et al., 2000). Thus, evolution cannot produce a faster enzyme. But, each hydrolyzed molecule in the reduced intracellular volume more effectively reduces the *concentration* of cGMP, and this raises transduction speed by 25-fold. Another factor of 4 is explained by increased body temperature: twofold from faster diffusion of the transduction proteins on the disc, which causes R^* to increase its encounter rate with transducin (Gt), and activated transducin (Gt^*) to increase its encounter rate with PDE; another twofold comes from PDE's accelerated catalytic rate, due to faster diffusion.

TRANSDUCTION PROTEINS AND ION CHANNELS ARE OPTIMIZED FOR SENSITIVITY, SPEED, GAIN, AND NOISE Only 20% of the disc membrane is occupied by rhodopsin, implying that denser packing could improve photon capture (sensitivity) by fivefold. In fact, insect rhabdomeres and bacteria do achieve crystalline packing of rhodopsin, so why hasn't evolution achieved this for vertebrate photoreceptors? Furthermore, why hasn't evolution accelerated transduction by increasing PDE density? The answers are not that "evolution is still in progress," but rather that additional factors must be optimized. For example, although rhodopsin density is too low

FIGURE 17.5. The foveal receptor mosaic is optimized for spatial resolution and contrast sensitivity; the peripheral mosaic is optimized for temporal resolution by day and absolute sensitivity by night. A, Human fovea, radial view. Cone inner segments are narrow and gently tapered; outer segments are long and fine. B, Human fovea, tangential view through the base of the inner segments. Hexagonal cone packing provides the finest possible spatial sampling in daylight, but the absence of rods renders the fovea blind from dusk to dawn. C, Human, near periphery, radial view.

Cone inner segments taper sharply and are surrounded by rod inner segments, which are much finer and untapered. D, Human, 20° nasal, tangential view. Large cone inner segments enhance sensitivity to high temporal frequencies, yet "spill" photons at night to surrounding rods. E to H, See text for explanation. IS, inner segment; OS, outer segment; ECS, extracellular space. (A–D, Video-DIC images from Curcio et al., 1990; E and F, Replotted from Packer et al., 1989. Used with permission.)

FIGURE 17.6. Cone structure varies across the retina, but rod structure is constant. Human photoreceptors dissociated and fixed with osmium. *Right-to-left*: Cones from the fovea to the periphery, plus one rod. The outer segment for the rod and foveal cone is long and columnar to maximize photon absorption; for the peripheral cone, it is short and tapered, possibly to radiate unabsorbed photons to surrounding rods (Miller and Snyder, 1973). The inner segment for the rod and foveal cone is long and columnar to allow dense packing. Photons that penetrate the cone obliquely escape, but then are captured by the densely packed, neighboring rods (see

Fig. 17.5). The peripheral cone inner segment is greatly enlarged, apparently to enhance photon catch and thus sensitivity to motion. The axon is thick for a cone and thin for a rod (see Fig. 17.8). The cone synaptic terminal is enlarged toward the periphery; the rod terminal is small. Basal processes on the cone terminal reach out to electrically contact other cones and also rods. All of these features appear to reflect the vastly different quantities of information collected by the cone and rod and more modest differences between cones at different eccentricities. (Reprinted from Greeff, 1899.)

FIGURE 17.7. Mammalian rod outer segments are small in order to be fast. The mammalian outer segment must ensure a high probability of encounter between a photon and a rhodopsin molecule. This is achieved by densely packing rhodopsin on both faces of a membrane disc and then stacking 900 discs at maximal density ($36/\mu\text{m}$), for a total length of $\sim 25\mu\text{m}$. Although slightly longer than a salamander outer segment, the mammal's is much thinner ($\sim 1\mu\text{m}$ vs. $11\mu\text{m}$ in diameter). This greatly reduces its cytoplasmic volume (4% of the salamander rod's). This in turn accelerates its light-evoked fall of cGMP by 25-fold. The mammal's higher temperature further accelerates this process by doubling the rate at which R^* activates transducin (Gt) and the rate at which Gt acti-

vates phosphodiesterase (PDE). Consequently, the mammalian rod's amplification constant is about 100-fold faster, and its integration time ($\sim 200\text{msec}$) is about 10-fold shorter than the salamander rod's. The salamander rod's broader cross section and longer integration time provide it with 250-fold more $R^*/\text{integration time}$ than the mammalian rod. Consequently, its later stages are more cone-like: thicker axon, larger synaptic terminal with multiple ribbons (~ 8 ; Townes-Anderson et al., 1985), electrical coupling (Attwell, 1986); and convergence with cones onto the same bipolar cell. D, disc of outer segment; M, mitochondria of inner segment. (Electron micrograph reprinted from Townes-Anderson, 1995.)

for best photon catch, it is already *too high* for greatest speed because crowding slows activated rhodopsin's diffusive search for transducin. Halving rhodopsin's concentration (to 10%) in a transgenic mouse accelerates transduction speed by 1.7-fold (Calvert et al., 2001). Thus, rhodopsin's space on the disc represents an evolutionary compromise that doubles photon catch but nearly halves transduction speed.²

²Given the early evolutionary "decision" to base transduction on multiple stages of protein-protein encounter, the hit rate is increased by restricting the diffusive search to two dimensions (on the disc), rather than three dimensions (Adam and Delbrück, 1968).

One photoisomerization (R^*) in a rod triggers hydrolysis of 10^4 molecules of cGMP, leading to a photocurrent equivalent to $\sim 10^6$ monovalent ions, a gain of 1 million-fold (Burns and Baylor, 2001; Liebman et al., 1987). Gain could be increased if each step in the transduction cascade were activated for longer. But the cost would be slowing of the visual response. As it stands, one R^* in a primate rod evokes a current whose average size is $\sim 0.7\text{pA}$ (Baylor et al., 1984). The event exceeds the continuous dark noise by about five-fold, so noise as large as the photon event will occur rarely ($\sim 1\%$ false alarms). But the S:N ratio in the mouse rod is slightly less, \sim threefold, so many photon events that are smaller than average are indistinguishable from the

continuous noise (see Fig. 17.11; Field and Rieke, 2002; Sterling, 2002). Thus, transduction, while maximizing gain, must also minimize noise due to dark fluctuations of cGMP.

These additional specifications, plus the need for speed, define the optimal molecular ratios of the cascade's effector proteins. Each square micrometer of disc membrane bears 25,000 R:2,500 G_t:330 PDE (Lamb and Pugh, 1992). At these densities, the mean time for an R* to find a G_t by diffusive search just equals the time for which R* binds to G_t. If G_t were sparser, R*'s search would be longer. Then, depending on R*'s lifetime, either transduction would slow, or the gain would fall. On the other hand, if G_t were denser, thermal activation would rise (yielding more false alarms). Similarly, PDE is just dense enough to be efficiently activated by G_t* and sparse enough to minimize basal hydrolysis of cGMP (continuous dark noise).

The rod outer segment bears about 10⁶ cGMP-gated channels, of which 10⁴ are held open by the standing concentration of a few micromolar cGMP. One R* hydrolyzes about 5% of the total cGMP and thus closes about 5% of the open channels. Why should a rod express 50,000 times more channels than needed to span its dynamic range? That is, why does it express 1 million channels instead of 20? Furthermore, why express 1 million channels since, at maximal dark current, only 100,000 channels open (Yau, 1994)?

Because channels behave stochastically (like photons), the ratio of photocurrent to continuous noise (S:N) is determined by n/\sqrt{n} , where n = mean number of channels. Thus, 20 channels could provide an S:N ratio of ~4.5, whereas 10,000 channels could provide an S:N ratio of ~100. By requiring at most 10% of the available channels to be modulated by a given change in cGMP, the channel's affinity for cGMP can be low, which allows a fast OFF rate, and thus rapid closure when cGMP falls. The channel's requirement for three cGMP molecules to open (Hill coefficient = 3) ensures a steep response to small changes in cGMP, that is, high gain (Koshland et al., 1982). Because the intrinsic channel conductance is about 20 pS, 5000 channels open in darkness might saturate the driving force. But this problem is avoided by designing the channel to be partially blocked at depolarized voltages by a magnesium ion, causing it to flicker rapidly and provide a mean functional current of 0.1 pS (Sesti et al., 1994; Yau, 1994).

The cone outer segment resembles the rod outer segment in many respects: opsin photoefficiency; speed of turn on (amplification constant); peak photocurrent; dark concentration of cGMP; number of CNG channels (Pugh and Lamb, 1993; Schnapf et al., 1990; Yau, 1994). In the cone, just like the rod, a single photon effectively triggers the transduction cascade. But, whereas one R* in a rod closes 5% of the open channels, in a cone it closes only

0.1% to 0.01% (Kraft et al., 1993; Schnapf et al., 1990). This sets the cone's gain ~50-fold lower than the rod's, rendering the cone most effective when there are more than 10³ photons/integration time, a regime where photon S:N is high. Cone sensitivity is lower because it depends multiplicatively on the time constant of each transduction step, and all are abbreviated compared to the rod. The advantage is greater temporal resolution and thus greater bandwidth. Because information capacity in any channel rises with the log of S:N ratio and *linearly* with bandwidth (Shannon and Weaver, 1949), the cone's information capacity greatly exceeds the rod's.

WHY THE CONE INNER SEGMENT VARIES The inner segment shifts markedly across the human retina (Figs. 17.5 and 17.6). At the fovea's center, it is tall and columnar, but across the fovea the inner segment gradually thickens. At greater eccentricities the inner segment becomes still broader, shorter, and tapered (quasi-ellipsoid), its aperture ultimately increasing in area by 20-fold. This shift produces concentric rings of cones with progressively greater inner segment diameter. Since the outer segments (both rod and cone) are rather constant, as is the rod inner segment, why should the cone inner segment vary?

The inner segment is crammed with mitochondria that generate ATP for the sodium/potassium transporters that maintain the circulating dark current (Fig. 17.7). But the mitochondria also enhance refractive index, and this converts the inner segment to an optical wave guide. Photons entering roughly parallel to the long axis are trapped and efficiently funneled to the outer segment (Enoch, 1981). The cone inner segments pack triangularly in fovea, so the inner segment diameter sets the number of cones per degree of visual angle and, since private lines are maintained from cone to striate cortex, this determines spatial resolution (Smallman et al., 1996). Of course, narrowing the inner segment to enhance resolution reduces photon catch and thus limits the cone's S:N ratio. Calculations prove that for each light level there exists an optimal balance of spatial resolution versus S:N ratio that maximizes total information (Snyder et al., 1977). Consequently, the fovea's array of concentric rings with progressively larger inner segments should maximize information uptake over a range of daylight intensities.

The inner segment's marked expansion beyond the fovea further enhances photon capture (Figs. 17.5 and 17.6). There is no cost to spatial resolution, which is set outside the fovea by the finest ganglion cell array. But the plump cone inner segments ultimately occupy 40% of the photoreceptor sheet, and appear to impinge on the collecting area needed by rods (Figs. 17.5 and 17.6). This problem seems solved when in dim light the pupil enlarges, allowing much of the light to enter peripheral cones at high angles to their optical

axes. Off-axis photons escape the light guide and spill into neighboring rods. Thus, although receptor ratios and dimensions are fixed, the proportion of light captured by cones and rods shifts adaptively with the optics of the eye. Peripheral cones *need* more light because the eye movements that steady an image on the foveal cones move the image across the peripheral cones, allowing less temporal integration (Eckert and Buchsbaum, 1993).

In summary, vertebrate photoreceptors exemplify the principle of symmorphosis: the mutual optimization of components across many levels. Here, we have considered the apportioning of: (1) space in the receptor mosaic; (2) outer segment volume; (3) numbers of key transduction proteins on a disc and their ratios; (4) reason for the disc; (5) number of cGMP-gated channels; (6) channel binding affinity, cooperativity, and partial blockage; and (7) inner segment size. These features all cooperate to set transduction efficiency, speed, gain, S:N, and bandwidth. They all match for a particular environmental state (e.g., starlight or daylight), and they compromise to promote overall performance (survival). These biophysical factors, by jointly setting the spatiotemporal integration of photons in a receptor, determine the size of its “information packet” to be relayed forward. This, in turn, determines many features of the downstream neural circuitry.

Transmitting the photoreceptor signal

ROD AXON IS THIN AND CONE AXON IS THICK Rod and cone axons are just long enough to traverse their nuclear layer and reach their synaptic targets. Typically, the distance is about 20 μm , but where their axons must course laterally to connect with second order neurons (near the fovea in primates), they are much longer, up to 500 μm (Polyak, 1941). Irrespective of length, the two axon types differ markedly in thickness. The rod axon is thin, about 0.45 μm in diameter, and invariant with species and retinal location; whereas the cone axon is thick, up to 1.6 μm , and varies across the retina, being thinner in the fovea and thicker toward the periphery (Figs. 17.6 and 17.8). The 4-fold difference in diameter implies a 16-fold difference in cross-sectional area.

This sets the number of microtubules in the axon cross-section, because microtubules are evenly spaced at a specific density that is the same for both axons (Fig. 17.8; Hsu et al., 1998). So, a cone axon has ~440 microtubules in its cross-section, whereas a rod axon has only ~35. The rod axon's smaller cross-sectional area also implies a 16-fold smaller volume. Volume of the rod axon terminal is also less than that of the cone axon terminal, so that the combined volume of the rod axon + terminal is less than the combined volume of the cone axon + terminal by 10-fold (Hsu et al., 1998). Were the rod signaling apparatus not

appropriately diminished but equal to that of the cone, the vast number of rods (20 rods/cone) would double the retina's postreceptoral thickness. So there must be pressure to minimize “wire volume” and match it to information capacity (Hsu et al., 1998).

ROD TERMINAL CONTAINS ONE ACTIVE ZONE AND CONE TERMINAL CONTAINS MANY We expect axon diameter to correlate with some *electrical* feature, such as space constant, conduction velocity, and temporal bandwidth. However, models suggest that outside the fovea a thin axon could adequately serve the cone's known electrical properties (Hsu et al., 1998). Instead, axon diameter correlates with the number of active zones.³ The thin rod axon supplies a small terminal with one active zone (Rao-Mirotznik et al., 1995); whereas the thick cone axon supplies a large terminal with many active zones (e.g., 17 in cat central retina, 20 in primate fovea, and 50 in primate periphery) (Fig. 17.9; Haverkamp et al., 2000). As the primate cone terminal enlarges from fovea to periphery, so does the axon (see Fig. 17.6). This rule (axon thickness proportional to number of active zones) also holds for bipolar axons in cat and mouse (Fig. 17.13C; Cohen and Sterling, 1990; Tsukamoto et al., 2001).

Because photoreceptors are tonically depolarized, each active zone releases vesicles tonically, at rates that seem astonishingly high. For example, the cat rod terminal with one active zone is calculated to release ~80 vesicles/second (Fig. 17.9C; Rao et al., 1994; Rao-Mirotznik et al., 1998; van Rossum and Smith, 1998), consistent with capacitance measurements of the salamander rod (Rieke and Schwartz, 1996). The cat cone terminal with 18 active zones (see Fig. 17.9B) is estimated to release ~1500 vesicles/second, consistent with noise measurements in turtle (Ashmore and Copenhagen, 1983). In these examples, transmitter release seems to match information capacity; that is, it is smaller in the rod terminal that transfers an irreducible binary signal (0 or 1 photon/integration time) and greater in the cone terminal that transfers a richer, graded signal (de Ruyter van Steveninck and Laughlin, 1996).

The cone's estimated 15-fold higher release rate apparently requires nearly 15-fold more microtubules. Because microtubules serve as “tracks” for molecular motors to shuttle supplies between cell body and synapse, it makes sense that a terminal whose vesicle release rate matches its information rate should also require a corresponding match of mechanisms for resupply. This observation implies another key constraint in retina, that *information capacity should match wire volume*.

³An active zone is the presynaptic site where synaptic vesicles dock near clusters of voltage-sensitive calcium channels.

FIGURE 17.8. *A*, Electron micrograph of cross-section through photoreceptor axons in macaque perfovea. Cone axons (CA) are fourfold thicker than rod axons (RA). Cone terminals (CT) are also much larger than rod terminals (RT). *B*, Cone and rod axons are

filled with microtubules at equal densities. The square indicates the region enlarged in *C*. *C*, Microtubules (mt) in the cone axon are evenly spaced and associated with patches of smooth membrane (arrows).

PHOTORECEPTOR SYNAPSES ARE STRUCTURALLY AND FUNCTIONALLY THREE-DIMENSIONAL A signal rich in information coupled to a channel of intrinsically limited capacity, would lose information (Laughlin, 1994). To prevent this, the photoreceptor synapse evolved several coding strategies: (1) compress the signal by bandpass filtering; (2) divide the filtered signal into multiple components and route them over parallel circuits with appropriately matched properties. For example, the weakest rod signals use a private, nonlinear circuit, whereas stronger rod and cone signals share a linear circuit. Strong signals sort further into circuits for different temporal bandwidth. To initiate these key steps in signal processing, the first synapse requires several types of lateral interneuron (horizontal cells) and also *many* types of relay neuron (bipolar cells). To connect with all these neurons while minimizing tissue volume, noise, and metabolic cost, photoreceptors employ a three-dimensional synapse (Haverkamp et al., 2000; Rao-Mirotznik et al., 1995; Vardi et al., 1998).

The synaptic ribbon tethers hundreds of vesicles and anchors to the plasma membrane. There, tens of vesicles along the base of the ribbon are apposed to the presynaptic membrane to form a linear active zone at the apex of an invagination that is 500 nm deep. The invagination houses multiple processes: two horizontal cell spines flank

one or more bipolar dendrites (Fig. 17.9). At the mouth of the invagination and tiling the base of the presynaptic terminal, other bipolar dendrites form specialized contacts: a few for the rod (Hack et al., 1999; Tsukamoto et al., 2001) and *hundreds* for the cone (Fig. 17.9; Haverkamp et al., 2000).

When a vesicle containing $\sim 10^3$ glutamate molecules fuses at the apex of the invagination, some of the molecules diffuse rapidly across the 20-nm cleft to AMPA receptors on the horizontal cell spines. Other glutamate molecules diffuse more slowly down the 500-nm invagination to encounter mGluR6 glutamate receptors on the invaginating or “semi-invaginating” bipolar dendrites (Fig. 17.9). Additional glutamate molecules diffuse still more slowly for 1000 nm or more to reach AMPA and kainate receptors on the “basal” bipolar dendrites that tile the terminal’s base. Consequently, each vesicle delivers glutamate as a brief “pulse” or a slower “puff” to more than 10 (probably closer to 50) postsynaptic processes (DeVries, 2000; Haverkamp et al., 2000; Rao-Mirotznik et al., 1995, 1998).

This three-dimensional synaptic architecture confers two important advantages. First, by allowing every vesicle to affect many postsynaptic processes, the apparent cost of the photoreceptor’s high basal rate of vesicle release is effectively reduced. Second, by allowing each active zone to affect

many postsynaptic processes, considerable synaptic divergence is achieved with minimum wire volume. Although many brain regions disallow “spillover” between synapses, the photoreceptors present a clear case where spillover is both extensive and deliberate; that is, it represents not a failure, but an intrinsic part of the design.

“Engineered spillover” requires that glial processes avoid the synaptic regions. For if the glia invaded, their transporters that rapidly bind and remove extracellular glutamate, would sharply restrict its spatiotemporal distribution (Lehre and Danbolt, 1998). Consequently, Müller glia avoid the invaginations and territory beneath the terminal

(Sarantis and Mobbs, 1992; Burris et al., 2002). Glial membranes do wrap the photoreceptor axon and the upper surface of the terminal (Fig. 17.9). They separate adjacent synaptic terminals except where the membranes are pierced by fine processes that form cone-cone and cone-rod gap junctions.

Three pathways divide the rod system’s intensity range

In starlight the rod system employs many detectors but catches only a few photons, so the signal in each detector is binary: usually 0 and rarely 1. In moonlight the detectors still operate in binary mode, but with fewer 0s and more 1s. In twilight (or dawn) each detector catches more than one photon and thus has a coarsely graded signal. Each condition presents a different challenge for signal processing, each solved with a different circuit (Fig. 17.10).

STARLIGHT CIRCUIT: TWO STAGES OF CONVERGENCE EMPLOY NONLINEAR AMPLIFICATION The challenge in starlight is to separate the small signal in one rod from the continuous dark noise in many rods. The voltage evoked by one photon rises above the dark noise only modestly, by a factor of ~ 4 (Baylor

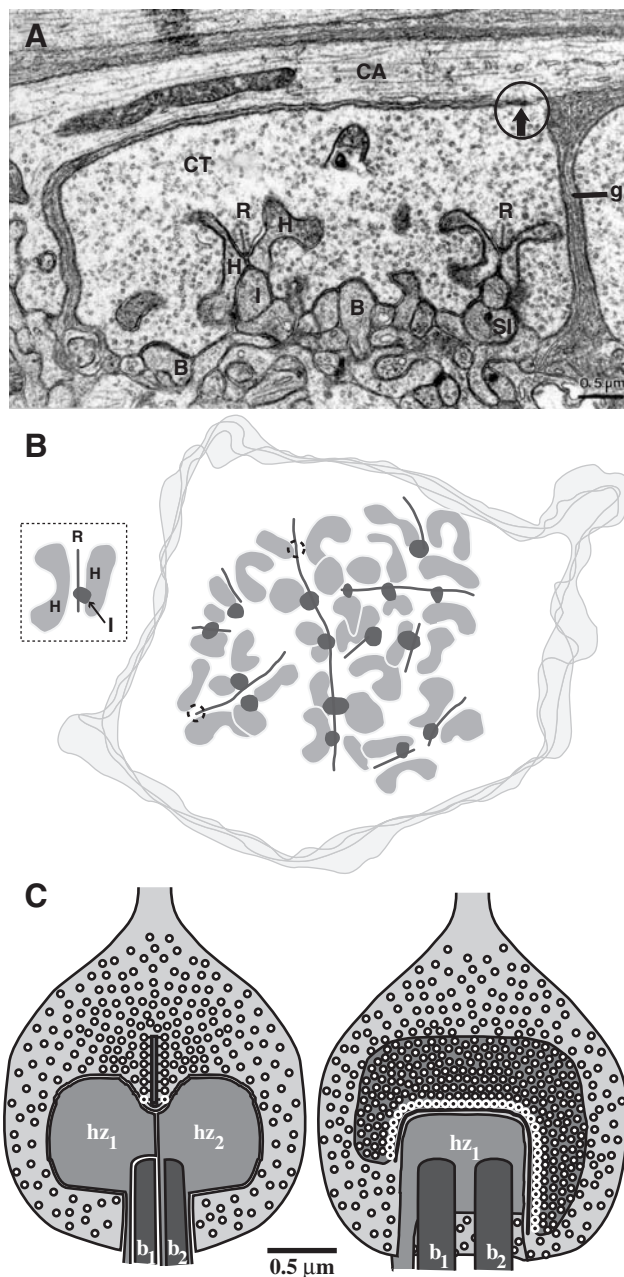

FIGURE 17.9. The cone uses many ribbon synapses to transmit a graded signal; the rod uses one ribbon to transmit a binary signal. *A*, Ultrathin section (~ 90 nm) through a macaque fovea cone terminal. Two ribbons (*R*) and their postsynaptic triads (*H*, *H*, *I*) are present, but full reconstruction shows 20 triads. At the base, semi-invaginating (*SI*) and basal (*B*) dendrites are also shown; full reconstruction shows several hundred such dendrites. The circled arrow indicates the gap junction with the adjacent terminal. Full reconstruction shows that every terminal connects to all its neighbors. Glial wrappings (*g*) separate the terminals, but avoid the terminal’s secretory region, consistent with “engineered spillover” of each vesicle to many postsynaptic processes. *B*, Cone terminal in tangential view, reconstructed from electron micrographs of serial sections (cat central area). Inset shows a triad:ribbon (*R*) with an ON bipolar dendritic tip (dark spot) flanked by two horizontal cell spines (*H*). The terminals contain 11.6 ± 0.9 ribbons. These vary in length from 0.2 to $3.5 \mu\text{m}$, but the total length per terminal is remarkably constant ($9.9 \pm 0.9 \mu\text{m}$; $N = 8$). This provides a constant number of docking sites for synaptic vesicles (~ 600) and a still larger “depot” of vesicles tethered to the faces of the ribbon (~ 3000). The cone terminal has 17 triads. Short ribbons serve a single triad; long ribbons serve up to 5 triads. *C*, Rod terminal in orthogonal views (from three-dimensional reconstruction, cat central area). A single tetrad is present, with one ribbon pointing between two horizontal cell processes (*hz*) toward two rod bipolar dendrites (*b*). Note that the bipolar dendrites are hundreds of nanometers distant from docked vesicles. (*A*, Electron micrograph from Tsukamoto et al., 1992, with permission. *B*, From Harkins & Sterling, unpublished work. *C*, From Rao-Mirotznik et al., 1995, with permission.)

FIGURE 17.10. The final common pathway to the ganglion cell is served by three circuits. In daylight, cone signals are graded and thus require many ribbon synapses for transfer (both at the outer plexiform layer [OPL] and the inner plexiform layer [IPL]). In twilight, rod signals are graded and also require many ribbon synapses. Rods access these synapses by turning on their gap junctions to cone terminals, in effect “parasitizing” the multiple ribbon synapses available at both stages of the cone bipolar circuit. In starlight, rod signals are binary and thus require only one ribbon synapse (see Fig. 17.9C). The single-photon response cannot transfer via coupling to the cone terminal because the many rods lacking a photon add too much noise. Therefore, the rod-cone junction may turn off to transfer the binary signal via the rod’s ribbon synapse to the rod bipolar cell. The latter’s response will be coarsely graded

over some part of the intensity range (owing to rod convergence) and will thus require multiple ribbon synapses, which are present in the rod bipolar terminal. The AII cell’s response will be more finely graded (owing to rod bipolar convergence) and will thus require yet more ribbon synapses. The AII cell gains access to these by turning on its gap junctions with cone bipolar terminals. Coupling of the AII cells—indirectly via the cone bipolar terminals and also directly via AII-AII junctions—spreads current widely enough to enlarge the ganglion cell’s summation area well beyond its dendritic tree. This improves the S:N ratio in very dim light, but would degrade acuity in brighter light. Therefore, both sets of junction are regulated and presumably uncouple in twilight and daylight. See text for further explanation. (Modified from Sterling, 1998.)

et al., 1984). But the next neuron in the circuit, the rod bipolar cell, pools input from many rods ($n = 20$ to 120). If the rod synapse were linear, noise in the bipolar cell would rise as \sqrt{n} and swamp the single-photon event (Baylor et al., 1984). The problem could be solved by a nonlinear synapse that selectively amplified larger signals. This would effectively remove the dark noise by “thresholding,” but at the cost of also removing single-photon events on the small end of the amplitude distribution (van Rossum and Smith, 1998). This mechanism has now been confirmed experimentally and shown to improve overall sensitivity compared to linear transfer (Fig. 17.11; Field and Rieke, 2002).

Of course, signals in each rod bipolar cell are also sparse and each has noise. So the circuit must converge tens of rod bipolar cells onto a second-stage interneuron, the AII amacrine cell, without swamping the signal (Fig. 17.10). Again the solution involves a nonlinearity: larger rod bipolar inputs are selectively amplified by voltage-sensitive sodium channels in the AII cell (Boos et al., 1993; Smith and Vardi, 1995). Then AII cells send current via gap junctions to depolarize ON cone bipolar terminals. Simultaneously the AII also releases inhibitory transmitter (glycine) to hyperpolarize the OFF cone bipolar terminals and OFF ganglion cells. The overall circuit allows a single-photon event to

evoke a discrete “firing event” (1 to 3 spikes) in several ON ganglion cells and to suppress an equal number of spikes in several OFF ganglion cells (Barlow et al., 1971; Mastronarde 1983).

MOONLIGHT CIRCUIT: LINEAR CHEMICAL SYNAPSE ONTO OFF CONE BIPOLAR As photon density rises slightly, a second rod pathway comes into play. Some rods synapse on dendrites of an OFF cone bipolar cell (Hack et al., 1999; Soucy et al., 1998; Tsukamoto et al., 2001). This synapse amplifies linearly and thus transfers all photon events, which when summed, exceed the noise (Fig. 17.11C; Field and Rieke, 2002; Sterling, 2002). Although only a few rods manage to contact a cone bipolar dendrite, the small gap junctions between rod terminals might couple them at this intensity to pool the signals (Fig. 17.11; Tsukamoto et al., 2001). This pathway has been found so far only in rodents.

TWILIGHT CIRCUIT: ROD ELECTRICAL SYNAPSE ONTO CONE When photon density reaches one photon/rod/ integration time (twilight, dawn), rod signals are processed by cone circuits (Fig. 17.10). Each rod terminal forms gap junctions with two cone terminals, and every cone terminal is

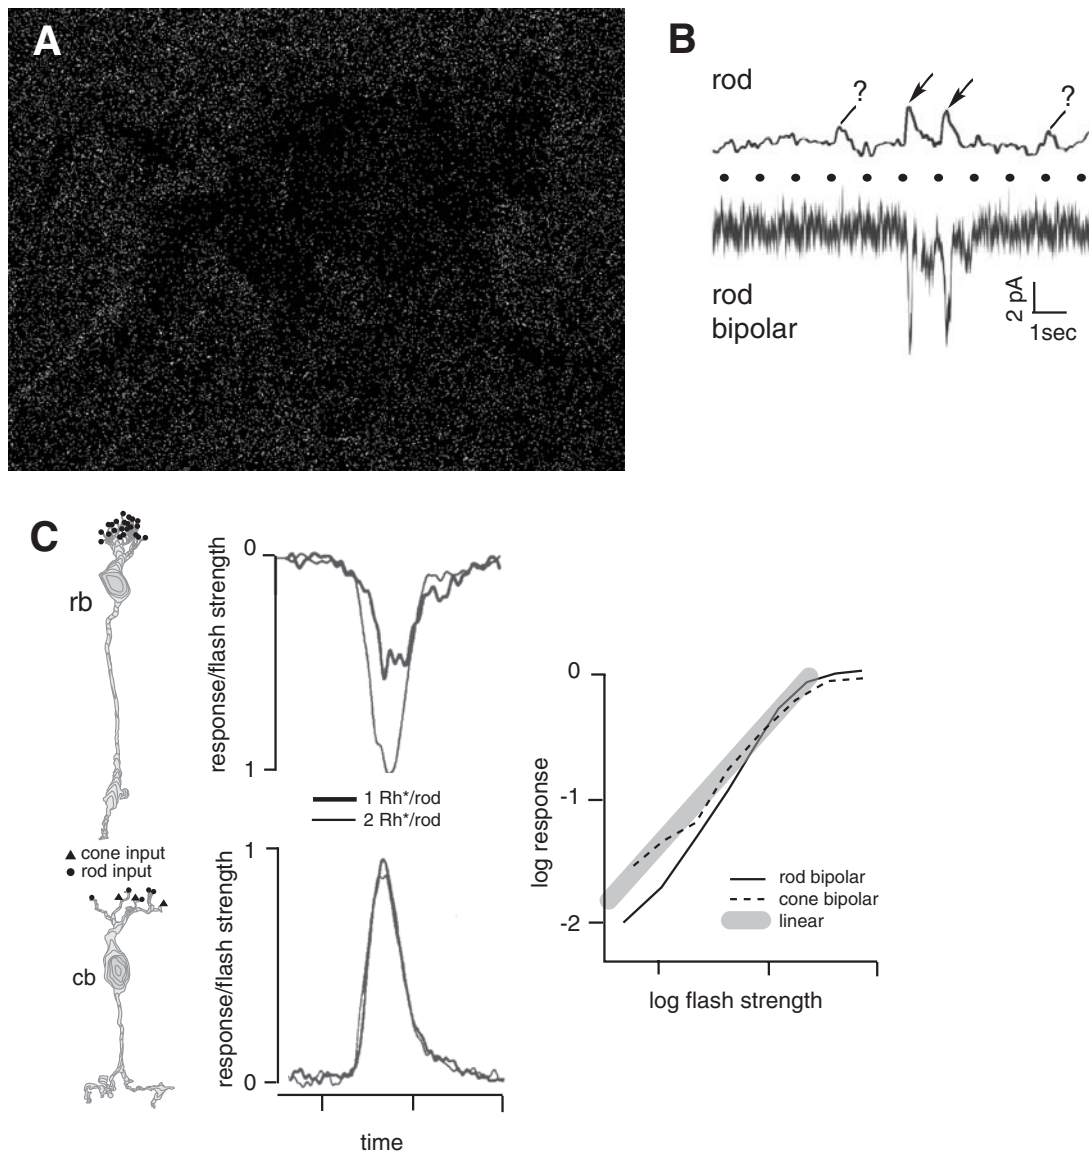

FIGURE 17.11. *A*, Faint image of a baboon in starlight painted by photons in “pointillist” fashion. The probability of each pixel receiving a photon is governed by a Poisson distribution, whose mean corresponds roughly to the intensities used by Field and Rieke (2002). *B*, Single-photon event in a rod rises clearly above the continuous noise (arrows) only when it is considerably larger than average. The same event in the rod bipolar cell is faster, with a much improved signal-to-noise ratio. The dotted trace represents flash timing. *C*, *Left*, A rod bipolar (rb) cell collects chemical synapses from 20 rods, whereas the cone bipolar (cb) cell collects

from only a few rods. However, each rod probably pools signals from neighboring rods via gap junctions. *Middle*, Response amplitudes normalized for flash intensity. The cone bipolar response doubles for twice the intensity, but the rod bipolar response more than doubles. *Right*, Input/output curve for the cone bipolar cell is essentially linear, in contrast to that for the rod bipolar cell, which is clearly nonlinear. (*A*, Image courtesy of A. Hsu and R. Smith. *C*, Neurons, reprinted from Tsukamoto et al., 2001; responses replotted from Field and Rieke, 2002.)

contacted by ~40 rods (Smith et al., 1986; Sterling et al., 1988). The rod signal (recognized by its spectral peak and time course) is observed in recordings from the cone (Nelson, 1977; Schneeweis and Schnapf, 1995, 1999). Rod signals are also present in horizontal cells whose dendrites do not contact rods (Nelson, 1977). Thus, electrical coupling from many rods to each cone allows the graded rod signal to be filtered and relayed by the same circuits used by the graded

cone signals. This design reduces wire volume and metabolic cost.

Daylight circuit requires “bandpass filter” at the cone synapse

Recall that most sensory systems convert a receptor cell’s graded potential into action potentials, either directly or

after interpolating a single synapse (Fig. 17.3). But this requires special mechanisms that precede or accompany transduction to filter out noise and redundant signals. For example, the auditory, vestibular, and somatosensory systems employ complex mechanical filters before transduction to select particular temporal frequencies. And the olfactory and taste senses use more than 1000 different heptahelical receptors to select particular chemical stimuli (Zhang and Firestein, 2002). The eye employs only mild optical filtering,⁴ and cones employ relatively minor molecular filtering (2 to 3 heptahelical receptors) to divide spectral bandwidth. Lacking vigorous preneural filtering or extensive molecular filtering by the transducer, the retina requires neural circuits to perform spatial and temporal bandpass filtering at the first synapse (Fig. 17.12).

The photovoltage arriving at the cone synaptic terminal spreads to neighboring cone terminals. This coupling filters noise intrinsic to the cones. In “steady” light, the cone voltage fluctuates owing to photon noise and biochemical noise arising from the transduction cascade. These noise sources are independent between cones, whereas the signals are locally correlated between cones owing to correlations in the visual scene plus optical blur. Therefore, coupling reduces noise more than the signal. For a coupling strength of about 1 nS, neural blur in human fovea is narrower than the optical blur. Yet, because it gives the cone a slightly broader receptive field than the cone’s optical aperture, it is detectable psychophysically. This lowpass filtering is calculated to improve the S:N ratio by about 60% at the cone terminal for spatial frequencies below 20 cycles/degree (DeVries et al., 2002).

The other essential step is to attenuate signals that are broadly correlated across cones. Correlations arise from the coarse structure in an image (low spatial and temporal frequencies) which delivers similar intensities to neighboring cones. (Think of a blackboard or a uniformly bright wall, or any spatial pattern that is temporally invariant.) These broadly correlated signal components carry little information about image structure and are therefore redundant. Removing them allows the cone synapse to use its dynamic range for what is essential, the *differences* between adjacent regions. In the jargon of signal processing, such filtering is

termed “background subtraction,” “contrast enhancement,” or “highpass filtering.” The theory for optimally matching the spatiotemporal bandpass filter to ambient light intensity is well developed (Srinivasan et al., 1982; van Hateren, 1992).

This essential integrative step is accomplished by the horizontal cell, which collects synaptic input from many cones (Fig. 17.12). The horizontal cell’s spines invaginate the cone terminal, forming the paired, lateral elements of the triad where they express AMPA receptors (Fig. 17.9A; Haverkamp et al., 2001). The horizontal cell pools its signal electrically with neighboring cells. These connections produce a broad receptive field that represents a slightly delayed, center-weighted average of the cone membrane potential. Many diurnal mammals (e.g., cat, rabbit, and guinea pig) express two types of horizontal cell that connect to the same cones. One type is narrow-field with weaker coupling, the other is broad-field with stronger coupling (reviewed by Mills and Massey, 1994; Vaney, 1993). The two patterns of connection cause correspondingly different weighting functions, but they both project feed back negatively onto the cone terminal and bipolar dendrites, creating a receptive field surround with the proper overall weight (see Fig. 17.12; Smith, 1995).

The negative sign of this feedback arises from gamma-aminobutyric acid (GABA), which the horizontal cells synthesize and release via an unconventional mechanism (Schwartz, 1987). These cells lack synaptic vesicles but release the transmitter by reverse action of a GABA transporter, apparently the vesicular GABA transporter (VGAT), which at conventional synapses loads GABA into vesicles (Haverkamp et al., 2000). GABA acts at the bipolar cell dendritic tips which express GABA_A and GABA_C receptors (Haverkamp et al., 2000; Vardi et al., 1992). These ligand-gated chloride channels pose an important puzzle: although GABA’s function is to antagonize the stimulus, light depolarizes some bipolar cells (ON cells) and hyperpolarizes others (OFF cells). So how can the same receptor molecule mediate opposite effects? The current idea is that ON bipolar dendrites express a cotransporter that *accumulates* chloride (NKCC), and OFF bipolar dendrites express a cotransporter that *extrudes* chloride (KCC2). This would set E_{Cl} for the two bipolar classes on opposite sides of the membrane potential, so that GABA would drive their voltages in opposite directions (Vardi et al., 2000). Experimental support for this idea is so far underwhelming (Sato et al., 2001; Billups and Attwell, 2002).

The cone terminal itself may express a GABA_A receptor, but this remains controversial (Pattnaik et al., 2000; Picaud et al., 1998). A different mechanism, perhaps equally controversial, has been proposed for horizontal cell feedback

⁴ Optical blur attenuates spatial frequencies greater than can be resolved by the cone array. For example, optics in the human fovea cut off frequencies above 60 cycles/degree. This precisely matches the foveal sampling rate (120 cones/degree), given Nyquist’s rule that there must be one detector for each half cycle. Although it might seem counterintuitive that optical blur could *improve* vision, frequencies higher than the sampling rate would be seen as lower frequencies, and thus cause a kind of noise termed “aliasing” (Williams, 2003). The matching of optics to cone sampling rate further exemplifies the principle of symmorphosis.

FIGURE 17.12. A center-surround receptive field (“bandpass filter”) arises at the cone terminal. *A*, Cone array, cat central area (24,000/mm²). A point of light striking the cornea spreads, owing to optical blur (PSF, point spread function), to stimulate about 10 cones. The signal spreads further, via coupling at cone terminals, creating a receptive field center (RFC) for one cone (*) that encompasses about 50 cones. Inhibitory feedback via horizontal cells creates a receptive field surround (RFS) encompassing about 1200 cones. *B*, Neural circuit that shapes the cone receptive field. The arrow between the terminals denotes coupling; the surround is shaped by inhibitory feedback (*inset*). *C*, Calculated sensitivity across

the cone receptive field (area between arrows in *A*). To achieve the proper spatial weight requires both optical blur and cone-cone coupling. For surround; narrow, deep region set by the narrow-field H_B cell; broad, shallow region set by the wide-field H_A cell. *D*, Calculated sensitivity as presented in *C*. *E*, Intracellular recordings from squirrel retina. Enlarging a bright spot over a horizontal cell, from 100 μm to 750 μm in diameter, gives progressively larger responses. The same sequence, when applied to a cone, gives the greatest response to a small spot (100 μm) and rising attenuation (somewhat delayed) to larger spots. (*A* to *D*, Adapted from Smith, 1995. *E*, Adapted from Leeper and Charlton, 1985.)

onto the cone terminal (Kamermans et al., 2001). The horizontal cell spine expresses a gap junction channel protein (connexin), but does not form a gap junction with the opposing cone membrane. This dab of connexin is thought to be a hemichannel, observed previously in isolated horizontal cells (DeVries and Schwartz, 1992). The idea is that when the horizontal cell depolarizes, releasing GABA onto bipolar

dendrites, it also injects negative current into the extracellular space near the cone terminal’s voltage-sensitive calcium channels. This reduces the calcium current and thus the cone terminal’s synaptic gain (Kamermans et al., 2002). How these apparently disparate mechanisms cooperate to remove redundant information from the cone terminal remains to be determined.

FIGURE 17.13. Two types of OFF cone bipolar cell (b3, b2) from a ground squirrel. *A*, Differences in axon caliber predict few ribbon outputs for b3 and more for b2. *B*, The difference also predicts higher temporal bandwidth for b2. Consistent with this, b2 shows much faster recovery from receptor desensitization, measured by removing the bipolar cells from a slice and measuring paired-pulse responses using a rapid perfusion system. *C*, ON cone bipolar cells (b1 to b4) from cat. Axons decrease in diameter from left to right, expressing fewer ribbons. OPL, outer plexiform layer; IPL, inner plexiform layer, expressing fewer ribbons. (*A* and *B*, From S. DeVries, unpublished. *C*, Modified from Cohen and Sterling, 1990.)

Ten bipolar pathways (!) divide the cone signal

In daylight, the cone system uses relatively few detectors but catches many photons, so the signal in each detector (derived from 10^3 to 10^6 photons) is finely graded. This challenges neural circuitry in a manner opposite to the rod system, not with sparse information, but with a plethora. Even after bandpass filtering, the information in a cone signal exceeds the coding capacity of a single second-order neuron. The solution is to divide the signal into different components and transmit them to the inner retina over multiple circuits (Boycott and Wässle, 1991; Cohen and Sterling, 1990; Euler et al., 1996; Kolb et al., 1981; McGillem and Dacheux, 2001; McGuire et al., 1984).

The contrast signal created by horizontal cell filtering is halved at the cone output⁵ (see Figs. 17.2, 17.4, and 17.12). Signals dimmer than the mean depolarize one class of bipolar cell (OFF cells), and signals brighter than the mean depolarize another class (ON cells). To achieve this, the cone releases glutamate simultaneously onto both bipolar classes, while their dendrites sense it with different receptors. The OFF bipolar dendrites express ionotropic receptors that *open* a cation channel; whereas the ON bipolar dendrites express a metabotropic receptor that *closes* a cation channel. The metabotropic receptor is mGluR6 (Masu et al., 1995; Nomura et al., 1994), which couples to $G_{\alpha o1}$ (Dhingra et al., 2000, 2002), but the rest of the cascade and the channel itself remain elusive.

OFF signals are routed to 3 to 5 types of bipolar cell (Fig. 17.13). The purpose is to divide the signal into different temporal components. In one bipolar type the excitatory postsynaptic current (EPSC) is slow and sustained; in another type it is intermediate; and in a third type it is fast and transient. These kinetic differences arise because the cone's tonic release of glutamate strongly desensitizes iGluR receptors, and the particular iGluRs expressed on each cell type recover

⁵Such circuits must have evolved quite early as they are present even in sharks, the most primitive fish.

at different rates (Fig. 17.13B; DeVries and Schwartz, 1999; DeVries, 2000). The OFF dendrites all contact the base of the cone terminal, but apparently at different distances from the sites of vesicle release: dendrites with large, fast currents are nearest, and dendrites with small, slow currents are farthest (DeVries, personal communication).

ON signals are also routed to five bipolar types, and for the same reason: to divide the signal into slow and fast components (Fig. 13B; Cohen and Sterling, 1990; Freed, 2000a). However, since ON dendrites express only one isoform of mGluR6, the temporal differences must arise differently than in the OFF system. One idea is that the calcium influx through the ON bipolar cation channel, which antagonizes the response (Nawy, 2000), might have different kinetics in each cell type (Awatramani and Slaughter, 2000). This is known to be true for photoreceptors. Further kinetic shaping of the bipolar responses certainly occurs at their axon terminals, owing to autofeedback onto group III metabotropic glutamate receptors and to extrinsic feedback from amacrine processes that release GABA onto GABA_C receptors (Awatramani and Slaughter, 2001; Euler and Masland, 2000; Freed et al., 2003).

BIPOLAR AXONS END IN DIFFERENT STRATA: STRUCTURE MATCHES INFORMATION CONTENT The two major classes of bipolar axon segregate at different levels of the inner plexiform layer, thus dividing it into OFF and ON laminae. Furthermore, within a lamina, each type of bipolar axon occupies a defined stratum, which can be quite thin (~2 μm) (Fig. 17.13). This implies that the inner plexiform layer finely stratifies temporal information, which can be further sharpened by amacrine circuits that extend laterally in fine strata (Roska and Werblin, 2001). Some of these signals are transmitted rapidly and regeneratively over long distances (millimeters) by spiking amacrine cells (Cook et al., 1998; Demb et al., 1999; Stafford and Dacey, 1997).

Because a channel's information content rises directly with bandwidth (Shannon and Weaver, 1949), the bipolar types that signal higher temporal frequencies convey more information. The structural correlates are the same as for the rod and cone. Low frequency ("sustained") bipolar cells have thinner axons with fewer ribbon synapses (~50 to 80); whereas high frequency ("transient") bipolar cells have thicker axons with more synapses (~100 to 120) (Calkins et al., 1994; Cohen and Sterling, 1990; Tsukamoto et al., 2001). The slowest, poorest signal of all belongs to the rod bipolar cell, which has the thinnest axon and fewest ribbon synapses (20 to 40) (Ghosh et al., 2001; McGuire et al., 1984; Tsukamoto et al., 2001).

Design of ganglion cell circuits

CERTAIN GANGLION CELLS SELECT ON OR OFF INPUTS, BUT OTHER TYPES COMBINE THEM Bipolar axons at the inner

plexiform layer deliver packets of information pooled from 5 to 10 cones. These graded signals are further pooled at the ganglion cell and re-encoded as spikes for transmission down the optic nerve. The specific pooling decisions are crucial because they irrevocably set the spatial and temporal resolution of all later stages. These decisions partly reflect the constraints already mentioned (dynamic range, noise, wire volume, and metabolic cost). But ganglion cells project to diverse brain regions that use different regions of the spatiotemporal frequency spectrum. Because further efficiencies can be achieved by matching the message to the "end user," ganglion cells are diverse, comprising some 10 to 20 types (Masland, 2001; O'Brien et al., 2002).

The separate ON and OFF channels established at the cone terminal are retained by ganglion cells. This is straightforward because bipolar cells employ ribbon synapses to release glutamate onto ganglion cell dendrites, and the latter always express iGluR receptors. Therefore, to collect either ON or OFF signals, a ganglion cell simply restricts its dendrites to either the upper or lower stratum of the inner plexiform layer. Indeed, many ganglion cell types continue to encode only the brighter or dimmer half of the contrast range. This is useful because the dynamic range of a neuron's spike-coding mechanism is limited, and this doubles the dynamic range available to encode contrast. Furthermore, to double the contrast range with one neuron, its spike number would need to rise fourfold, a metabolically costly strategy (Attwell and Laughlin, 2001; von der Twer and MacLeod, 2001).

Certain ganglion cells break this rule by sending one set of dendrites to the OFF layer and another to the ON layer. For example, one ganglion cell collects synapses from an ON bipolar cell with exclusively S-cone input (sensitive to **s**hort wavelengths) and additional synapses from OFF bipolar cells with M- and L-cone input (sensitive to **m**iddle and **l**ong wavelengths). This wiring renders the cell most sensitive to light rich in short wavelengths and least sensitive to light rich in middle and long wavelengths (Calkins et al., 1998; Chichilnisky and Baylor, 1999; Dacey and Lee, 1994; Martin et al., 1997). By encoding a spectrally opponent signal (colloquially, "blue minus yellow"), this cell discards spectrally redundant information that in a "generalist" ganglion cell occupies considerable dynamic range and metabolic energy. The spectrally filtered signal is clearly optimized for its particular end user, the koniocellular layer of the lateral geniculate nucleus, which projects to "color circuits" in striate cortex (reviewed in Calkins and Sterling, 1999).

"BRISK" GANGLION CELLS COMPRISE NARROW-FIELD AND WIDE-FIELD TYPES More than half of all ganglion cells fire "briskly" (Fig. 17.14). The spike autocorrelograms rise steeply, and the peak rates are high, more than 100

spikes/second (Cleland and Levick, 1974a; DeVries and Baylor, 1997). The axons of brisk cells are relatively thick and rapidly conducting (e.g., Kirk et al., 1975; Rowe and Stone, 1976a), so their wire volume occupies more than 95% of the optic nerve's cross section (Sterling, unpublished).

About 90% of brisk cells have narrow dendritic fields that collect from relatively few bipolar cells. Transient and sustained bipolar types both contribute, and accordingly, the narrow-field ganglion cell responds to both stimulus components (Cohen and Sterling, 1992; Freed, 2000b). Narrow-field ganglion cells tile the retina (independently for both ON and OFF types), and because they sample space most densely and project 1:1 to parvocellular geniculate neurons, these two cell types set spatial acuity for their main end users, namely, simple cells in striate cortex (Wässle and Boycott, 1991; Smallman et al., 1996).

About 10% of the brisk cells have wide dendritic fields that collect from many bipolar cells. The wide-field ganglion cell is 3-fold broader than the narrow-field cell at the same retinal locus and thus collects from nearly 10-fold more bipolar cells—all of the transient type—and nearly 10-fold more bipolar synapses (Kier et al., 1995; Freed and Sterling, 1988; Freed, 2000a). This design has several important consequences for the end users (superior colliculus and magnocellular pathways of the geniculostriate system). First, summing from many cones via many bipolar cells and bipolar synapses, the wide-field cell, compared to the narrow-field cell, has better S:N ratio and thus greater contrast sensitivity (Kaplan and Shapley, 1986). Threshold for the wide-field, brisk-transient ganglion cell to a spot over its dendritic field can be as low as 0.8% contrast (Dhingra et al., 2003). Second, wide spatial summation reduces sensitivity to high spatial frequencies (which are more effectively carried by narrow-field cells). This frees the cell's limited dynamic range to encode higher *temporal* frequencies and thus to match the input provided by transient bipolar cells (Figs. 17.4 and 17.14).

A third consequence of wide-field summation is that the ganglion cell responds vigorously to a fine stimulus that reverses contrast or moves within the dendritic field (Fig. 17.14; Hochstein and Shapley, 1976). Although the *array* of wide-field cells cannot detect fine detail when it is stationary (Fig. 17.4), the individual wide-field ganglion cell responds sensitively when the grating flickers or drifts (Fig. 17.14). This serves end users, such as neurons in cortical area MT that detect motion based on changes in luminance and contrast (Demb et al., 2001a, 2001b). This response property is termed “nonlinear” because brightening one region while dimming another evokes a vigorous response, whereas in a linear system (such as the narrow-field ganglion cell) the two changes simply cancel.

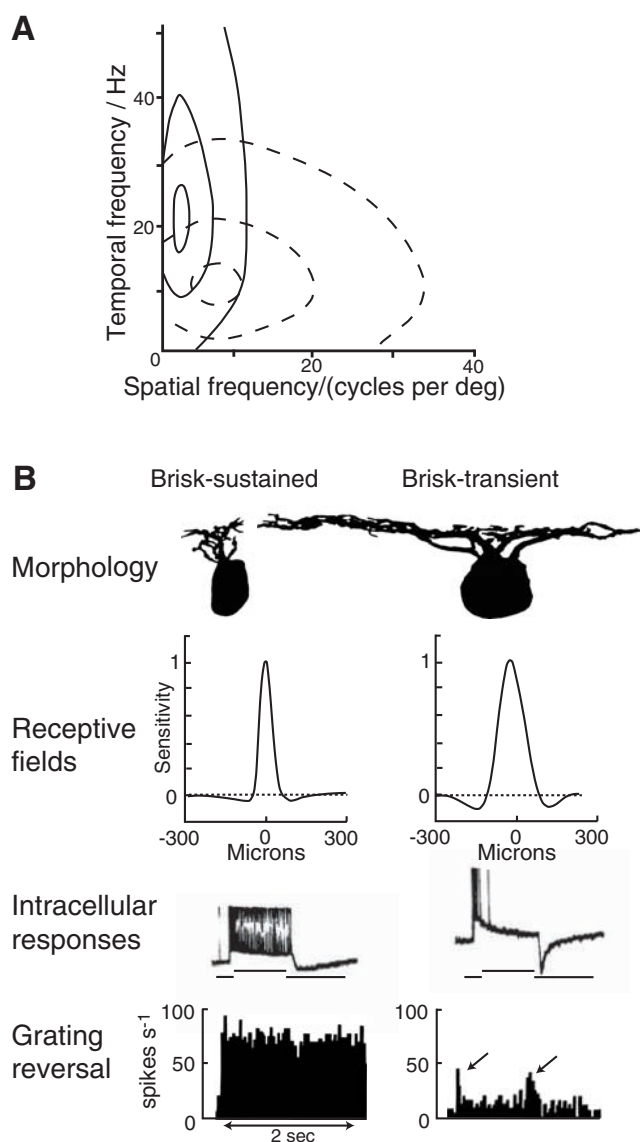

FIGURE 17.14. *A*, The spatiotemporal transfer function of the brisk-transient and brisk-sustained pathways. Contours are at 0.1, 0.5, and 0.9 of the maximum values. The brisk-sustained pathway is tuned to higher spatial frequencies and lower temporal frequencies. *B*, Radial views of ON brisk-sustained (narrow-field) and ON brisk-transient (wide-field) ganglion cells. The narrow-field cell collects 150 synapses (total) from several bipolar cells of each type (b1 to b4 in Fig. 17.13C). Because the bipolar cells have receptive fields broader than their spacing, their rectified responses cancel in the narrow-field ganglion cell and give no response to reversal of a fine grating. The wide-field cell collects about 600 synapses from about 150 bipolar cells, mostly from the transient bipolar cell (b1 in Fig. 17.13). Because the bipolar receptive fields are narrower than the large convergent array, the wide-field cells respond at each grating reversal (arrows). This “frequency doubling” arises because the rectified responses of individual bipolar cells are collected across such a wide field that they cannot cancel (Demb et al., 2001a). (*A*, Reprinted from Eckert and Buchsbaum, 1993. *B*, Modified from Sterling, 1998. Intracellular records from Saito, 1983. Spike histograms from Hochstein and Shapley, 1976.)

The nonlinear mechanism was initially attributed to amacrine circuits because bipolar circuits were thought to be linear. But we now know that the bipolar cell synapse expresses an important nonlinear property, “rectification.” The bipolar synapse releases vesicles at a low basal rate; consequently, depolarization can increase release, but hyperpolarization cannot decrease it. Therefore, dimming an OFF bipolar cell increases release but brightening does not decrease it (and vice versa for an ON bipolar cell). This nonlinearity hardly affects a narrow-field ganglion cell because the bipolar receptive fields overlap due to cone coupling (Cohen and Sterling, 1992; Smith and Sterling, 1990). However, it strongly affects a wide-field cell because bipolar receptive fields are smaller than the extent of the convergent array (Demb et al., 2001a; Freed and Sterling, 1988). This important property of wide-field cells, which arises simply from their extent of spatial convergence, may be the clearest example at the circuit level of an “emergent property.”

SLUGGISH GANGLION CELLS: SMALLER, SLOWER, CHEAPER Nearly half of the ganglion cells fire “sluggishly.” Their spike autocorrelograms show a gradual rise and plateau, and their peak rates are ~10-fold lower than for brisk cells (Cleland and Levick, 1974a; DeVries and Baylor, 1997). The axons of sluggish cells are thin and slowly conducting (Stone and Fukuda, 1974). Consequently, their wire volume is minimal, occupying less than 5% of the optic nerve’s cross-section (Sterling, unpublished). Sluggish cells (also termed “W”) comprise many types with complex response properties, such as directional selectivity and local-edge detection (e.g., Caldwell and Daw, 1978; Cleland and Levick, 1974b; Rowe and Stone, 1976a, 1976b).

Sluggish types have been relatively little studied, partly because, compared to types that fire briskly, these cells seem somehow disadvantaged. Yet, this might actually imply a different coding strategy (Meister and Berry, 1999; Victor, 1999). A cell that responds only to motion of a local edge at low velocity carries fewer possible messages than a cell that responds to a wider range of stimuli. The simpler message might be encoded efficiently by fewer spikes that cost less in energy and in wire volume (Ames and Li, 1992; Ames et al., 1992; Attwell and Laughlin, 2001; Balasubramanian and Berry, 2002). For these benefits, slower conduction velocity seems to be an acceptable cost.

IS INFORMATION CONTENT THE SOLE DETERMINANT OF WIRE VOLUME? The hypothesis that wire volume matches information content arouses a healthy skepticism and thus needs some elaboration. The hypothesis tries to unify three facts: (1) axon thickness rises with number of output synapses; (2) the neurons with thicker axons and more outputs are the ones that transmit higher temporal frequen-

cies; (3) higher temporal frequencies transmit more information. Points 1 and 2 are illustrated in Figure 17.8, 17.13, and 17.14; point 3 comes from Shannon’s equation. The hypothesis claims that more synapses are required at the output because the information capacity of the synapse is limited (de Ruyter van Steveninck and Laughlin, 1996; Laughlin, 1994).

Of course, there may be other reasons why a neuron might need additional synapses and thus a larger axon. For example, the brisk-transient ganglion cell (but not the brisk-sustained cell) typically sends one branch to innervate the lateral geniculate nucleus and another branch to the superior colliculus. Thus, its greater axon thickness may be partly attributable to its greater number of boutons in the geniculate and partly to its need to support an additional arbor. In short, the hypothesis does not exclude additional determinants of wire volume.

Conclusion

Many features of retinal design seem interpretable as evolutionary adaptations to a surprisingly small number of lifestyle decisions and physical constraints:

1. Because mammals move fast, their photoreceptors must be small. Because mammals forage night and day, they need both rods and cones. So rods must be numerous and information poor, whereas cones can be sparse and information rich.
2. The two receptor arrays require different circuits. Rods must converge in large numbers—yet not accumulate noise that would swamp their information-poor signals. This requires several stages, each equipped to remove noise by nonlinear amplification. Cones must converge in smaller numbers—yet not allow their information-rich signals to saturate postsynaptic neurons. This requires bandpass filtering to reduce redundancy and noise.
3. The retina must remain thin and cannot increase its metabolic rate. Therefore, rod and cone circuits must jointly minimize total cellular volume and metabolic cost. Indeed, each circuit seems constrained to expend these quantities in proportion to its information content.

Some additional circuits (mainly amacrine) are known but not described here, and many additional amacrine circuits remain to be discovered. But quite likely their purposes will prove generally similar: to optimize signal transfer using various forms of neural adaptation or gain control. Many of the matches suggested here under the rubric of symmorphosis lack quantitative rigor. This suggests the next large task: to quantify for each retinal circuit, its information rate, metabolic cost, and wire volume, and to test quantitatively the relationships between these three variables. When this is accomplished, the retina will finally be “understood.”

Acknowledgments

I thank Drs. Robert Smith, Martin Wilson, and David Vaney for comments on the manuscript, and Sharron Fina for preparing it. My research has been supported by NEI grants EY00828 and EY08124. I thank Drs. Steven DeVries and Amy Harkins for providing unpublished data for Figures 17.9 and 17.13.

18 ON and OFF Pathways in the Vertebrate Retina and Visual System

RALPH NELSON AND HELGA KOLB

ON and OFF pathways are feature detectors

A key concept in visual system physiology is the notion of “feature detectors.” The idea of feature detection is that the visual system separates the visual image into components, much the way a publisher creates a color print by separating the picture into separate masks for different colored inks. The idea of feature detection was most forcefully presented by Lettvin et al. (1959) in the classic paper, “What the Frog’s Eye Tells the Frog’s Brain.” In this article, the authors described four different physiological classes of retinal output neurons, that is, four classes of retinal ganglion cells. Ganglion cell axons collectively bundle to form the optic nerve, transmitting visual information to brain visual centers. In this study, each of these classes of ganglion cells was found to be excited by a separate aspect of the visual image. Collectively, the cells sent the visual image to the brain decomposed as four separate channels. Among these four were ON-center and OFF-center cells, ganglion cells selectively specialized for the detection of *highlights* and *shadows*.

Clearly, highlights and shadows are two of the most fundamental features of images. In all vertebrate visual systems studied thus far, highlights and shadows are universally represented, not only by separate sets of ganglion cells, but by separate systems of cells throughout the retina and central nervous system. These are the ON and the OFF pathways. Researchers have come to understand the neural circuitry of these pathways, the cell types that are involved, their morphology and synaptic interconnections, the specialized neurotransmitter systems and receptors used, and the way in which these pathways project to, and are integrated by, the brain.

The lens of the eye projects an optical image of visual space onto the retina. The retina separates this optical image into multiple components. At the outset, this occurs at the photoreceptor level, where rods and cones report different image properties in parallel. Rods deal exclusively with dim signals of slowly varying brightness. Cones deal with bright signals and can detect rapid light fluctuations. Separate cone types sense wavelength with different efficiency, allowing the visual system to detect color. Thus, photoreceptors are the

first neurons in the visual chain to decompose the image into separate parts. The image is differentiated further into component elements at the first synapses of the visual pathway: the synapses between photoreceptors and bipolar cells. Here, typically a dozen different bipolar cell types selectively express different types of receptors for glutamate, the neurotransmitter released in light-modulated fashion by photoreceptors. These different glutamate receptors cause each bipolar type to respond to photoreceptor input in a different manner. As with rods and cones, some bipolar cells are tuned to faster fluctuations and some are tuned to slower fluctuations in the visual signal. There are some bipolar cells expressing rapidly desensitizing, rapidly resensitizing AMPA¹ receptors. AMPA¹ is an acronym for $\pm\alpha$ -Amino-hydroxy-5-methylisoxazole-4-propionic acid. There are others expressing the slowly resensitizing kainate receptors. These kinetic differences allow bipolar cells to respond selectively to different temporal components of visual signals (DeVries, 2000). However, the most extraordinary difference occurs between bipolar cells that express excitatory glutamate receptors versus those that express inhibitory glutamate receptors. Inhibitory glutamate receptors are an uncommon class, but are uniquely emphasized in vertebrate retinas. Excitatory and inhibitory glutamate receptors lead to OFF-center and ON-center bipolar cell responses, respectively. Together, these bipolar cells initiate a set of parallel visual pathways, for shadow and for highlight detection. These are the beginnings of the ON- and the OFF-center pathways.

ON and OFF signals are prominent in retinal field potentials

When the retina is exposed to light, a time-varying transretinal field potential develops. This is referred to as the electroretinogram (ERG). The waveform of the ERG proceeds through a sequence of peaks and troughs. The sequence at light onset and at light offset is roughly similar (Fig. 18.1). Although not a proof, this pattern is certainly suggestive of separate and parallel processes involved in detection of light onset and offset, corresponding to highlights and shadows, respectively. The description of these similar ON and OFF waves of the ERG in a variety

of vertebrate species is generally attributed to Ragnar Granit (1935), winner of a Nobel prize for retinal physiology in 1967. Although all species tested have prominent ON response components, those with high cone density exhibit the greatest OFF component. This difference is attributed to two factors. The first is the relatively sluggish responses of the rods themselves to light offset. The second is a separate and different neural organization within the retina for the processing of rod and cone signals. Figure 18.1 demonstrates the ERG response of a zebrafish eye, typical of cone-dominated retinal responses. The electrical responses at light onset and light offset both exhibit positive-going waves, as if arising from parallel, yet similar, processes. The corneal positive response at light onset is called the b wave. The comparable response at light offset is called the d wave.

Discovery of ON and OFF ganglion cells

Although ERG responses are suggestive, in themselves they are not uniquely interpretable. To help resolve the way the retina actually works, one needs to identify the light responses of individual neurons. This was first achieved by recording the impulse activity of individual nerve fibers in the frog retina (Hartline, 1938). Using the technology available at the time, Hartline lifted bundles of optic nerve fibers onto a cotton wick electrode, similar to the sort used to record ERGs, but much finer. Amplification sometimes consisted of just a single vacuum tube. There were no oscilloscopes. A string galvanometer was used to project a vibrating beam of light onto a moving motion picture film at some distance across a dark room. One would be fortunate to find

FIGURE 18.1. Light-evoked electrical response of in vitro zebrafish eye. Distinct and nearly symmetrical responses to light onset and light offset are evident. This suggests parallel systems for handling these stimulus events. The a wave (A) is generally attributed to a combination of photoreceptor onset response and inner retinal processing. The b wave (B) response arises, directly or indirectly, from the activity of ON-type bipolar cells. The d wave (D) response arises from the activity of OFF-type bipolar cells. Stimuli are white (xenon arc) and photopic, in the cone range of action. (From Wesolowska et al., 2002.)

such a device in a technological museum today. Nonetheless, recordings of impulse activity from single, isolated, ganglion cell axons were, for the first time, documented by this technique. These impulses were the visual signals sent from retina to brain.

What Hartline found was not a single, monolithic pattern of responses to light, but three different patterns. His classic results appear in Figure 18.2. Although modern recordings are of higher technical quality, in many cases, they represent only a refinement of Hartline's original design. The upper tracing in Figure 18.2 illustrates an ON cell. In addition to a heightened discharge at stimulus onset, it maintains a steady stream of impulses throughout the light stimulus. This stimulus is a small spot positioned in the center of the cell's receptive field. The idea of receptive field is also a concept developed by Hartline (1940). Receptive field defines the restricted regions of space over which ganglion cells respond to photic stimulation. In this region, there is a center of peak sensitivity. The middle tracing in Figure 18.2 illustrates a fiber that exhibits bursts of discharges at stimulus onset and offset, but that is otherwise quiet. This is an ON-OFF retinal ganglion cell. The lower tracing (see Fig. 18.2) shows a ganglion cell fiber with a burst of impulse activity only at stimulus offset. This is the response of an OFF-type retinal ganglion cell.

The multiplicity of light responses in frog ganglion cells surprised Hartline because in parallel studies of invertebrate vision, only a single response pattern had been

FIGURE 18.2. Hartline's early recordings from retinal ganglion cell axons revealed three different impulse discharge patterns in response to spots of light centered in the receptive field. The ON cell gives a burst of activity at stimulus onset, followed by a maintained discharge during the stimulus. The OFF cell has no discharge during light stimulation, but gives a burst of activity followed by prolonged spiking when the stimulus is turned off. The ON-OFF cell responds with transient bursts of activity at both light onset and offset. (From Hartline, 1938.)

observed: excitation to light (Hartline and Graham, 1932). The results suggested that a good deal of information processing took place within the retina, and this discovery sowed the seed for the development of the notion of parallel visual channels and feature detection. Keffer Hartline won the Nobel Prize in 1967 for his work on the frog's visual system.

Sustained and transient ON and OFF pathways

As mentioned earlier, Lettvin and colleagues (1959) extended the number of physiological ganglion cell types from the three described by Hartline to four. The current theory is that there are about a dozen different physiological types of ganglion cell (Cleland and Levick, 1974b; DeVries and Baylor, 1995). Different types typically project to distinct brain centers. The most sophisticated types are directionally selective ganglion cells. These are excited by movements in one direction, but inhibited by movements in the opposite direction (Barlow and Hill, 1963). Although such cells can be classified, on the basis of stationary spot stimulation, as either ON, ON-OFF, or OFF types, clearly, highlights and shadows are not their specialty. These cells respond equally well to bright or dark objects, so long as the direction of motion is the preferred one.

Among different physiological types of ganglion cell are several distinct classes of ON and OFF center types. The most prominent of these are X (brisk-sustained) and Y (brisk-transient) types (Cleland and Levick, 1974a; Enroth-Cugell and Robson, 1966). X and Y types each come as ON-center and OFF-center varieties, comprising a net of four separate channels from retina to brain: X_{ON} and X_{OFF} , Y_{ON} and Y_{OFF} . X and Y types are distinguished by a battery of properties. Y cells are large in dendritic and receptive field and fast in axonal conduction velocity. Typically, Y-cell processes cover a circular region that is 500 μm in diameter at the surface of the cat retina. These cells are relatively low in density ($\sim 20/\text{mm}^2$). They are excited vigorously by image changes within their receptive field, but appear relatively less interested in standing contrast. These cells are thought to provide a high-speed alerting function for changes in the visual environment. X cells, by contrast, are relatively smaller cells, with dendritic processes covering a diameter of just a few tens of micrometers at the cat retinal surface. They have a high density ($\sim 2000/\text{mm}^2$). They have slower conduction velocities to the brain than Y cells, and respond patiently and in a sustained fashion to steady image patterns. These are thought to be high-acuity cells for fine visual discrimination (Wässle and Boycott, 1991). Comparable sets of cells exist in the primate retina, termed parasol (P) and midget (MP) cells, respectively.

Impulse discharge patterns of an X_{OFF} and a Y_{OFF} cell are shown in Figure 18.3. The stimulus is a one-dimensional

spatial-sine-wave grating, covering a large area of retina. This stimulus is designed to arise suddenly from a homogeneous background of equal mean luminance. When the position of the sine wave is adjusted so that stimulus presentation brightens the receptive field center, the X_{OFF} cell responds with a sustained increase in firing to stimulus withdrawal (see Fig. 18.3, X-type). When the position is adjusted so that the center darkens, the X_{OFF} cell responds with a maintained decrease in firing to stimulus withdrawal. Sustained responses to standing stimuli are characteristic of X cells. For stimulus phases positioned in between, there is a null in the X-cell response. The null suggests net spatiotemporal linearity for X cells; that is, the time course and amplitude of signals arising from regions of the field that are inhibited by increases in brightness are exactly canceled by excitatory signals arising from receptive field regions where brightness is reduced.

No such null positions appear in the Y-cell response (see Fig. 18.3, Y-type). For intermediately positioned stimuli that might be expected to evoke a null response, excitations at both insertion and removal of the stimulus are seen instead. This seems reasonable, as responses to introduction and withdrawal of the stimulus for centered stimuli are far from

FIGURE 18.3. Spatial properties of X- and Y-type cat retinal ganglion cells. X- and Y-type cells occur in both ON- and OFF-center varieties. OFF types are illustrated here. The stimulus, a one-dimensional spatial-sine-wave grating, is designed to test linearity of spatial summation. This patterned stimulus is turned on from a homogeneous background of equal mean luminance (upward deflections of lowermost traces). As the spatial phase of the stimulus is shifted in respect to the ganglion cell's receptive field, nulls can be found in the X-cell response, indicating spatiotemporal linearity. No such spatial null is recorded for the Y cell. The records are spike-frequency histograms with units of impulses per second. Each record is 2 seconds in length. Downward deflections of the lower traces indicate withdrawal of the pattern. (From Enroth-Cugell and Robson, 1966.)

mirror-symmetric in Y cells. Onset and offset responses are not treated equivalently at any stimulus position: the cell is said to be temporally nonlinear. The mechanisms generating such different waveforms in X cells and Y cells appear not to be intrinsic to the ganglion cells themselves, but rather to selective innervations by physiologically different sets of bipolar cells (Demb et al., 2001). Using the electron microscope, only a single bipolar type can be seen to innervate individual Y cells (Freed and Sterling, 1988; Kolb and Nelson, 1993), whereas two to three types innervate individual X cells (Cohen and Sterling, 1991; Kolb and Nelson, 1993; McGuire et al., 1984). Golgi, flat-mount images of tiny X_{ON} and X_{OFF} beta cells can be seen embedded amongst the dendrites of a much larger Y_{ON} alpha cell in Figure 18.4, together with characteristic stratification patterns, as discussed in a later section.

Discovery of ON and OFF bipolar cells

Retinal ganglion cells are typically only two synapses distant from retinal photoreceptors, yet ganglion cell responses are far more diverse than those of photoreceptors. The most direct pathway from photoreceptors to ganglion cells is through retinal bipolar cells. Thus, it is of great interest to understand how bipolar cells function and, indeed, how all retinal interneurons respond to photic stimuli and interact through synapses and retinal circuitry to produce the diverse types of ganglion cell responses through which visual information is reported to the brain. Extracellular electrodes of the glass or metal type, typically used for ganglion cell recordings, are of little use for recording interneurons within the retinal depths, as impulse activity is rarely produced. Rather, sharp electrode recording holds the greatest promise. With these electrodes, one can penetrate cell membranes and record not only impulse activity, but maintained changes in membrane potential in response to stimuli. Werblin and Dowling (1969) advanced the art of sharp electrode recording in the retina using ultra-high impedance microelectrodes ($10^9\Omega$), and they were among the first to use biological amplifiers based on high-input impedance ($10^{13}\Omega$) field effect transistors. They also introduced intracellular marking of retinal neurons through electrophoretic stain injection. They developed the mudpuppy retina as an animal model of vision processing. This was largely for technical reasons; retinal interneurons in this species are uniformly large and good microelectrode targets. This species, and the closely related tiger salamander, have remained favorites for studies of retinal circuitry. Werblin and Dowling (1969) proposed a physiological, organizational scheme, not just for bipolar cell responses, but for all retinal interneurons. Present research on retinal information processing is, in many cases, based on refinement or modification of the Werblin and Dowling scheme.

FIGURE 18.4. Flat-mount images of Golgi-stained ON and OFF beta (X-type) ganglion cells in cat retina. Beta dendritic fields are embedded among the dendrites of a much larger ON alpha (Y-type) ganglion cell. *A*, Dendrites of an ON-center beta ganglion cell in the cat retina occupy a plane of focus (*left*) near ganglion cell bodies. The dendrites of an overlying ON alpha (Y-type) ganglion cell cross the field from top to bottom in the same focal plane. This plane is in sublamina *b* of the IPL. *B*, Another, similar-appearing beta ganglion cell lies with its dendritic tree in sharp focus (*right*) deeper in the IPL. This is an OFF-center beta (X-type) ganglion cell. The dendritic plane of focus is in sublamina *a*. ON-type dendrites do not occupy this plane. (From Wässle et al., 1981a.)

Werblin and Dowling (1969) posited that retinal bipolar cells lack impulse activity, and that they process visual signals through integration of synaptic and voltage-gated currents alone. This theory persists. Sodium channels, required for the generation of impulse activity, have not been observed in retinal bipolar cells (Connaughton and Maguire, 1998; Karschin and Wässle, 1990; Lasater, 1988), although under conditions of dark adaptation, 50-msec-long Ca^{2+} spikes have been found in some rod bipolar cell presynaptic terminals (Protti and Llano, 1998). Recent studies have reported voltage-gated Na^+ currents in some cone bipolar cells (Pan and Hu, 2000; Zenisek et al., 2001), though these do not produce spikes.

Werblin and Dowling (1969) proposed also that retinal bipolar cells come in two fundamental varieties: ON-center and OFF-center types (Fig. 18.5). ON-center types were found to be depolarized by small spot stimuli positioned in the receptive field center. OFF-center types were hyperpolarized by the same stimuli. Both types were repolarized by light stimulation of the peripheral receptive field outside the center (see Fig. 18.5). This is the classic, antagonistic, center-surround organization also described for ganglion cell receptive fields (Kuffler, 1953). ON-OFF bipolar cells were not encountered. ON-OFF responses, as described by Hartline (1938), occurred only among neurons at least two synapses removed from photoreceptors. This was the major response type among mudpuppy retinal amacrine cells (Werblin and Dowling, 1969). Thus, although true ON-OFF pathways to brain visual centers exist (Isayama et al., 2000), they originate in the proximal, not the distal retina.

Anatomical investigations of bipolar cells reveal typically a dozen different types in each species (Connaughton and Nelson, 2000; Euler et al., 1996; Kolb et al., 1981; Wu et al., 2000), more than just the two that early physiology implied. Nonetheless, all of these are either ON or OFF types. Their diversity results from other factors, such as differing connectivity with photoreceptors. There are bipolar cells devoted to rods, and others devoted to cones. There are wide-field and narrow-field types, and there are cells expressing various subvarieties of glutamate receptors so as to extract different aspects of the photoreceptor glutamate signal.

FIGURE 18.5. ON and OFF pathways begin with retinal bipolar cells. Intracellular recordings from mudpuppy retina reveal two sorts of retinal bipolar-cell light responses: those that are hyperpolarized by central illumination (OFF bipolar cell) and those that are depolarized by central illumination (ON bipolar cell). In each case, membrane potential is restored by concomitant illumination of annular regions surrounding the center. Such responses are typically 10 mV in amplitude. They always lack impulse activity. No ON-OFF responses are found. The absolute response latency to the light step is about 100 msec for these suprathreshold stimuli. (From Werblin and Dowling, 1969.)

Different glutamate receptor populations in ON and OFF bipolar cells

ON BIPOLAR CELLS Photoreceptors release only one neurotransmitter—glutamate (Ayoub and Copenhagen, 1991)—yet bipolar cells react to this stimulus with two different responses: ON and OFF. The first investigations into the underlying receptor mechanisms revealed different conductance changes associated with the two responses. The conductance of ON bipolar cells increased in the light, whereas OFF bipolar cell conductance decreased (Nelson, 1973; Toyoda, 1973). The conductance decrease of OFF bipolar cells was easily explained as a loss of excitation by glutamate released from photoreceptors in the dark. The conductance increase in the light, with a positive reversal potential (Nelson, 1973), implied that glutamate was blocking a cation-permeable channel. This was the first evidence of what is now known as *metabotropic* glutamate receptors. These receptors do not form ion channels themselves, but act as isolated antennae on the cell surface, sensing glutamate and activating intracellular pathways and mechanisms that can indirectly affect membrane potential. Whereas elsewhere in the brain, these receptors are involved in regulating synaptic transmission and modifying the activity of voltage-gated channels, thus altering the tuning of neural circuits (Conn and Patel, 1994), in the retina, they are used uniquely in a direct signal transmission pathway: from photoreceptors to ON bipolar cells.

Slaughter and Miller (1981) were the first to observe that the metabotropic glutamate agonist 2-amino-4-phosphonobutyric acid (APB or DL-AP4; it is the L enantiomer that is effective) completely blocks the light responses of ON bipolar cells. In ON bipolar cells, APB acts as a substitute for photoreceptor-released glutamate (Fig. 18.6). These neurons, in the mudpuppy retina at least, use only a metabotropic pathway to sense light-induced variations in photoreceptor glutamate. It is the metabotropic glutamate receptor mGluR6 that is expressed in ON bipolar cells (Nakajima et al., 1993; Nomura et al., 1994). Transgenic knockout mice lacking the mGluR6 gene lack ERG b-wave responses (Fig. 18.7), reflecting a loss of ON bipolar activity (Masu et al., 1995). In addition to mGluR6, the G protein G_o is cytoplasmically localized in the dendritic tips of ON bipolar cells (Vardi et al., 1993). Removal of G_{α_o} by knockout results in loss of ON responses in such mutant mouse retinas (Dhingra et al., 2000), similar to the mGluR6 knockout. This suggests that G_o is directly in the pathway between mGluR6 activation by photoreceptor glutamate and the closing of nonselective cation channels, which leads to the ON response. The exact cascade by which this happens is still unclear; however, it appears that intracellular cyclic guanosine monophosphate (cGMP) is not a

FIGURE 18.6. Metabotropic glutamate receptors in the ON pathway. The glutamate agonist 2-amino-4-phosphonobutyric acid (APB, later terminology DL-AP4) interferes with light responses and membrane physiology of ON-center bipolar cells in mud-puppy retina. *A*, APB abolishes light responses (the rectangular depolarizing events), hyperpolarizes the membrane potential, and increases the membrane resistance. The latter is measured by the size of voltage responses to an injected current pulse (arrows). *B*, Here, 3 mM of cobalt, a blocker for synaptic release of glutamate from photoreceptors, abolishes light responses in an ON bipolar cell and depolarizes the membrane potential. The membrane potential can later be restored by application of APB, which acts as a substitute for the cobalt-blocked photoreceptor glutamate. As APB is selective for a subset of metabotropic glutamate receptors, synaptic transmission of light responses to ON bipolar cells must rely on a metabotropic mechanism. (From Slaughter and Miller, 1981.)

carrier of the light signal as previously suspected (Nawy, 1999).

Metabotropic receptors for ON-center bipolar cells have both sustained and transient subtypes (Awatramani and Slaughter, 2000). The molecular basis is not yet known; however, it appears increasingly likely that sustained and transient responses of ON-center ganglion cells, such as the classic X- and Y-types, may have their origin, at least in part, in the types of glutamate receptors expressed by selectively innervating bipolar cells (Demb et al., 2001).

Ionotropic receptors also exist for ON-center bipolar cells. When these receptors are activated by glutamate released from photoreceptors, a chloride conductance is activated, thus hyperpolarizing the cells in the dark (Fig. 18.8). Release from this inhibition occurs in the light, and bipolar cells depolarize (see Fig. 18.8). The receptor is related to glutamate transporters and requires $[Na^+]_o$. Thus far, this mechanism has been found only in bipolar cells of teleosts (Connaughton and Nelson, 2000; Grant and Dowling, 1995; Grant and Dowling, 1996), although it has been reported in both turtle and salamander photoreceptors (Grant and Werblin, 1996; Picaud et al., 1995; Tachibana and Kaneko, 1988) and in mammalian central nervous system (Otis and Jahr, 1998). The ionotropic mechanism is used for maintained transmission between cones and bipolar cells in

FIGURE 18.7. Light-evoked responses from the eye of a wild-type mouse (+/+) and a mutant mouse (-/-) deficient in the gene encoding mGluR6, the metabotropic glutamate receptor used in ON bipolar cells. The b wave, which originates in the light responses of ON bipolar cells, is absent in the mutant mouse. (From Masu et al., 1995.)

teleost retinas (Saito et al., 1981), and is likely to be a fast mechanism as compared to metabotropic pathways which are often relatively slow (Nelson, 1973).

OFF BIPOLAR CELLS Like ON bipolar cells, OFF bipolar cells express a diversity of glutamate receptor types. In the case of OFF bipolar cells, all the receptors are ionotropic; none are metabotropic. There are three principal types of ionotropic glutamate receptor: AMPA, kainate, and *N*-methyl-D-aspartate (NMDA). OFF bipolar cells have never been observed to utilize NMDA receptors, but in the retina of the ground squirrel, there are types that selectively express either AMPA or kainate receptors (DeVries, 2000; DeVries and Schwartz, 1999). These receptors resensitize at different rates after exposure to glutamate (Fig. 18.9), and as a result, emphasize different temporal characteristics of the light signal.

Kainate-type glutamate signals are able to transfer the sustained characteristics of the visual stimulus. AMPA receptors are more selective for the transient components of the signal (DeVries, 2000). The situation is interesting in that neurons that use kainate receptors exclusively are rare in the central nervous system. Nonetheless, AMPA and kainate receptors on retinal bipolar cells are pharmacologically well behaved. Bipolar-cell, AMPA-type responses can be suppressed by the lipophilic AMPA receptor antagonist, GYKI 52466. This ligand does not affect glutamate responses originating from OFF bipolar cells expressing kainate-type receptors. Conversely, bipolar-cell kainate-type

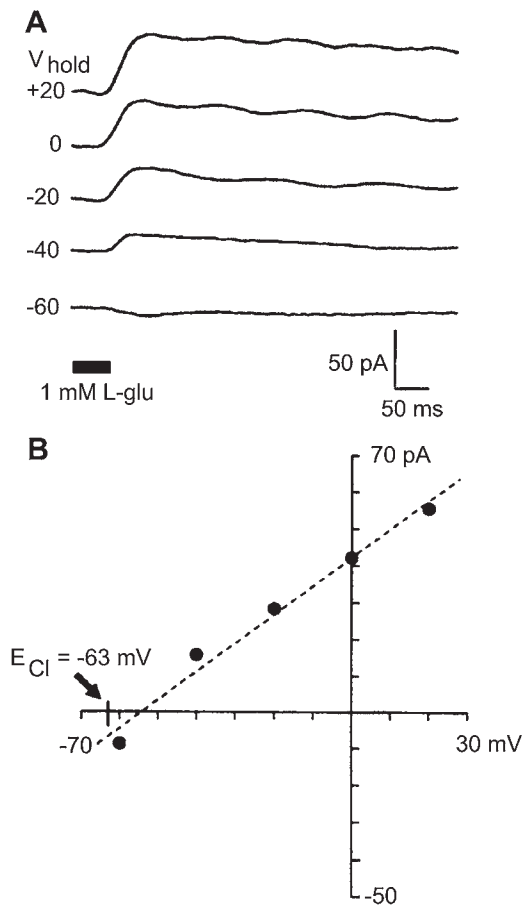

FIGURE 18.8. Ionotropic chloride mechanism for the ON pathway. Puffs of glutamate mimic photoreceptor release in patch recordings from bipolar cells in a zebrafish retinal slice. *A*, Glutamate-evoked currents are outward for physiological ranges of membrane potential, which is consistent with an ON-center mechanism. *B*, The -63 mV reversal potential is consistent with a model in which photoreceptor glutamate opens chloride channels. (From Connaughton and Nelson, 2000.)

responses are blocked by the desensitizing kainate receptor agonist, SYM 2081. This ligand does not interact with bipolar cells that express AMPA receptors (DeVries, 2000).

Although all retinas contain ON and OFF pathways, it is easy to imagine that, among these pathways, natural selection would cause divergence, depending on the visual requirements of the species. The need to flee quickly at the sign of a shadow would be an example. Species diversity appears to be the case. As mentioned earlier, functional ionotropic glutamate channels in ON-type bipolar cells appear to be expressed exclusively in fish retinas. Conversely, in salamander retina, OFF bipolar cells appear to utilize only AMPA receptors (Maple et al., 1999). This may also be the case in zebrafish retina. In this species, dissociated cells fail to respond to the kainate agonist, SYM 2081 (Nelson et al., 2001), and ERG-recorded OFF responses (d waves) are

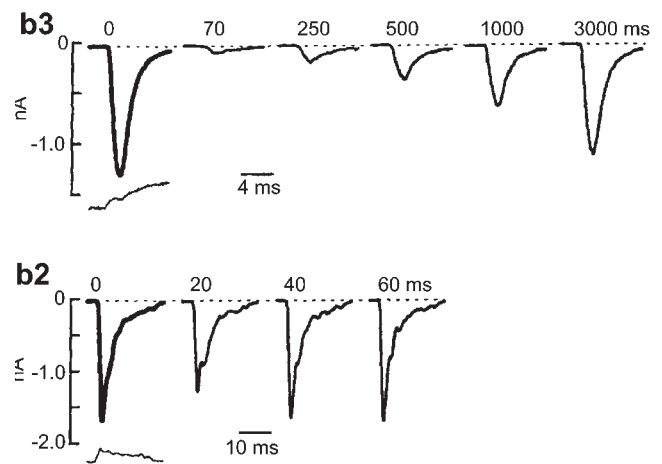

FIGURE 18.9. Different OFF bipolar cells respond to photoreceptor glutamate release with different resensitization rates. In whole-cell patch recordings from ground squirrel retina, bipolar cells are desensitized to an initial glutamate pulse (0). The time course of recovery is followed by the response to a second pulse after different delays. Type b3 bipolar cells use kainate-type glutamate receptors and require several seconds for complete recovery. Type b2 bipolar cells use AMPA-type glutamate receptors and recover 100 times faster. (From DeVries, 2000.)

blocked by the AMPA antagonist, GYKI 52466, but not the kainate-desensitizing agent, SYM 2081 (Wesolowska et al., 2002). One might expect also that, even within the broad classes of AMPA and kainate receptors, subforms may have evolved to fit particular visual niches. This appears to be the case. In the salamander retina, there appear to be separate classes of AMPA receptors that are postsynaptic to rods and to cones (Kim and Miller, 1993; Maple et al., 1999). Thus, the process of splitting the visual signal into multiple pathways tuned to selective visual features begins with differentiation of different photoreceptor types and is greatly elaborated at the synapses between photoreceptors and bipolar cells.

ON and OFF stratification in the inner plexiform layer

GANGLION CELLS In work performed at the National Institutes of Health in the mid-1970s, a collaborative study by Ralph Nelson, Helga Kolb, and Ted Famiglietti revealed that the ON or OFF property of cat retinal ganglion cells was related to the level of stratification of dendrites within the retinal inner plexiform layer (IPL). In Golgi studies, pairs of cells were often found that were otherwise identical, except for stratification level. An example of this appears in Figure 18.4, where two adjacent beta cells are stained. The dendrites of these cells occupy entirely different planes of focus. Beta ganglion cells, with their characteristic compact, bushy, dendritic arbors, are associated with X-type physiological responses (Boycott and Wässle, 1974). Similar

stratification pairing was also found in cat alpha ganglion cells. These are cells with very wide dendritic arbors, particularly narrowly stratified in either of just two IPL bands. Alpha cells are the morphological types associated with Y-type physiological responses (Boycott and Wässle, 1974).

Famiglietti and Kolb (1976) proposed that anatomically paired cell types were, in fact, the physiological ON and OFF types. At roughly the same time, intracellular marking experiments were progressing in an adjacent laboratory (Nelson et al., 1978). These marking experiments generated direct evidence that the theory was not only true, but also held for all morphological types of ganglion cell, regardless of whether they were paired types. This led to the schema illustrated in Figure 18.10. The dendrites of OFF-center ganglion cells always arborize distal to the dendrites of ON-center ganglion cells. The zone of OFF-center dendritic arborization is called sublamina *a*, whereas the zone of ON-center dendritic arborization is called sublamina *b* (see Fig. 18.10). Within each sublamina, ganglion cells make selective contacts with ON- or OFF-type bipolar cells. The pattern of ON and OFF layering of ganglion cells in the IPL, originally discovered in cat retina, has proved to be general and applicable to other vertebrate retinas, including rabbit (Amthor et al., 1989b; Bloomfield and Miller, 1986).

ON and OFF stratification is particularly pronounced in retinas in which ganglion cell types are predominantly monostратified. In more anatomically complex retinas, such as in the turtle, which has many multistratified or diffusely stratified ganglion cell types, the branching rule still applies to monostратified types, but is more difficult to apply

with the others. Nonetheless, even among multistratified ganglion cell types, it appears that morphological and physiological patterns are closely linked (Ammermüller and Kolb, 1995).

The discovery of ON and OFF layering in the IPL has generated further conjecture, namely, the theory that true ON-OFF ganglion cell types would be bistratified, receiving OFF inputs from sublamina *a*, and ON inputs from sublamina *b*. In fact, there is such a population of ON-OFF cells in the cat retina (Isayama et al., 2000). Moreover, there is a major class of ON-OFF, directionally selective cells in the rabbit retina, also bistratified (Amthor et al., 1989a). On a further variation of the theme, a blue-ON, yellow-OFF color opponent cell in the primate retina has been found to be bistratified. Blue excitation arises from the dendrites stratified in sublamina *b*, whereas yellow inhibition arises from dendrites stratified in sublamina *a* (Dacey and Lee, 1994).

The discovery of ON-OFF stratification also prompted a reevaluation of the spatial distributions of alpha and beta cat ganglion cells, as spatial mosaics are thought to govern spatial acuity (DeVries and Baylor, 1997; Wässle and Boycott, 1991). When this was done, it was discovered that Y_{ON} types and Y_{OFF} types were individually much more regularly arranged than the combined ON-OFF grouping (Peichl and Wässle, 1981; Wässle et al., 1981b). The same was found for X_{ON} and X_{OFF} types (Wässle et al., 1981a). Nonetheless, the ON and OFF mosaics themselves appear to be linked spatially (Zhan and Troy, 2000). In situations in which ganglion cell mosaics limit visual acuity, such as with the beta ganglion cells of cat retina, it is an open question whether the

FIGURE 18.10. ON and OFF stratification patterns in the retinal inner plexiform layer (IPL). OFF ganglion cell dendrites (OFF α GC and OFF β GC) and OFF cone bipolar (OFFcb) cell axons costratify in sublamina *a* of the IPL. ON bipolar axons (ONcb) and ON ganglion cell (ON α GC and ON β GC) dendrites costratify in

sublamina *b* of the IPL. Thus, the sign of the cone bipolar response generated at the cone pedicle through different glutamate receptor mechanisms is faithfully passed to ganglion cells through separate systems of connections within the neuropil of the IPL. These are the parallel ON and OFF cone-system pathways. (See color plate 6.)

limit is achieved jointly or separately among ON and OFF systems.

CONE BIPOLAR CELLS The work of DeVries (2000) and Awatramani and Slaughter (2000) suggests the hypothesis that each bipolar cell type expresses a unique glutamate receptor, and that this receptor expression is somehow linked to a corresponding, discrete, axonal layering pattern within the IPL. That is an exciting scheme to contemplate. At present, though, what appears to be generally true is that axon terminal arborizations of OFF-type bipolar cells lie in sublamina *a*, together with the dendrites of OFF-type ganglion cells, whereas the axon terminal arborizations of ON type bipolar cells lie in sublamina *b* of the IPL, together with the dendrites of ON-center ganglion cells. This is the classic circuitry model (see Fig. 18.10) put forward by Nelson et al. (1978) and Famiglietti and Kolb (1976). Indeed, direct, selective, synaptic contacts between OFF bipolar cells and OFF ganglion cells within sublamina *a*, or ON bipolar cells and ON ganglion cells within sublamina *b*, have been observed with the electron microscope (Cohen and Sterling, 1991; Kolb, 1979; Kolb and Dekorver, 1991; Kolb and Nelson, 1993; McGuire et al., 1984; Nelson and Kolb, 1983). Synapses between unmatched pairs of bipolar and ganglion cells are never observed, even where processes come in close proximity (Kolb, 1979).

After studying salamander retina, Awatramani and Slaughter (2000) proposed a further refinement of the stratification scheme for bipolar cell axons. They suggested that bipolar cells with a glutamate receptor physiology that emphasized transients in the visual pattern were layered more toward the center of the IPL, whereas those with receptor patterns emphasizing sustained contrast were layered more toward the inner and outer edges of the IPL. Such a pattern would be in agreement with the layering of the sustained X- and transient Y-type ganglion cells of the cat retina, as well as the P and M cells of the primate retina. Wu et al. (2000) discovered a similar pattern, but attributed it to the expression of fast signals from cone bipolar terminals in the middle of the IPL, and the expression of slow signals from rod bipolar terminals at both edges of the IPL. Although this further overlay of functional organization within the IPL is exciting to contemplate, most of the evidence is as yet limited to one species.

Relatively exhaustive correlations of ON or OFF bipolar cell physiology with axonal stratification patterns are now available for several species. These involve measurements of light responses or, as a surrogate for light responses, dendritic glutamate responses, coupled with observations of axonal morphology through microelectrode staining. In rat retina, bipolar-cell, axon-terminal arborization appears to obey perfectly the rule of ON and OFF layering. Five cone bipolar-cell morphological types with axons branching in the

outer half of rat IPL were identified. These responded with inward currents when stimulated with kainate. This is the response appropriate to OFF bipolar cells. Of a combined total of 15 recordings, only 1 of these *a*-layered cells responded to APB (DL AP-4), a glutamate agonist selective for ON-center bipolar cells. Three cone bipolar cell types with axons branching in the inner half of rat IPL were identified. In net, 12 of 14 of these *b*-layered cells responded with outward currents to APB, whereas only 1 responded to kainate (Euler et al., 1996). This suggests better than 90% compliance with the ON and OFF stratification rule for bipolar cell axon terminals in rat retina. A limited number of recordings in cat and monkey retinas also suggest that there may be good adherence to this pattern (Dacey and Lee, 1994; Nelson and Kolb, 1983). The salamander retina too appears to be in excellent compliance with ON and OFF stratification of bipolar cell axon terminals (Wu et al., 2000), as does carp retina (Famiglietti et al., 1977; Saito et al., 1985).

This orderliness breaks down to some extent in species in which multistratified, bipolar cell axons are common. Although monkeys and cats have some multistratified cells (Kolb et al., 1981; Mariani, 1983), these types are very much more common in lower vertebrates, such as birds, reptiles, and fishes, or cone-dominant mammals, such as squirrels. Such types are typically cone-contacting bipolar cells (Scholes, 1975), and so may be characteristic of cone-dominated species. Where broad or multistratified patterns are restricted to either the ON or the OFF sublaminae, the ON and OFF stratification rules apply, but not where the axonal stratification pattern crosses the ON-OFF boundary. In this case, cells may be either ON-type or OFF-type (Ammermuller and Kolb, 1995; Connaughton and Nelson, 2000; Wu et al., 2000). In some cases, such multistratified bipolar cells may even express both physiologies (Wu et al., 2000). Stratification patterns of bipolar axon terminals of the zebrafish retina represent this more general vertebrate pattern (Fig. 18.11). Bipolar cells with one or two terminal boutons restricted either to sublamina *a* or sublamina *b* obey the ON and OFF stratification rule. OFF cells branching in sublamina *a* express AMPA/Kainate-type receptors. ON cells branching in sublamina *b* express either or both of two inhibitory glutamate mechanisms: ionotropic or metabotropic. Multistratified bipolar cells with boutons in both sublaminae may be either ON or OFF types. Multistratified ON types use only the inhibitory ionotropic glutamate mechanism (Connaughton and Nelson, 2000).

ROD BIPOLAR CELLS Rod bipolar cells represent a unique case. Judged by the axonal stratification pattern and contacts with photoreceptors, there is only a single class of rod bipolar cell in mammals (Cajal, 1972; Kolb, 1970). The

FIGURE 18.11. ON and OFF stratification patterns of bipolar-cell axon terminals in zebrafish retina. Monostratified or bistratified cells with terminal boutons only in sublamina *a* express AMPA/Kainate receptors (AMPA/KA) appropriate to OFF-type bipolar cells (OFF BCs). Those with either one or two boutons only in sublamina *b* express metabotropic (APB-sensitive) glutamate receptors, glutamate-gated chloride channels (I_{glu}), or both. These receptors are both appropriate for ON center cells. Bistratified or tristratified cells with terminal boutons in both sublaminae *a* and *b* express either AMPA/KA, an OFF-type receptor, or I_{glu} , an ON-type receptor. Curiously, metabotropic ON receptors are not seen in *a/b* branching cells, perhaps because these are cone-selective types. (From Connaughton and Nelson, 2000.)

bulbous axon arborizes deep in the ON sublamina of the IPL, just adjacent to ganglion cells. The rod bipolar cell is an ON type (Dacheux and Raviola, 1986), using metabotropic APB-sensitive, glutamate receptors (de la Villa et al., 1995; Yamashita and Wässle, 1991).

For the rod signals transferred by rod bipolar cells, ON and OFF pathways begin in the IPL. This bipolar cell does not contact ganglion cells directly, but instead contacts amacrine cells. It is the AII rod amacrine cell (Kolb and Famiglietti, 1974; Nelson, 1982) that is the intermediary in transferring rod bipolar signals to ON and OFF cone bipolar pathways. It achieves this through direct innervation of cone bipolar processes within the IPL. Cone bipolar cells also participate, even without amacrine intermediation, in transferring ON and OFF rod signals from the distal to the proximal retina. This occurs because of direct rod-cone interphotoreceptor contacts, a pathway emphasized in higher

mammals (Kolb, 1977; Nelson, 1977; Raviola and Gilula, 1973; Smith et al., 1986; Tsukamoto et al., 2001). It may also occur through direct dendritic contact of cone bipolar cells with rods (Dacheux, 1982; Hack et al., 1999; Ishida et al., 1980; Jacobs et al., 1976; Lasansky, 1973; Stell, 1977; Tsukamoto et al., 2001), a pathway particularly prominent in lower vertebrates.

AMACRINE CELLS Amacrine cells are interneurons of the retinal IPL. Most of them are inhibitory and release either gamma-aminobutyric acid (GABA) or glycine. Although this class of cells contains both ON, OFF, and ON-OFF light responses (Ammermüller and Kolb, 1995; Bloomfield and Miller, 1986; Kolb and Nelson, 1996; Naka et al., 1975; Nelson, 1982; Nelson and Kolb, 1985; Werblin and Dowling, 1969), it is among the least obedient to ON and OFF layering within the IPL. Only the widely studied cholinergic “starburst” amacrine cells consistently follow this rule (Bloomfield and Miller, 1986; Famiglietti, 1991; Tauchi and Masland, 1984; Taylor and Wässle, 1995). Starburst amacrine cells are prominent, monostratified types found in morphological pairs, one monostratified in sublamina *a*, the OFF type, and the other monostratified in sublamina *b*, the ON type. These cells provide additional center excitation selective for moving stimuli to ON- and OFF-type retinal ganglion cells (He and Masland, 1997).

Even in retinas with predominantly monostratified bipolar and ganglion cells, such as those in the cat (Kolb et al., 1981) or human (Kolb et al., 1992), about half of amacrine types arborize in both ON and OFF IPL sublaminae. Broadly stratified amacrine cells may be either ON or OFF types (Ammermüller and Kolb, 1995; Kolb and Nelson, 1996). Furthermore, monostratified ON-OFF amacrine types are commonly encountered (Ammermüller and Kolb, 1995; Freed et al., 1996; Jensen and DeVoe, 1982), although other ON-OFF types are clearly bistratified (Ammermüller and Kolb, 1995).

Cross-correlation in the firing patterns of retinal ganglion cells suggests that amacrine cells, and particularly broadly stratified types, provide for cross talk between ON and OFF pathways (Mastrorade, 1983a, 1983b). The AII amacrine cell of mammalian retinas may be thought of as the archetypical example of the broadly stratified amacrine pattern. The AII cell is a narrow-field, concentric, ON-center cell (Bloomfield, 1992; Dacheux and Raviola, 1986; Nelson, 1982). Its principal roles appear to be receiving signals from rod bipolar cells, spatially integrating them, transforming the rod pathway signals to emphasize ON transients, and distributing these signals to ON and OFF pathways (Kolb and Famiglietti, 1974; Nelson, 1982; Vardi and Smith, 1996). The AII amacrine dendrites branch within all strata of the IPL, yet the ultrastructural organization within IPL layers differs (Fig. 18.12). Deep in the prox-

imal IPL, near ganglion cell bodies, the AII dendritic terminals receive ON-center ribbon synaptic input from rod bipolar axon terminals. In the middle of the IPL, they transfer this signal to ON-center cone bipolar cells through heterologous gap junctions. High in the distal IPL, near amacrine cell bodies, AII amacrine processes synapse directly onto OFF-center ganglion cells (Kolb, 1979; Kolb and Nelson, 1993) and OFF-center bipolar cells (Chun et al., 1993; McGuire et al., 1984) using a glycinergic inhibitory mechanism. Glycinergic ON inhibition, perhaps originating with the AII cells, has been confirmed in dark-adapted, OFF-center ganglion cells (Wässle et al., 1986).

Examination of other narrow-field, diffuse amacrine cells in cat retina suggests that, despite lack of clear evidence for ON-OFF layering at the light microscopic level, such cells exhibit stratified synaptic input and output at the ultrastructural level (Kolb and Nelson, 1996). In the rod system, broadly stratified amacrine cells perform a function similar to cone bipolar cells, generating dual ON and OFF path-

FIGURE 18.12. The rod pathway through the mammalian retina splits into parallel ON and OFF channels within the inner plexiform layer (IPL), where amacrine cells contact bipolar and ganglion cells, rather than at the outer plexiform layer (OPL), where photoreceptors contact bipolar cells. ON rod bipolar signals are established at metabotropic glutamate receptors on dendritic spines within OPL rod spherules. This rod ON signal is split into ON and OFF components by the AII amacrine (*AII am*) cell. Rod ON signals flow from rod bipolar (*ONrb*) to *AII* to ON cone bipolar (*ONcb*) at gap junctions (*asterisk*) in sublamina *b*. Rod OFF signals are generated at the inhibitory glycinergic synapses between AII amacrine cells and both OFF cone bipolar cells (*OFFcb*) and OFF ganglion cells (*OFF GC*) within sublamina *a*.

ways from a single signal substrate, in this case, the rod bipolar cell. In the cone system, broadly stratified amacrine cells may act to reinforce ON and OFF signals through inhibitory cross talk (Mastronarde, 1983a; Mastronarde, 1983b).

Central projections of ON and OFF ganglion cells

Ganglion cells send axons across the retinal surface to form the optic nerve. Optic nerve axons terminate in brain visual centers. In higher mammals, the principal target is the dorsal lateral geniculate nucleus (LGNd), the visual part of the thalamus. In lower mammals and cold-blooded vertebrates, the principal target is the superior colliculus. Neurons of LGNd project through optic radiations to the visual cortex. Neurons of LGNd are all ON-center or OFF-center types. In the visual cortex, "simple cells" are found in layer 4, the layer where axons of LGNd output neurons terminate after traveling through the optic radiations. These cortical "simple cells" are clearly either ON-center or OFF-center types, although unlike ganglion cells, they are very elongate in terms of receptive field structure. Other visual cortical cells are "complex" and often difficult to classify as either ON or OFF types (Hubel, 1988; Hubel and Wiesel, 1959). These complex types finally appear to combine signals from both pathways. Thus, ON and OFF emphasis remains distinct, even to the early stages of visual cortical processing in the occipital lobe.

Some ganglion cells project to brainstem visual centers, either solely or by axon collaterals arising from within the LGNd. Y-type ganglion cells represent a major bifurcating pathway. The principal target in the brainstem is the superior colliculus or optic tectum. This is the main termination of the optic nerve fibers in fishes, reptiles, birds, amphibians, and lower mammals, such as rabbits, rodents, and ground squirrels. Many ganglion cells projecting to the superior colliculus have receptive fields more complex than simple ON or OFF types.

By simultaneous recording of light responses from individual ganglion cells and LGNd neurons in the cat, it can be shown that each geniculate neuron is innervated by one to three retinal ganglion cells. ON-type ganglion cells synapse only with ON-type LGNd neurons; likewise, OFF-type ganglion cells synapse only with OFF-type LGNd neurons (Cleland et al., 1971a). Furthermore, X and Y (sustained and transient) pathways are not mixed on LGNd neurons. These pathways, too, are maintained as separate through to the visual cortex (Cleland et al., 1971b).

LATERAL GENICULATE LAYERS KEEP THE INPUTS FROM EACH EYE SEPARATE The LGNd is a layered structure. The exact number of layers varies from species to species. Common

household pets, like the cat and ferret, have three layers (Fig. 18.13). Primates typically have six layers. Each layer reflects the input of only one of the two eyes. The layers are organized, however, so that equivalent parts of the visual image, as seen by each eye, are in registry. Despite this very organized anatomical overlaying of image inputs from the two eyes, there are no binocularly driven geniculate cells. In the cat, layer A₁ receives input from the ipsilateral eye (see Fig. 18.13), whereas layers A and C receive input from the contralateral eye. Although not illustrated in Figure 18.13, it should be noted that layer C can be subdivided into four sublayers: C, C1, C2, and C3, with C3 lying closest to the optic radiations. Sublayer C contains larger cell bodies than sublayers C1 to C3. Although sublayers C1 to C3 are not histologically distinguishable in themselves, retrograde tracers indicate alternating projection of contralateral and ipsilateral eyes; C1, like A₁, receives ipsilateral input, whereas C2, like C, receives contralateral input. C3 does not receive ocular input (Hickey and Guillery, 1974).

The size and patterns of X-type and Y-type ganglion cell axonal arborizations within the geniculate differ (Bowling and Michael, 1980; Bowling and Michael, 1984; Sur and Sherman, 1982; Sur et al., 1987; Tamamaki et al.,

1995). Y-cell arbors are broader than X-cell arbors within the A layers and have many more boutons (see Fig. 18.13). Furthermore, Y cells always send branches to layer C, as well as the superior colliculus. X cells rarely arborize in layer C, and they never send branches to the superior colliculus (Tamamaki et al., 1995). Projections to the pretectum by axon collaterals of both X-type and Y-type ganglion cells have also been identified (Tamamaki et al., 1995).

ON AND OFF LEAFLETS IN THE LATERAL GENICULATE LAYERS

The synaptic fidelity of ON and OFF pathways within the LGNd argues for an underlying morphological segregation of processes. In the cat, there is a suggestion of ON and OFF layering within LGNd. Y_{ON} axonal arborizations may be more hour-glass in shape, whereas Y_{OFF} axon terminals may be more pyramidal (see Fig. 18.13). Y_{ON} terminals ascend into the upper half of layer A₁, whereas Y_{OFF} terminals are densely clustered in the lower half. Although this subtle morphological distinction between Y_{ON} terminals and Y_{OFF} terminals has not been noted by all investigators (Sur et al., 1987), a corresponding and distinct predominance of ON-type units is found in the upper half of layers A and A₁, whereas OFF-type units are more common toward the bottoms of these layers, that is, the edge closer to the optic tract. Layer C contains mainly OFF units (Berman and Payne, 1989; Bowling and Wieniawa-Narkiewicz, 1986). There is also a strong suggestion of columnar or modular clustering of ON and OFF units within all geniculate layers of the cat (Berman and Payne, 1989).

The tendency toward sublaminal distribution of ON and OFF geniculate pathways in LGNd is much more pronounced in ferret and mink retinas, where layers A and A₁ each are composed of two bisublaminal leaflets, one for OFF-center cells, and one for ON-center cells (LeVay and McConnell, 1982; Stryker and Zahs, 1983). There is also evidence for anatomical segregation of ON and OFF geniculate pathways in the monkey and tree shrew LGNd (Conway and Schiller, 1983; Schiller and Malpeli, 1978). In the macaque, geniculate layers 5 and 6 contain mainly ON types, whereas layers 3 and 4 contain mainly OFF types. Layers 1 and 2 are mixed in type (Michael, 1988; Schiller and Malpeli, 1978). No anatomical separation of ON or OFF pathways has been seen in cat or monkey visual cortex; however, there is evidence for ON and OFF patchiness in ferret visual cortex (Zahs and Stryker, 1988). The continued physiological and anatomical separation of ON and OFF pathways in the central nervous system strengthens the notion that vertebrates contain paired visual systems that, from retina to brain, are functionally separate.

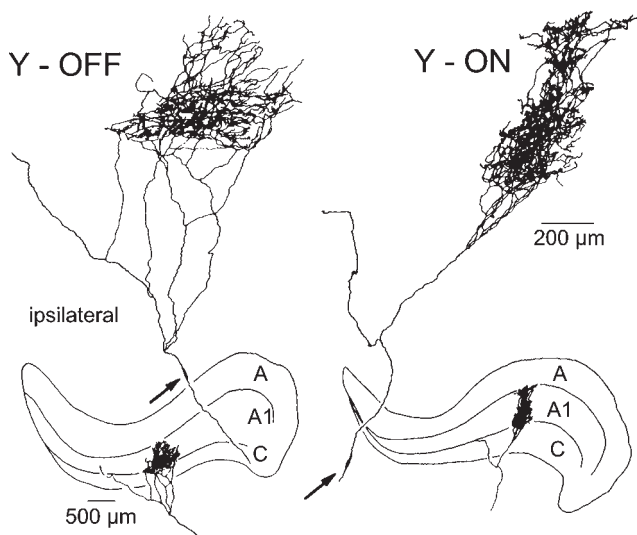

FIGURE 18.13. Axons of ON and OFF Y-type ganglion cells have terminal arborizations in the dorsal lateral geniculate body (LGNd). Axons from the ipsilateral eye project to layer A₁, whereas axons from the contralateral eye project to layers A and C. Projections are organized so that features of the visual images from each eye overlay one another. The Y-OFF axon branches densely in the lower leaflet of lamina A₁ while the Y-ON axon projects, in addition, to the upper leaflet. Although the difference in ON and OFF stratification is subtle in the cat, ON and OFF geniculate sublamination is quite pronounced in other species. Y cells also project to layer C, to the pretectum, and to the superior colliculus. Some X-cells project to the pretectum also. (From Bowling and Michael, 1984.)

Behavioral and clinical implications of ON and OFF pathways

The evidence presented thus far suggests that ON and OFF pathways are deeply embedded in the visual processing of vertebrates. These two processing systems remain separate through at least the first four synapses in vision, until being combined in visual cortex. The reasons for a two-system approach are less clear. Photographic film does not utilize ON and OFF substrates, nor do video cameras. Nonetheless, these media readily transcribe detailed and recognizable images. Hartline, the discoverer of ON and OFF systems in vertebrates, spent much of his career studying the limulus visual system. The optic nerve of the limulus contains only ON-center responses (Hartline and Graham, 1932). One might also argue that either ON or OFF X-type vertebrate retinal ganglion cells, with linear summation of dimming and brightening areas of the stimulus (see Fig. 18.3), are quite capable individually of transmitting information about both shadows and highlights within the image.

The uniqueness of the metabotropic glutamate receptor mGluR6 utilized in the ON pathway of vertebrate vision makes it vulnerable to selective elimination without affecting other neural pathways. Thus, the behavioral implications of eliminating the ON pathway can be studied. This can be accomplished either by the use of selective pharmacological blocking agents, such as APB, or by site-directed mutagenesis designed to eliminate the mGluR6 receptors themselves from the genome. Further, there are naturally occurring mutations and disease processes that selectively affect the ON system. Surprisingly, humans and animal models with ON-system deficit perform visual tasks relatively normally. The major deficit is loss of nocturnal vision, which appears to be dependent on the ON pathway.

MICE WITH ON-PATHWAY KNOCKOUT PERFORM VISUAL TASKS The electrophysiological consequences of site-directed mutagenesis directed at the ON pathway are seen in Figure 18.7 for mGluR6-deficient mice. The electroretinographic b-wave component, which arises from the activity of ON bipolar cells, is abolished (Masu et al., 1995). Furthermore, this study demonstrates that light-evoked field potentials from the superior colliculus, which in the mouse is the main termination site for ganglion cell axons, lack ON responses. In wild-type mice, transient collicular waves are seen at both onset and cessation of light stimuli, but in the mutant, only OFF-type waves appear.

Nonetheless, no deficit in visual behavior was readily observed. In a shuttle box avoidance learning analysis, both mutant and wild-type mice performed equally well. Although the mutant mice were capable of performing visual tasks, some visual system alterations were noted. Mutant mice had normal circadian clocks, but the daily

activity pattern was altered. The normal light-induced reduction in activity was greatly delayed (Takao et al., 2000). Pupillary responses were observed only at high light levels, and optokinetic responses were noted only at high contrasts in mutant mice (Iwakabe et al., 1997), suggesting a general loss of sensitivity. Nonetheless, these studies indicate that the OFF pathway alone can mediate vision, even if in a somewhat impaired way. Interestingly, the morphological layering of ON and OFF ganglion cell types persists in the mutants (Tagawa et al., 1999).

DISEASES OF THE ON PATHWAY

Melanoma-associated retinopathy. Some patients with malignant melanomas lose night vision. They may further report hallucinations consisting of shimmering blobs of white light (Berson and Lessell, 1988; Ripps, 1982). Visual processing in daylight appears otherwise normal. Color vision is not affected, nor is visual acuity dramatically worsened. ERG studies reveal ON pathway deficits for these patients. As with mGluR6-deficient mice, the b wave is selectively absent in both rod- and cone-driven responses (Alexander et al., 1992). The ON pathway loss is more serious for the rod system, as it is the only rod pathway, or at least the only one involved in processing of nocturnal vision. The syndrome is termed “melanoma-associated retinopathy” (MAR). Although originally thought to be a side effect of chemotherapy (Ripps, 1982), it became clear that the syndrome might arise in patients prior to chemotherapy (Alexander et al., 1992; Berson and Lessell, 1988). The immunoglobulin G (IgG) serum fraction of patients with MAR induces reversible electroretinographic disturbances similar to those associated with MAR when injected into the eyes of monkeys (Lei et al., 2000). The ERG documented a waves and d waves remain, but the b wave is lost from both rod and cone responses (Fig. 18.14). MAR appears to be caused by an autoimmune attack on retinal ON pathways for rod and cone vision. Antibodies induced against the melanoma cause the visual deficit.

Congenital stationary night blindness. Congenital stationary night blindness (CSNB) is an inherited retinal disease producing very similar symptoms to MAR. In the Schubert-Bornschein or complete type of the dysfunction (Schubert and Bornschein, 1952), there is loss of nocturnal or rod vision, but in daylight, cone-mediated color vision and visual acuity are relatively normal (Goodman and Bornschein, 1957; Miyake et al., 1986). The sensitivity of cone vision is somewhat reduced (Miyake et al., 1986). The disease appears to be X-linked, affecting primarily males (Miyake et al., 1986). ERGs reveal a loss of b waves for both the rod and cone systems. ON pathways for both rod and cone signals appear greatly depressed or absent, OFF cone

FIGURE 18.14. In melanoma-associated retinopathy (MAR), autoantibodies are generated that attack the retina, selectively targeting the ON pathway. The ERG recordings shown here are from a nonhuman primate model of the disease. The thin black trace represents a normal ERG with a, b, and d waves. The heavier gray trace was recorded from an eye treated with an intravitreal injection of IgG from a patient experiencing MAR. The immune serum causes a marked reduction in the b wave, an index of ON pathway activity in the retina. (From Lei et al., 2000.)

pathways, as represented by the ERG d wave, are spared (Alexander et al., 1992), as is the rod a wave (Goodman and Bornschein, 1957). The presence of a rod a wave but not a b wave provided the first suggestion of a genetic, postreceptor, neural processing disease in the retina (Goodman and Bornschein, 1957).

CSNB can be separated into two types: *complete* and *incomplete*. Genetic analysis reveals that the *complete* form involves defects in the glycoprotein nyctalopin (Bech-Hansen et al., 2000). Mutant nyctalopin may disrupt ON bipolar-cell development. The genetic defect in *incomplete* CSNB occurs in a gene similar to the L-type calcium channel alpha subunit, but uniquely expressed in retina (Bech-Hansen et al., 1998). The gene is CACNA1F—an example of a human retinal channelopathy.

VISUAL PROCESSING WITH PHARMACOLOGICAL BLOCKADE OF THE ON PATHWAY The responses of visual neurons in the central nervous system of primates have been investigated under conditions of ON-channel blockade using the metabotropic glutamate receptor agonist APB (DL AP-4). Recordings from LGNd indicate that light responses of ON-center geniculate neurons are completely blocked by APB applied to the retina. This includes both center and surround components. At the level of this thalamic relay, there appears to be no cross-innervations of ON by OFF channels (Schiller, 1982; Schiller, 1984). ON-center geniculate cells are also blocked selectively in rabbit LGNd (Knapp and Mistler, 1983). The performance of geniculate neurons with pharmacological blockade of the ON pathway confirms conclusions reached earlier by simultaneous recording of ganglion and geniculate cells, namely, that ON and OFF

pathways do not interconnect in LGNd (Cleland et al., 1971a).

Recordings of light responses of individual neurons in visual cortex suggest final integration of ON and OFF pathways. Complex cells, which under control conditions respond to both the leading and trailing boundaries of a bright square passing through the receptive field, only respond to the trailing light-dark transition after perfusion of the eye with APB (Fig. 18.15). In other words, the ON responses of complex cells are selectively eliminated, whereas the OFF responses remain. Even simple cells, normally classifiable as either ON or OFF types, reveal underlying input from both pathways (Schiller, 1982). Consistent with behavioral results, other properties of neurons in the visual cortex remain unperturbed by APB blockade of the ON system. These include preferred orientation and selectivity for direction of motion. These properties appear to be built up separately in each channel and then combined (Schiller, 1982). In a parallel study, monkeys undergoing APB blockade were found to have much poorer perception of light increments than light decrements, but relatively unimpaired perception of simultaneous spatial contrast (Dolan and Schiller, 1994).

DIM LIGHT RESPONSES ARE CONVEYED BY ON PATHWAYS

One common feature of rod-dominated mammalian retinas is the emergence of a single, ON-type rod bipolar cell (Dacheux and Raviola, 1986; de la Villa et al., 1995; Yamashita and Wässle, 1991) dominated by the metabotropic, mGluR6 glutamate receptor. Pharmacological blockade of this pathway leads to severe behavioral, as well as physiological, deficits in night vision. This is true behaviorally for both light increments and decrements (Dolan and Schiller, 1989), as well as for dim light responses in ON or OFF ganglion cells (Müller et al., 1988). Blockade of the ON pathway in mGluR6-deficient mice also leads to loss of light sensitivity, as is evident on ERG studies (Masu et al., 1995). As noted earlier, ON pathway diseases in humans are always accompanied by a loss of nocturnal vision. The secondary rod pathways that utilize cone-system OFF bipolar cells appear not to be involved in rod-mediated nocturnal vision.

Perspectives

In the parallel ON and OFF pathways to the brain, one sees a nearly coequal pair of image detection systems. The systems are based on feature detectors for highlights and shadows, each with separately evolved neurotransmitter systems expressed at photoreceptor to bipolar cell synapses. Each of these images, both the ON and the OFF, appear to be separately competent. Each is a separate visual system capable of color discrimination and sophisticated spatial

FIGURE 18.15. Effects of ON pathway blockade on a complex cortical cell. At the top, a bright square moves through the receptive field of a complex cell in the visual cortex. Vigorous discharges occur as the leading edge (an ON transition) and the trailing edge (an OFF transition) pass through the field. The neuron is selectively excited only by movements in one direction (arrow). With the ON pathway responses blocked by APB (below), the leading edge (ON) excitation disappears. Only the trailing edge (OFF) excitation remains. This complex cell integrates information from both ON and OFF pathways for edge responses of each contrast. (From Schiller, 1982.)

analysis of features, such as contrast and motion. In mammals, one system—the ON-pathway—dominates nocturnal vision. When the ON pathway is lost, loss of nocturnal vision is the most obvious deficit. That aside, both ON and OFF pathways are competent visual subsystems whose separate analyses are only combined late in the visual process. Although feature detectors may be a universal strategy of visual systems (exquisite, directionally selective cells are found in the medulla of the insect visual system [DeVoe and Ockelford, 1976; Riehle and Franceschini, 1984]), ON and OFF pathways are not invariably found. These may instead be a particular strategy, developed early in the vertebrate lineage, as a solution to unique environmental issues, but there is little to suggest a universal necessity.

19 Retinal Synapses

MARTIN WILSON

SYNAPSES ARE THE CORE of the retina as a computational machine, so much so that a proper review of retinal synapses would, in effect, be a description of how the retina works. We are still a long way from a complete description of how the retina works, but the last few years have seen great advances in our understanding of retinal synapses, and it seems likely that the retina will be the first neural machine of any complexity that we will truly understand at a cellular level.

An understanding of retinal synapses requires answers to two related but distinct questions. The first is the question of connectivity: which types of retinal neuron synapse with which other types of neuron? The second question relates to how these synapses behave. As has become increasingly clear over the last decades, this is not simply a question of whether a synapse is excitatory or inhibitory, but requires knowledge of the kinetics of transmitter release and clearance, details of postsynaptic channel gating and modulation, and more. The two issues—connectivity and function—have very different histories, and it is worth reflecting that, whereas the outline of connectivity was appreciated by Cajal in the early 1890s, the mechanisms of synaptic function were a complete mystery as recently as the middle of the twentieth century. To gauge how far the field has developed in the last 50 years, we might consider the state of contemporary understanding of retinal synaptic function, as summarized by Steven Polyak writing in 1955: “Speaking figuratively, it seems that there is not so much an actual passage of a material substratum or a direct transmission of nervous excitation as rather an emanation of a certain imponderable ‘influence’ as yet to be precisely defined in terms of microdynamics” (Polyak, 1957).

What has happened with retinal synapses since Polyak wrote this unenlightening synopsis? Several advances spring to mind. First, the work begun by Cajal in providing anatomical descriptions of synapses between the cell types in the retina has been enormously extended, largely through the electron microscope, to the point that there are now quantitative descriptions of the synapses between some retinal neurons. Second, the identity of transmitter substances in the retina has been almost completely uncovered. This has not been a straight path, and even in the case of the photoreceptor transmitter, there have been numerous wrong turns. The simple story, now firmly established, is that glutamate is the transmitter in the direct pathway, photorecep-

tors to bipolar cells, bipolar cells to ganglion cells; and that gamma-aminobutyric acid (GABA) is the main transmitter in the lateral and feedback pathways mediated by horizontal cells in the outer retina and amacrine cells in the inner retina. Third, something is now known about the molecular identity of the transmitter receptors found on many of the cells in the retina. This molecular characterization is still at an early stage, but has already indicated a level of complexity in retinal organization that goes well beyond our present understanding of how the retina works, leaving the unsettling impression that the retina is a much more subtle machine than we presently acknowledge. Lastly, the way in which transmitters are released from presynaptic terminals in the retina is beginning to be understood, although clearly there are major advances still to be made in this area.

Fifty years have produced a vast increase in the understanding of retinal synapses, but even so, it would be quite wrong to imagine that, but for a few details, retinal synapses are understood. Certainly, the outer retina is much better understood than the inner retina, largely because it has fewer types of neurons and has a simpler organization. Even in the outer retina though, there are important, unanswered questions, and the patterns of connectivity, although closely investigated for several decades, continue to reveal unexpected novelty. Two recent examples of this are provided by two studies describing an uncommon, unsuspected but nevertheless important synapse between mammalian rods and OFF cone bipolar cells (Hack et al., 1999; Tsukamoto et al., 2001), as well as the finding that there may be a layer of anatomically strange and unexplored synapses lying beneath the terminals of mammalian cones (Haverkamp et al., 2000).

The connections within the inner retina, with the exception of a few special pathways, are not known in detail, and our understanding of the physiology of defined synapses is scant. A major task in the inner retina will be the elucidation of the many modulation pathways that are suspected to exist there. This is a particularly challenging area because not only are the mechanisms of modulation largely unknown, but it is also not really clear what modulation contributes to retinal processing.

My intentions in this review are to set out the basic pattern of synaptic organization in the retina, to draw attention to recent advances, and to point out the unsolved problems

of retinal synapses. The direct pathway of photoreceptors to bipolar cells to ganglion cells is presented first; then, lateral pathways and feedback loops involving horizontal cells and amacrine cells are described. Lastly, a brief description of spinules highlights an example of plasticity in the retina. Synaptic function, rather than connectivity, is the focus of this chapter, but even with this restriction, a great amount of important work has to be left out including, among other things, any discussion of efferent input, interplexiform cells, and glycine or dopamine as transmitters.

The basic plan

The synaptic plan of the vertebrate retina is shown in Figure 19.1 in a way that emphasizes the symmetry of its organization. In both the outer and the inner retina, there is a direct transmission pathway, from photoreceptors to bipolar cells, and from bipolar cells to ganglion cells, as well as transmission to lateral interneurons that provide both feedback and negative feedforward. Although this is the basic plan, it must be emphasized that each element in this diagram represents not a single cell, but a class of cells comprising more than one type, each of which makes a characteristic pattern of connections with a subset of types from the other classes. There are species variations in the number of types in a class, but an “average” retina might have 4 types of pho-

toreceptors, 2 types of horizontal cell, 10 types of bipolar cell, several dozen types of amacrine cell, and about 20 types of ganglion cell. The rules of connection for most of these neuronal types are those set out in Figure 19.1, but there are numerous deviations from this plan too tedious to enumerate. One well-known and important exception, though, is the major pathway from rod photoreceptors in the mammalian retina. These photoreceptors have their own exclusive bipolar cell that synapses, not with a ganglion cell, but with an amacrine cell, the AII amacrine, which forms a glycinergic synapse onto a cone bipolar cell and is electrically coupled to yet another type of bipolar cell (Muller et al., 1988).

The direct pathway

PHOTORECEPTORS

Photoreceptor to bipolar cell; presynaptic mechanisms. The first synapses in the retina sort information into categories that are kept separate for several more processing steps. Signals representing local increments or decrements in luminance are separated into two streams, carried by the ON and OFF bipolar cells. Within these two general classes, there is a further splitting of signals into channels in which luminance changes are represented with different temporal filtering. How do synapses achieve this sorting and respond reliably

FIGURE 19.1. Schematic layout of the retina showing the basic plan of its synaptic organization. Photoreceptors (P) synapse with the two classes of second-order neurons, bipolar cells (B) and horizontal cells (H). Horizontal cells are lateral interneurons and provide both feedback to photoreceptors and feedforward to bipolar cells. The same general pattern is repeated in the inner retina, where bipolar cells synapse directly with ganglion cells (G),

but also provide input to amacrine cells, the lateral interneurons of the inner retina. Amacrine cells (A) provide feedback to bipolar cells and feedforward to ganglion cells, in addition to having extensive synaptic connections amongst themselves. Electrical synapses mediated by gap junctions couple many of the neuron types within and, in some cases, between classes, but for simplicity, these connections have been omitted.

to signals in photoreceptors that are as small as 1 mV (Schneeweis and Schnapf, 1995)?

Photoreceptors make two anatomically distinguishable kinds of synapses with second-order cells. These have several names, but they are referred to here as superficial and invaginating synapses. Superficial synapses are relatively simple structures with postsynaptic densities and intramembranous particles presynaptically, not unlike many synapses elsewhere

in the brain. Invaginating synapses, in contrast, are remarkably complex. Typically, there are three postsynaptic elements at an invaginating synapse, all of which are pushed into the synaptic terminal of a photoreceptor (Fig. 19.2) and constitute a "triad." Usually, the central element of these three is a bipolar cell dendrite; the two lateral elements are the dendrites of horizontal cells. On the presynaptic side of this synapse, a flat plate, the synaptic ribbon, is held

FIGURE 19.2. Schematic layout of a cone terminal synapse in a mammalian retina. Shown here are the distributions of receptors, identified immunocytochemically, and other membrane-associated features from which synaptic interactions (numbered arrowheads) can be inferred. The presynaptic ribbon, in reality a plate upon which synaptic vesicles are aligned, is shown cut transversely. The dendrite of an ON bipolar cell forms the central element of a triad in which the lateral positions are taken by horizontal cell dendrites, seen here also in transverse section. The dendritic tips of OFF bipolar cells do not invaginate the cone terminal, but instead make superficial synapses. Ionotropic glutamate receptors are found on horizontal cell membranes apposed to the likely site of presynaptic vesicle fusion (7). Glutamate released at this fusion site diffuses

some distance to reach the mGluR6 receptors and the ionotropic GluRs on the dendrite of the ON bipolar cell (3). Tips of the OFF bipolar cells express iGluRs, but it is not entirely clear where transmitter for this synapse originates (2). GABA_A receptors are found on both ON and OFF bipolar cells adjacent to superficial horizontal cells (4, 5), from which GABA is thought to be released. GABA_A receptors are also found on the tips of ON bipolar dendrites (4), where they probably receive input from the lateral elements of the triad (4). The presence of GABA_A receptors on the synaptic ridge of the cone is speculative, but may be the location of the feedback to cones (6). (Reprinted from Vardi et al. [1998], copyright 1998 with permission from Elsevier Science.)

perpendicular to the presynaptic membrane, and about 60 nm from it, by filamentous connections to an electron-dense material, the arciform density adjacent to the plasma membrane. Ribbons, or similar structures, are found also in retinal bipolar cells, auditory hair cells, and the electroreceptors of fish. All of these cells carry small, graded, voltage signals and are thought to have the capacity to release transmitter continuously.

Ribbons are very complex structures built from many proteins, most of which have not yet been identified. However, they include forms of the motor protein, kinesin (Muresan et al., 1999), and probably myosin (el-Amraoui et al., 1996; Schlamp and Williams, 1996). Ribbon synapses, despite their unique presynaptic anatomy, have many of the synaptic proteins found at more commonplace synapses (Von Kriegstein et al., 1999), with the notable exception of synapsin (Mandell et al., 1990), which, in other synapses, anchors synaptic vesicles to the cytoskeleton but releases them when phosphorylated. Ribbons themselves are able to bind synaptic vesicles in an orderly array on both faces of the ribbon by holding them on thin filaments approximately 20 to 30 nm long. One protein of unknown function, RIBEYE, is a major component of ribbons and thus far is the only protein unique to these structures (Schmitz et al., 2000). Very likely, ribbons serve in some capacity to collect vesicles from the surrounding cytoplasm and facilitate release, although exactly how this is accomplished is not yet certain.

Patterns of connections between photoreceptors and their postsynaptic partners vary with species and the particular class of photoreceptor. In mammals, a cone makes 25 to 40 invaginating synapses, but a rod makes only a single invaginating synapse that, in darkness, has been estimated to release transmitter at a minimum rate of 40 vesicles per second (Rao et al., 1994). The anatomy of this synapse has been carefully examined (Rao-Mirotznik et al., 1995) with the aim of finding out how it is suited to its unique task of transmitting one bit of information: the presence or absence of a single photon. At the presynaptic membrane, on either side of a ribbon, is a row of about 65 docking sites, making a total of 130 sites at this single active zone, many more than found at conventional bouton synapses. The double row of docking sites is, at least superficially, similar to the structure found at the neuromuscular junction (Harlow et al., 2001), but the presence of the ribbon has no obvious counterpart. The ribbon, in addition to holding 130 vesicles at docking sites, holds a reserve of some 640 vesicles. Both the large number of docking sites and the reserve of available vesicles on the ribbon would appear to be adaptations to permit continuous, high rates of release.

Although invaginating synapses in the outer retina characteristically have three postsynaptic elements, the mammalian rod synapse actually has four, two dendritic processes

from rod bipolar cells flanked by two horizontal cell processes. The three-dimensional synaptic cleft created by this complicated geometry is about 20 times the volume of a typical bouton synapse; moreover, the receptors on the bipolar cell dendrites are at some distance (400 to 800 nm) from the active zone (Vardi et al., 2000). Why? A possible advantage of this arrangement might be that the shot noise of quantal release is smoothed out by the relatively long diffusion pathway, whereas the penalty of slowness imposed by long diffusion is unimportant, as a single-photon signal in a rod has a time course measured in hundreds of milliseconds (Burns and Baylor, 2001).

Glutamate is the transmitter used by both rods and cones. A great deal of work has contributed to this conclusion, but several clever experiments have helped to clinch this. The release of an excitatory amino acid from turtle rods and cones was demonstrated by showing that depolarization of these cells released a substance that could open *N*-methyl-D-aspartate (NMDA) receptors in an isolated patch of membrane on the tip of a recording pipette held near the photoreceptor terminal (Copenhagen and Jahr, 1989). The fact that this amino acid was L-glutamate was demonstrated in an experiment in which a single photoreceptor terminal was drawn into the lumen of a pipette containing NAD^+ and the enzyme glutamate dehydrogenase, which can use only L-glutamate as a substrate. The production of NADH, detected by an increase in fluorescence when the photoreceptor was depolarized, indicated that L-glutamate was released (Ayoub and Copenhagen, 1991).

Release of transmitter from photoreceptors is continuous in darkness while photoreceptors experience a relatively depolarized membrane potential of about -40 mV. Light hyperpolarizes photoreceptors, thereby closing voltage-gated Ca^{2+} channels in the synaptic terminal and diminishing transmitter release. Unlike fast synapses, such as the squid giant synapse at which hundreds of μM Ca^{2+} are required to activate transmitter release (Adler et al., 1991), rods release glutamate in the dark at an estimated Ca^{2+} concentration of between 2 and $4 \mu\text{M}$. As would be expected of a continuously releasing synapse, the rate of endocytosis of vesicles is closely matched to the rate of exocytosis (Rieke and Schwartz, 1996), although exactly how this is achieved is not clear.

A problem posed by the release of photoreceptor transmitter as a consequence of Ca^{2+} influx through voltage-gated Ca^{2+} channels is that these channels activate only positive to about -45 mV, implying that only small-voltage signals close to the photoreceptor dark potential can be transmitted to second-order cells. This actually seems to be the case for dark-adapted salamander rods, but for reasons related to the electrical coupling of rods in this retina, the limited transmission window may not be a problem (Attwell et al., 1987). For cones, though, this problem may be solved by having a

separate mechanism of Ca^{2+} entry, independent of voltage-gated Ca^{2+} channels, that permits transmitter release over the entire voltage range of the cone from -40 mV down to -70 mV . This entry pathway is thought to be a cyclic guanosine monophosphate (cGMP)-gated channel (Rieke and Schwartz, 1994), but it is not at all clear how cGMP concentration at the terminal is coupled to the cone membrane voltage, as it would have to be if this mechanism is used for transmitting cone signals. Cones express soluble G cyclase, and this is probably the source of cGMP in the synaptic terminal. Because nitric oxide, which upregulates this cyclase, is known to be synthesized in the outer retina (Blute et al., 2000), it may well serve to modulate Ca^{2+} entry, and it could perhaps be involved in light adaptation, but it is too slow to transmit cone signals.

All information passing from photoreceptors to second-order cells is first coded as glutamate concentration in the synaptic cleft. In principle, this could be done in two different ways. Each vesicle of transmitter could produce a brief pulse of postsynaptic current integrated by the relative slow electrical time constant of the postsynaptic dendrite. Alternatively, the large volume of the synaptic cleft and the relatively long distances to postsynaptic receptors might imply that transmitter concentration is effectively smoothed out. This issue is not completely settled yet, but on balance, quantitative analysis of this problem favors the idea that smoothing of the concentration seen by the postsynaptic receptors is a minor effect (Rao-Mirotznik et al., 1998). In either case, the rate of glutamate removal from the cleft is an important consideration. High-affinity glutamate transporters, found on the plasma membranes of photoreceptor terminals and glial cells (Eliasof et al., 1998), clearly play a critical role in this, as inhibiting them leads to glutamate concentrations that saturate postsynaptic receptors (Eliasof and Werblin, 1993). The exact disposition of these transporters, though presently unknown in any retina, is likely to be a crucial factor in determining how far glutamate can diffuse from its release site, which, as discussed later, is key to understanding cone synapses. A salient aspect of glutamate transport by photoreceptors is that it is coupled to a Cl^- conductance, as first described by Sarantis and colleagues (1988). Because the glutamate transporter acts as an autoreceptor and opens a Cl^- channel, this arrangement works as a negative feedback on transmitter release by photoreceptors (Picaud et al., 1995).

Multiple forms of negative feedback apparently act at the photoreceptor synapse, quite apart from the feedback mediated by horizontal cells. In rat retina, photoreceptor terminals express the group III metabotropic receptor mGluR8, which functions as an autoreceptor, decreasing Ca^{2+} concentration in the terminal, and thereby decreasing glutamate release (Koulen et al., 1999). Very likely, this works via G-protein control of L-type Ca^{2+} channels. In the cat retina,

mGluR1 is found presynaptically in rod terminals (Cai and Pourcho, 1999), but it is presently unknown how this works. Even more mysterious than this is the expression of NMDA NR1 subunits in the terminals of both rods and cones of the rat (Fletcher et al., 2000). A particularly interesting form of negative feedback has recently been suggested at mammalian cone terminals (DeVries, 2001). At this synapse, and perhaps others, too, the release of transmitter is accompanied by the release of protons that are highly concentrated within synaptic vesicles. This has the effect of acidifying the synaptic cleft and immediately suppressing the Ca^{2+} current by acting directly on the nearby Ca^{2+} channels. This, in turn, is thought to diminish glutamate release.

BIPOLAR CELLS In all retinas, the subclasses of bipolar and horizontal cells are restricted in the types of synapse they make with photoreceptors, some types being postsynaptic only at invaginating synapses and others only at superficial synapses. In the mammalian retina, ON bipolars are postsynaptic only at invaginating synapses, whereas OFF bipolars synapse only at superficial synapses. In other retinas, such as the amphibian retina, the rules are different (Lasansky, 1978). Unlike invaginating synapses, where synaptic vesicles coat both sides of the ribbon and are found in an abundant cloud around the ribbon, the presynaptic locations of superficial synapses are generally almost devoid of vesicles. Whether this implies an unusual, avascular form of transmitter release at superficial synapses is not yet clear. An alternative possibility is that the transmitter released at ribbon synapses is able to diffuse to the receptors at superficial synapses, a pathway that is approximately 500 to 950 μm long (Morigiwa and Vardi, 1999). The suggestion that the ribbon provides glutamate even to superficial synapses casts the cone “synapse” as an extraordinarily complex, layered structure with numerous, carefully positioned, postsynaptic elements (Fig. 19.3) (Haverkamp et al., 2000; Vardi et al., 1998).

Photoreceptor to bipolar cell; postsynaptic mechanisms. At photoreceptor synapses, signals are channeled to ON bipolar cells that depolarize to increments of light and to OFF bipolar cells that hyperpolarize to increments of light. Because photoreceptors hyperpolarize to increments of light, this means that the photoreceptor to OFF bipolar cell synapse is sign preserving, whereas the synapse to ON bipolar cells is sign inverting.

The postsynaptic mechanism of ON bipolar cells is unusual. Here, the transmitter glutamate decreases a postsynaptic conductance to cations. In this way, then, hyperpolarization of photoreceptors by light, because it reduces glutamate release, results in the depolarization of the bipolar cell. The glutamate receptor through which this mechanism operates is mGluR6, a member of the type III mGluR

FIGURE 19.3. Schematic drawing of the synaptic complex (A) of a cone terminal showing the layering of transmitter receptors (B). ON bipolar cells are shown in green, OFF bipolar cells are depicted in blue, and the dendrites of horizontal cells are colored red. The whole structure shows a precise lamination in the expression of glutamate and GABA receptor subunits. In addition to receptors at

invaginating and superficial synapses, there appears to be yet another layer of receptors lying 1 to 2 μm below the cone terminal associated with desmosome-like junctions (indicated by double black bars). (Reprinted from Haverkamp et al. [2000], copyright 2000 with permission from Elsevier Science.) (See color plate 7.)

receptors for which APB (L-2-amino-4-phosphonobutyric acid, also known as L-AP4) is a selective and potent agonist (Slaughter and Miller, 1981). The binding of glutamate to mGluR6 results in the closure of cation channels through which Ca^{2+} enters the cell and plays a role in postsynaptic light adaptation (Nawy, 2000; Shiells and Falk, 1999). Until recently, the mechanism of channel closure was thought to resemble phototransduction in that the cation channels were thought to be gated by cGMP, which was destroyed by a phosphodiesterase (PDE) whose activity, in this case, was increased when glutamate was bound by the receptor. The similarities to phototransduction turn out to be more superficial than was at first thought. The G protein, G_o , rather than transducin, the G protein of phototransduction, is involved here, as suggested by the anatomical finding that G_o alpha colocalizes with mGluR6 in bipolar dendrites on the tips of ON bipolar cells (Vardi, 1998). This was confirmed by the absence of ON bipolar responses in the G_o alpha null mouse (Dhingra et al., 2000). The notion that the cation channels are gated by cGMP was supported by results showing that PDE inhibitors could increase the cation current; however, in a recent study glutamate responses were found to be unaffected by PDE inhibitor, as well as by non-hydrolyzable cGMP (Fig. 19.4) (Nawy, 1999). From these experiments, one might reasonably conclude that cGMP is a modulator of the cation channel, but is not in the direct-signaling pathway. A crucial gap in our understanding of this system concerns the identity of the cation channel; until the channel is identified, progress on this problem is likely to be slow.

We might wonder why such an unusual postsynaptic mechanism is employed in ON bipolar cells. Some insight into this issue is provided by a recent study examining rod

to rod (ON) bipolar cell transmission in the mouse retina (Field and Rieke, 2002; discussed in Wilson, 2002). Counterintuitively, this study showed that at very dim light levels a majority of the scarce photon signals generated in rods are not transmitted to rod bipolar cells. In fact, only the biggest amplitude single-photon signals are passed through this synapse. Although the synapse wastes precious photon signals in doing this, it actually confers a net benefit by also filtering out the inevitable and irreducible noise generated in the rods that would otherwise be indistinguishable from genuine photon hits. Very likely, the essential mechanism for this thresholding operation at the synapse lies in the postsynaptic transduction machinery, so that as suggested by van Rossum and Smith (1998), the fluctuating levels of glutamate in the dark are saturating, and only when glutamate falls below some threshold concentration is this able to cause an opening of cation channels.

The APB-sensitive cation channel system, although incompletely understood, is widely acknowledged to be the chief postsynaptic mechanism at photoreceptor to ON bipolar synapses. There are, nevertheless, several other mechanisms that, with different degrees of certainty, are thought to play a role. The best documented of these is the conductance associated with cone input to ON bipolar cells found in teleost fish (Saito et al., 1979). Although rod synapses on these neurons use the APB-sensitive mechanism, glutamate from cones causes a conductance increase to anions. The properties of this glutamate current are unusual, in that it is not blocked by any ionotropic or metabotropic glutamate receptor antagonists, nor by strychnine or picrotoxin. The reversal potential for this current follows E_{Cl} but it has a requirement for extracellular Na^+ (Grant and Dowling, 1995, 1996). Almost certainly, this

FIGURE 19.4. cGMP potentiates the glutamate response of ON bipolar cells, even when cGMP hydrolysis is inhibited. *A*, Glutamate suppresses an inward current seen in the ON bipolar cells of the tiger salamander retina. *B*, Inward current is increased when cGMP is included in the patch pipette. The times noted (0.5 and 3 minutes), refer to the time after internal perfusion of the cell begins. *C* and *D*, Two nonhydrolyzable analogs of cGMP also

potentiate the inward current, but do not interfere with the ability of glutamate to close these cation channels. The implication of these experiments is that cGMP, though it modulates the cation channel, is not the messenger whose destruction is responsible for channel closure. (From Nawy [1999], copyright 1999, the Society for Neuroscience.)

cone-driven mechanism is mediated by a glutamate transporter that gates a Cl^- channel the same as, or similar to, that seen in the terminals of photoreceptors.

In mammalian retinas, immunocytochemistry shows that rod bipolar cell dendrites express α -amino-3-hydroxy-5-methyl-4-isoxa-2-oleopropionate receptor (AMPA) subunits (Hack et al., 2001; Hughes, 1997; Morigiwa and Vardi, 1999). This finding is shocking, as it implies that rod bipolar cells have a sign-preserving synapse from photoreceptors working against the APB-sensitive, sign-inverting synapse. The most careful physiological study to date finds no evidence for an ionotropic GluR in these bipolar cells (Hartveit, 1996), but the issue is not yet resolved. It is possible that these channels contribute little to the postsynaptic current of the cell, but nevertheless might admit some Ca^{2+} that plays a modulatory role (Hack et al., 2001). A more radical alternative is that these AMPAR subunits, instead of forming channels, associate with G-protein subunits and have a metabotropic role, as they do in some cortical neurons (Wang et al., 1997). Even less well understood than the presence of AMPAR subunits is the possible presence of NR1 subunits (Hughes, 1997), which are capable of forming homomeric channels. In addition to mGluR6, the group I receptors mGluR1 and mGluR5 (Koulen et al., 1997) are found in ON bipolar dendrites. Presumably, these have a modulatory role, but what that might be remains unknown.

In comparison to the unusual postsynaptic mechanisms of ON bipolar cells, those found at OFF bipolar cells are orthodox, involving AMPA- or kainate (KA)-preferring receptors. In the mammalian retina, there are approximately three to five anatomically defined classes of OFF bipolar cells. Although all of these connect to every cone cell, they each carry a different signal by virtue of their different glutamate receptors. Of the three types examined in the ground squirrel retina (DeVries, 2000), two are kainate-preferring and one is an AMPA-preferring receptor. The important difference between these receptors seems to be the rate at which they recover from desensitization. The AMPA receptor on the B2 bipolar cell recovers quickest, and the kainate receptor on the B3 the slowest, with the kainate receptor on B7 having an intermediate recovery rate. The consequence of these kinetic differences is that, while they probably all experience similar glutamate kinetics, the glutamate receptors filter the signal differently, determining that the B2 cell will carry a transient signal and that the B3 cell will carry a sustained signal. Similar kinetic differences are thought to exist among ON bipolar cell classes, but in that case, it is not known how these kinetic differences are achieved.

Bipolar cell to ganglion cell; presynaptic mechanisms. Bipolar cells pass signals to ganglion cells. ON bipolar cells synapse chiefly with ON ganglion cells; similarly, OFF bipolar cells synapse with OFF ganglion cells. The synapses of OFF cells

lie in sublamina *a* of the inner plexiform layer, and ON cells synapse in the lower sublamina *b*. Bipolar cell terminals make dyad ribbon synapses at which there are typically two postsynaptic elements, one usually a ganglion cell dendrite and the other belonging to an amacrine cell. Glutamate is thought to be the transmitter used by bipolar cells. Tachibana and Okada (1991) demonstrated directly, by using a catfish horizontal cell as a detector, that an isolated bipolar cell releases an excitatory amino acid when depolarized in the presence of extracellular Ca^{2+} . Glutamate is certainly the transmitter used by most bipolar cells, but is it the exclusive transmitter for all bipolar cells? Suggestive evidence exists that, at least in the amphibian retina, some bipolar cells may use GABA as a transmitter, perhaps in addition to glutamate (Yang and Wang, 1999).

Much of what is known about transmitter release from bipolar cells comes from work on the Mb1 bipolar cell from goldfish (reviewed in Lagnado, 2000; Tachibana, 1999; von Gersdorff and Matthews, 1999). These bipolar cells are driven chiefly by rods and, in response to a step of light, show a transient depolarization of about 200 msec followed by a smaller tonic depolarization (Saito et al., 1979). The chief recommendation of these cells is that they possess a single, giant, synaptic terminal having a diameter of about 10 μm . Two indirect methods have been applied to these terminals to examine transmitter release. The first method uses a high-frequency voltage sinusoid to determine the membrane capacitance of a voltage-clamped cell. The fusion of vesicles with the plasma membrane increases membrane capacitance linearly with the number of vesicles fused, and though vesicles are too small to be resolved individually, the concerted fusion of thousands of vesicles generates a signal that allows insight into the rapid kinetics of vesicle cycling. A limitation of this technique is that it reports the difference between exocytosis and endocytosis, giving rise to an ambiguity if neither of these rates is known. The second method is complementary to the capacitance method, as it has a lower time resolution but is able to report exocytosis and endocytosis independently. In this method, the fluorescence of a styryl dye, usually FM1-43, is monitored as it partitions into newly exposed vesicle membranes, or is lost from vesicle membranes in exocytosis.

A combination of these two methods has provided a picture of release more complete than at any other synapse, and it is one that integrates very well with the anatomy of these terminals (Fig. 19.5) (von Gersdorff et al., 1996). A typical terminal has 60 ribbons holding on either face, an array of about 66 vesicles. The bottommost row on either face of a ribbon is thought to be aligned with 11 fusion sites on the plasma membrane. L-type Ca^{2+} channels, very likely situated just beneath the ribbon, open with membrane depolarization (Heidelberger and Matthews, 1992), thereby increasing the Ca^{2+} concentration in the immediate vicinity

of the docked vesicles. This first row of vesicles held at docking sites can be exocytosed very quickly (Neves and Lagnado, 1999), with a time constant of 0.5 msec when the activation of the Ca^{2+} current is not the rate-limiting step (Mennerick and Matthews, 1996). Maintained high Ca^{2+} levels lead to a second phase of release, lasting about 200 msec, associated with the release of the rest of the 4500 or so vesicles attached to the ribbons (von Gersdorff et al., 1996). Interestingly, the release of this pool of vesicles seems to occur at a fixed rate until it suddenly runs out of vesicles, suggesting perhaps that vesicles are moved in a coordinated fashion down the ribbon to the release site (Neves and Lagnado, 1999). ATP is a necessary factor for exocytosis, but is apparently not required for the release of vesicles once they are docked (Heidelberger, 1998). Because ribbons contain a kinesin motor protein, it might be thought that the ATP is required to allow movement of vesicles on the ribbon. However, this seems unlikely since, without ATP, the number of vesicles that can be released is more than just those initially held at the docking sites (Heidelberger, 1998). The ATP-dependent step seems to be a required readying step that happens to vesicles while they are aligned on the ribbon.

A third kinetic component of release is indefinitely sustainable at a rate of about 1000 vesicles per second and involves recruitment of vesicles to ribbons from the reservoir of about 750,000 vesicles found throughout the terminal (Neves and Lagnado, 1999; Rouze and Schwartz, 1998). This tonic form of release is not universally accepted (Matthews, 1998) and is invisible as a capacitance change, arguably because exocytosis and endocytosis are balanced. Nevertheless, a technically sophisticated study combining capacitance measurements with the use of AMPARs as transmitter detectors failed to document any continuous release; instead, it showed that the vesicle pool could readily be exhausted (von Gersdorff et al., 1998). How this important discrepancy can be resolved remains to be seen.

Retrieval of vesicle membranes by endocytosis occurs in two kinetic forms, one with a time constant of about 1 second and a slow form with a time constant about 10-fold longer (Neves and Lagnado, 1999; von Gersdorff and Matthews, 1994). The molecular processes controlling these different retrieval mechanisms are presently unknown, but might correspond to a "classical" endocytosis needing clathrin and a rapid form of endocytosis without clathrin that recovers incompletely collapsed vesicles (Pyle et al., 2000). Once endocytosed, recovered vesicles are refilled with transmitter and returned to the releasable pool within 1 minute (Lagnado et al., 1996), thereby allowing continuous turnover of the entire pool of 750,000 vesicles in a terminal within a few minutes.

Calcium has several described effects on vesicle cycling in Mb1 bipolar cells. It can, for example, increase the recruit-

ment of vesicles to the ribbon and the rate of movement along the ribbon (Gomis et al., 1999), but there are contradictions in the quantitative account of the most central of these processes, exocytosis. Studies using FM1-43 show that no exocytosis takes place at resting levels of Ca^{2+} , but that only a moderate increase—to around 500 nM (Lagnado et al., 1996) or 800 nM (Rouze and Schwartz, 1998)—is necessary to promote continuous vesicle fusion. An important technical point is that these studies raised the level of Ca^{2+} uniformly within the terminal by uncaging it photolytically, rather than admitting it through Ca^{2+} channels, where it would have created very local domains of high concentration. Set against these results are those based on capacitance measurements, showing that phasic exocytosis requires at least 50 μM Ca^{2+} (von Gersdorff and Matthews, 1994) and is only half-saturated at 194 μM Ca^{2+} (Heidelberger et al.,

1994), similar to the high Ca^{2+} requirement found in the squid giant synapse (Adler et al., 1991). One potential resolution of these discrepancies is that both a high Ca^{2+} - and a low Ca^{2+} - affinity mechanism of exocytosis exist at this synapse, and they separately mediate continuous and phasic release of transmitter. This possibility may not seem to fit well with a structure as homogeneous as the presynaptic ribbon, but as described later, release at the bipolar cell ribbon may not be completely uniform. An alternative possibility is that the Ca^{2+} dependence of exocytosis might be modifiable, perhaps in a Ca^{2+} -dependent way. Some evidence consistent with this general idea comes from experiments examining use-dependent synaptic depression. In addition to depression resulting from depletion of vesicle pools (von Gersdorff and Matthews, 1997), there is evidence that, after an episode of exocytosis, further exocytosis is less sensitive to Ca^{2+} (Burrone and Lagnado, 2000).

A clever variation on the FM1-43 method employs evanescent wave microscopy to look exclusively at the behavior of single vesicles very close to the plasma membrane as they dock and fuse (Zenisek et al., 2000). From this work, several new findings have emerged. Vesicles are held about 20 nm from the plasma membrane, presumably at the bottom of a ribbon, before undergoing docking to the plasma membrane. Once docked, about 250 msec is required for “priming” before fusion can take place.

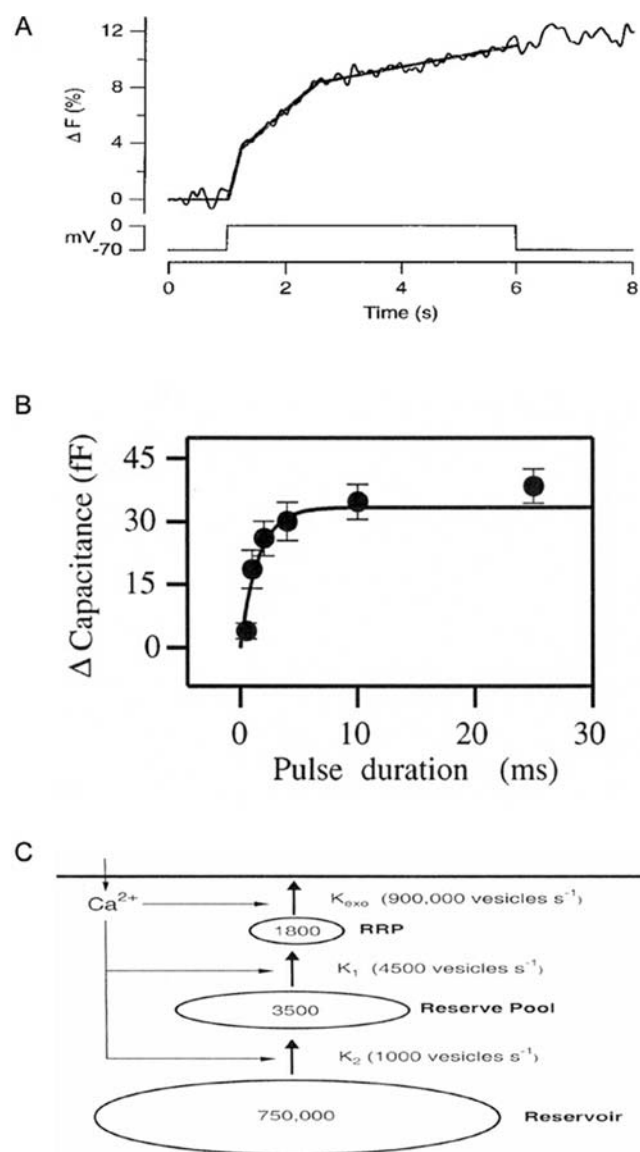

FIGURE 19.5. Transmitter release from Mb1 cells of the goldfish has three kinetic components. *A*, Vesicle fusion with the synaptic terminal membrane, measured as an increase in fluorescence of the dye FM1-43 entering newly exposed vesicle membrane. Immediately after the membrane voltage is stepped from -70 to 0 mV, a very rapid increase in fluorescence corresponds to the fusion of all the docked vesicles. Following this, there is a linear increase at a lower rate corresponding to the exocytosis of all the vesicles on all the ribbons of the terminal. An even slower subsequent rate corresponds to the continuous exocytosis of vesicles as they are recruited from the reservoir pool to the ribbon and then docked and released. *B*, The fastest phase of exocytosis is better resolved from measurements of membrane capacitance. By varying the length of a depolarizing pulse, the kinetics of this form of exocytosis can be investigated. The time constant of this phase, shown by the exponential fit, is 1.5 msec. *C*, The relative numbers of vesicles in the three pools and their rates of movement are indicated in this diagram. The rapidly releasable pool (RRP) of 1800 vesicles corresponds to all the vesicles docked below all of the ribbons in the terminal. The reserve pool corresponds to vesicles held by ribbons, and the much larger reservoir of 750,000 vesicles represents those vesicles that form a cloud around the ribbons and can be recruited to them. Calcium is thought to affect the movement of vesicles in each of these three steps. (*A*, From Lagnado [2000], copyright 2000, Experimental Physiology and the Physiological Society. *B*, From Mennerick and Matthews [1996], copyright 1996, with permission from Elsevier Science. *C*, From Gomis et al. [1999], copyright 1999, the Society for Neuroscience.)

However, fusion is not inevitable, and some docked vesicles escape, implying that docking is reversible. Although most vesicles dock and fuse at a few sites believed to correspond to ribbons, some fusions occur elsewhere, suggesting, as is thought to be the case for hair cells in the auditory system (Lenzi et al., 1999), that ribbons are not absolutely required for vesicle fusion.

Just as the photoreceptor synapse has autoreceptors that extend the dynamic range of the synapse by applying negative feedback, so, too, at the output synapses of bipolar cells. mGluRs, which by their pharmacological profile belong to group III, exercise rapid feedback for moderate and strong stimulation of salamander bipolar cells (Awatramani and Slaughter, 2001). The identity of the mGluR in the experiments of Awatramani and Slaughter is not certain, but it is probably not mGluR7; it may, however, be mGluR8. Because mGluR7 is also known to be located at the presynaptic terminal of bipolar cells (Brandstätter et al., 1996), it presumably is exercising a different kind of feedback. There is some evidence that mammalian rod bipolar cells express NMDA receptor subunits in their terminals (Wenzel et al., 1997), but as is often the case, whether these are functional and what function they might serve is unknown.

Bipolar cell to ganglion cell; postsynaptic mechanisms. The organization of glutamate receptors in the inner retina is much less well described than is the case for the outer retina. Numerous studies have examined the distribution of the different glutamate receptor subunits within the inner plexiform layer, and though it is clear that almost the whole inventory of receptors can be found in ganglion cells, the resolution of this picture allows only a few isolated examples where the identity of both presynaptic and postsynaptic partners are known. Of the AMPA receptor subunits, GluR2, at least in the cat (Qin and Pourcho, 1999), is relatively scarce among ganglion cells. Because this is the subunit that can render an AMPAR impermeable to Ca^{2+} , it might be expected that, in general, AMPARs in ganglion cells will admit Ca^{2+} . NMDARs are commonly found in ganglion cells and are usually seen at one of the two postsynaptic elements of a dyad (Fletcher et al., 2000; Pourcho et al., 2001). Metabotropic glutamate receptors are also common, with almost all ganglion cells of the rat having mGluR1 and mGluR4, and some having others besides (Hartveit et al., 1995).

Consistent with this immunocytochemical picture, numerous physiological studies indicate that both NMDA and AMPA/KA receptors mediate excitatory input from bipolar cells to ganglion cells (e.g., Mittman et al., 1990). In the salamander retina, studies with selective antagonists have shown that AMPA receptors, rather than KA receptors, provide the non-NMDA input (Lukasiewicz et al., 1997), although in

other retinas, KA subunits are found in ganglion cells (Qin and Pourcho, 2001).

Much of the interest in glutamatergic input to ganglion cells has centered on the question of how ganglion cells acquire their kinetic and receptive field properties. As already described, it is now clear that some bipolar cell types have transient responses, whereas others are sustained. Because transient bipolar cells generally connect to transient ganglion cells, and sustained bipolar cells generally connect to sustained ganglion cells (Awatramani and Slaughter, 2000), part of the kinetic difference between ganglion cell types is already accounted for. Along with amacrine cell input to ganglion cells, the behavior of postsynaptic glutamate receptors in ganglion cells also contributes to the kinetic properties of ganglion cells responses. Inferences from fluctuation analysis, a method for estimating the responses to single vesicles of transmitter from an examination of voltage noise, suggest that different bipolar cells converging to the same ganglion cell release transmitter at very different rates and have very unequal quantal responses. The response of a cat ON-beta ganglion cell to a vesicle of transmitter from a b1 bipolar cell is estimated to be $240\mu\text{V}$, whereas $30\mu\text{V}$ is all that the b2 and b3 cells produce (Freed, 2000). Most likely, this is due to differences in the type or number of postsynaptic channels at the different synapses, but conceivably, it could be due to differences in a presynaptic property, such as the number of glutamate molecules per vesicle.

Desensitization of AMPA receptors abbreviates the bipolar input to ON-OFF ganglion cells in salamander, as revealed in experiments in which AMPA receptor desensitization was abolished by thiazide compounds (Lukasiewicz et al., 1995). A second contributor to this abbreviation of glutamate inputs is made by glutamate transporters, probably on Müller cells, which play an important role in reducing glutamate responses tens of milliseconds after the stimulus (Higgs and Lukasiewicz, 1999). Although single quanta of transmitter are cleared effectively by diffusion, multiple quanta are not cleared well by diffusion and rely on uptake, suggesting that some degree of spillover of glutamate from one synapse to another might occur during strong stimulation.

Surprisingly, perhaps, physiological and pharmacological studies of ganglion cells reveal no differences between types. For example, alpha and beta cells of the cat (Cohen et al., 1994) and both ON and OFF midget and parasol ganglion cells from the primate retina are indistinguishable in terms of their ionotropic GluRs (Zhou et al., 1994). Does this mean that all ganglion cells are physiologically identical? Probably not. Very likely, differences between ganglion cells exist at a finer scale than is at present experimentally approachable and different bipolar cells are presynaptic to different combinations of glutamate receptors, as suggested

by the fluctuation analysis of Freed (2000). What is needed is a map of which receptors are postsynaptic to which bipolar cells.

NMDA receptors clearly contribute a significant fraction of excitatory input to ganglion cells, and this helps shape ganglion cell responses (Diamond and Copenhagen, 1993), but what function, if any, is served by the Ca^{2+} admitted through these channels? One possible role for this Ca^{2+} is the stimulation of nitric oxide synthase and the production of nitric oxide. Ganglion cell bodies, as well as dendrites, are known to produce nitric oxide when stimulated through NMDAR-mediated Ca^{2+} influx (Blute et al., 2000) and, unexpectedly, nitric oxide does not appear to spread extensively once generated. The functional significance of nitric oxide production for ganglion cell behavior is presently unknown, but very likely, its effects are via stimulation of soluble G cyclase.

NMDA receptors are themselves modulated by Ca^{2+} . The NMDA component of excitatory postsynaptic potentials (EPSPs) is reduced when Ca^{2+} is raised, either by influx through voltage-gated Ca^{2+} channels or else by release from the ER (Akopian and Witkovsky, 2001). Ca^{2+} seems to play an important and complex role in regulating the behavior of ganglion cells. Moreover, Ca^{2+} , admitted through different mechanisms, exercises different kinds of control. In salamander ganglion cells, glutamate acts at a group III mGluR to inhibit L-type Ca^{2+} channels via the release of Ca^{2+} from internal stores; however, glutamate also acts to inhibit N-type Ca^{2+} channels via Ca^{2+} admitted through ionotropic GluRs (Shen and Slaughter, 1998).

The Lateral Pathways

HORIZONTAL CELLS

Photoreceptor to horizontal cell; postsynaptic mechanisms. Horizontal cells constitute the pathway for lateral information flow in the outer retina. They mediate lateral inhibition that subserves gain control and, in some retinas, color opponency. Horizontal cells are the lateral elements in invaginating synapses, where they receive glutamatergic input from both rods and cones. Glutamate receptor subunits have been localized on the horizontal cell membranes at triads, and there is abundant physiological evidence for glutamatergic input. In the mammalian retina, immunocytochemistry shows the presence of AMPA-preferring subunits (e.g., Qin and Pourcho, 1996), for which there is also physiological evidence (Blanco and de la Villa, 1999), as well the KA-preferring subunits GluR6/7 (Morigiwa and Vardi, 1999), all located on the invaginating tips of horizontal cell dendrites. Good physiological evidence shows the presence of NMDA receptors on the horizontal cells of stingray and catfish retinas (Linn and Christensen, 1992; O'Dell and

Christensen, 1989), but this is not usual, even in other fish. The AMPA receptors of fish horizontal cells admit Ca^{2+} (Linn and Christensen, 1992; Okada et al., 1999), which, at least in some retinas, is part of the pathway that controls the rapid changes in synaptic morphology that accompany light and dark adaptation (Okada et al., 1999), described later.

Transmission from horizontal cells. Horizontal cells are widely thought to use GABA as a transmitter and to generate the surrounds of bipolar cells by being presynaptic to both photoreceptor terminals and bipolar cells; however, every one of these points has been challenged. A curious feature of horizontal cells is that their cytoplasm at presumed synapses is generally without the typical aggregation of presynaptic vesicles. It is generally accepted now that GABA release from horizontal cells is unconventional and uses a transporter whose rate and direction depend on membrane voltage and the Na^+ gradient, but not strongly on Ca^{2+} concentration (Schwartz, 1987). Calculations of the concentrations for external GABA suggest that, even assuming a constant Na^+ gradient, this mode of transmission generates equilibrium values for external GABA of between $4\mu\text{M}$ at -70mV membrane potential and $28\mu\text{M}$ at a horizontal cell membrane potential of -20mV . Very likely, this is within the useful range for postsynaptic GABA receptors (Attwell et al., 1993).

It was thought that the GABA transporter in horizontal cells was probably GAT-1, as this is commonly found in neuronal plasma membranes and has similar biophysical properties to those of the horizontal cell transporter (Cammack et al., 1994). No GAT-1 immunoreactivity, however, has been found on horizontal cells (Yang et al., 1997); instead, VGAT, the GABA transporter thought to be unique to synaptic vesicles, is located at or close to the plasma membrane of horizontal cells at triads (Haverkamp et al., 2000). This might, therefore, be the transporter responsible for GABA release. If so, it raises a number of questions, not the least of which is how a transporter that normally operates at the very low pH of synaptic vesicles could work efficiently at extracellular pH. The most recent work on rat and mouse retina (Cueva et al., 2002) suggests that VGAT is actually found in the cytoplasm of the tips of horizontal cell processes where, presumably, it is associated with the small number of vesicles found there. This finding might resolve the problem of what VGAT is doing in horizontal cells, but at the same time, it reopens the question of how GABA is released from horizontal cells.

Horizontal cell to horizontal cell. Horizontal cells have GABA receptors. The immunocytochemical evidence for this is not overwhelming, but physiological evidence supports this statement. Isolated rabbit horizontal cells show pharmacological

evidence of GABA_A receptors (Blanco et al., 1996), and fish and amphibian horizontal cells show both GABA_A and GABA_C ionotropic receptors (Dong et al., 1994; Qian and Dowling, 1993). These GABA receptors probably mediate chemical transmission between adjacent horizontal cells, but they also act as autoreceptors. A striking feature of horizontal cell light responses is that they can be remarkably slow in the dark-adapted retina, even though their glutamate receptors comprise unremarkable subunits closer to the synaptic release site of photoreceptors than those of ON bipolar cells, whose responses are much faster.

The slowness of horizontal cell light responses is the consequence of positive feedback, in that depolarization of horizontal cells increases extracellular GABA concentration, via the GABA transporter, which, in turn, further depolarizes the horizontal cell through ionotropic GABA receptors (Kamermans and Werblin, 1992). In horizontal cells, E_{Cl} is between -10 mV and -20 mV , so Cl^- conductances are generally depolarizing. When light hyperpolarizes photoreceptors, the glutamatergic input to horizontal cells is reduced quickly. However, the positive feedback loop considerably slows the horizontal cell hyperpolarization, not because the loop has any long delays, but rather because the loop gain is very low when the horizontal cell is depolarized but increases as the membrane potential gets further away from E_{Cl} .

Horizontal cell to photoreceptor. The properties of the synapses from horizontal cells to cone terminals and bipolar cells are not well described and have been obtusely resistant to simple characterization. With the exception of Greferath et al. (1995), who showed GABAR subunits in rod and cone terminals, antibodies have failed to locate GABARs in photoreceptors, although Vardi et al. (1998) reported that PCR finds alpha subunit mRNA in rat rods. A simple, robust result that compels belief in a GABAergic feedback pathway is that isolated cones show strong GABA_A responses when GABA is applied to their terminals (Tachibana and Kaneko, 1984). Nevertheless, careful physiological examinations of this synapse have turned up results that do not easily fit with this idea. In the salamander, a careful study (Hare and Owen, 1996) showed that surround responses in bipolar cells were not abolished with the combined presence of antagonists to GABA_A, GABA_B, and GABA_C receptors. Conceivably, the pharmacology of the receptor is novel, or perhaps the drugs used were unable to reach their targets, but the simplest explanation, as the authors conclude, is that GABA input from horizontal cells does not generate the receptive field surround of bipolar cells.

Parallel difficulties exist in the fish retina, where feedback to cones from horizontal cells establishes spectral opponency (Kamermans and Spekrijse, 1999). As a way of accommodating a number of awkward experimental results, it

has been proposed that the feedback mechanism is not GABAergic, but rather works by an electrical mechanism (Kamermans et al., 2001). The idea, similar to one suggested originally by Byzov and Shura-Bura (1986), is that horizontal cell terminals act as current sinks within the restricted space of the invaginating synapse. An unexpected finding supporting this idea is that the terminals of horizontal cells express connexin 26, a gap junction protein for which no partner exists on the apposed cone terminal membrane (Kamermans et al., 2001). The resulting hemijunctions, in effect, couple horizontal cells to the extracellular space of the synaptic triad. Because the Ca^{2+} channels responsible for photoreceptor transmitter release experience their voltage as the voltage difference between this extracellular space and the cone cytoplasm, this might allow horizontal cells to exercise an ephaptic feedback on the release of photoreceptor transmitter.

Horizontal cell to bipolar cell. Bipolar cell dendrites receive GABAergic input from horizontal cells. GABA_A subunits are found on the dendrites of both ON and OFF bipolar cells adjacent to horizontal cell processes (Haverkamp et al., 2000; Vardi et al., 1998). GABA_C subunits are also seen in dendrites, but they are not obviously located at synapses (Haverkamp et al., 2000; Wässle et al., 1998) and their function is unknown. Physiological recordings from bipolar cells confirm that bipolar dendrites have both GABA_A and GABA_C receptors (e.g., Du and Yang, 2000).

Because both ON and OFF bipolar cells have apparently similar GABA receptors, a problem is posed as surround illumination hyperpolarizes ON bipolars but depolarizes OFF bipolars, even though both effects are mediated by the same horizontal cells. A solution to this problem is suggested by the finding that the Cl^- transporters in the two types of bipolar cell are different (Fig. 19.6; Vardi et al., 2000). The dendrites of OFF bipolars heavily express KCC2, a Cl^- transporter that normally extrudes Cl^- , thus making E_{Cl} more negative. ON bipolar cells, on the other hand, express NKCC, a transporter that imports Cl^- and normally makes E_{Cl} more positive. This suggests that E_{Cl} is different in the two classes of bipolar cell in just the way that could explain how GABA depolarizes one while hyperpolarizing the other. Perhaps surprisingly, rod ON bipolar cells also express KCC2, but at the other end of the cell, in the axon terminals, implying that E_{Cl} is different in those two regions of a cell that are only $100\text{ }\mu\text{m}$ apart. On its face, this would imply a continuous and energetically wasteful Cl^- flux from the dendrites to the axon terminal unless these neurons have some way to compartmentalize Cl^- .

AMACRINE CELLS In the inner plexiform layer, synaptic patterns become very complex and the pharmacology of

FIGURE 19.6. Diagram summarizing the distribution of the two Cl^- transporters, KCC2 and NKCC, at bipolar cell membranes. KCC2 is found in the dendrites of OFF bipolar cells and is thought to produce a negative E_{Cl} . ON bipolar cells, by contrast, express NKCC in their dendrites, implying a more positive E_{Cl} . These presumed differences in E_{Cl} are consistent with bipolar cell inhibitory surrounds, depolarizing in OFF bipolar cells and hyperpolarizing in ON bipolar cells, produced by GABA from horizontal cells. Both rod (ON) bipolar cells and OFF bipolar cells express KCC2 in their terminals, where GABAergic input from amacrine cells is hyperpolarizing. (From Vardi et al. [2000], copyright 2000, the Society for Neuroscience.)

synaptic responses is only vaguely understood. The basic plan, though, is that most amacrine cells are inhibitory, and of these, most are GABAergic, with a minority being glycinergic and an even smaller minority using other transmitters. In goldfish, a recent study (Marc and Liu, 2000) estimated that 92% of synapses in the inner plexiform layer, excluding those made by bipolar cells, were made by GABAergic amacrine cells. Amacrine cells receive glutamatergic input from bipolar cells and, in turn, provide negative feedback to bipolar cell terminals and inhibitory feedforward to ganglion cells, as well as input to other amacrine cells. As described later, the individual feedback and feedforward pathways are complex, both in their pharmacology and especially in their modulation, about which little is understood. The task of working out the patterns of synaptic connections is truly daunting, especially since we do not yet have a complete classification of the dozens of amacrine cells likely to be found in any retina. Beyond these difficult questions, though, are higher-order questions of how and why inhibitory amacrine

cells are connected in networks, and why so many inhibitory cells are needed.

Bipolar cell to amacrine cell. Only a few studies have examined the bipolar input to amacrine cells, and of these, most are concerned with input from the mammalian rod bipolar cell to the two postsynaptic partners at the dyad, the AII amacrine cells and the A17 amacrine cells (also known as AI amacrine cells). The AII amacrine cells lie on the direct signal pathway to ganglion cells, and the A17 cells are lateral elements providing feedback. These two different roles are subserved by different teams of postsynaptic receptors whose identity is now becoming clearer. Physiological work shows that AMPA/KA receptors dominate input to A17 amacrine cells in the rat (Menger and Wässle, 2000), and in these cells, there seems to be no NMDA input. Immunohistochemical studies have shown that A17s are likely to have kainate-type receptors incorporating the orphan δ receptor subunit (Ghosh et al., 2001). AII amacrine cells, on the other hand, express standard AMPAR subunits, but in addition to responding to non-NMDAR agonists, they also respond to NMDA (Hartveit and Veruki, 1997). This does not necessarily imply that normal bipolar input is mediated through these receptors, though. A cautionary result is reported by Matsui et al. (2001) for transient ON amacrine cells of the mouse retina. In these cells, bipolar input is normally mediated by AMPA receptors; only when the inhibitory feedback from amacrine cells is disabled is the enhanced release of glutamate from bipolar terminals able to activate NMDA receptors.

Metabotropic glutamate receptors are found in amacrine cells and very likely play important modulatory roles. A member of the group II mGluRs, mGluR2 has been found in cholinergic amacrine cells in both ON and OFF sublaminae (Hartveit et al., 1995) and also in A17 cells, where it has been proposed as a mechanism that decreases GABA release at the reciprocal synapse back to rod bipolar cells (Brandstätter et al., 1998). Group I mGluRs are also found on amacrine dendrites postsynaptic to bipolar cells (Koulen et al., 1997). Group I mGluRs are characterized by their coupling to phospholipase C (PLC) and the release of Ca^{2+} from internal stores. Ca^{2+} imaging experiments on amacrine cells from the chick show that two distinct mGluRs are functional in these cells (Kreimborg et al., 2001).

The typical pattern of connection in the inner plexiform layer is that bipolar cells make synapses with two postsynaptic elements, of which one is generally an amacrine cell. However, in addition to this usual arrangement, there are also monads, triads, and tetrads (Marc and Liu, 2000). It is not presently clear what the significance of these patterns is, nor the extent to which these arrangements are specific to particular neuronal types, rather than inconsequential

variations on a theme. Some electron microscopic sections show an amacrine cell process postsynaptic to a bipolar cell that is itself receiving a synaptic feedback from the same amacrine cell. This common anatomical arrangement is termed a “reciprocal synapse.”

Amacrine cell to bipolar cell. Tachibana and Kaneko (1987), using isolated Mb1 bipolar cells from the goldfish retina, showed that GABA sensitivity was high at the axon terminal where GABAergic amacrine cells could provide negative feedback (Fig. 19.7). Like the glutamatergic input to bipolar cells in the outer plexiform layer, the GABAergic input in the inner plexiform layer is turning out to be different in different classes of bipolar cell (Euler and Wässle, 1998; Lukasiewicz and Wong, 1997; Shields et al., 2000), reinforcing the idea that every bipolar cell type carries a unique representation of the pattern of photoreceptor signals. All three kinds of GABA receptor—the ionotropic A and C and the metabotropic $GABA_B$ receptors—are thought to be expressed in bipolar cell terminals. $GABA_C$ receptors activate and deactivate relatively slowly, show little desensitization, and, compared to $GABA_A$ receptors, require a low concentration of GABA for their activation. There is general agreement from both immunocytochemical and physiological studies that $GABA_C$ receptors provide a large fraction of the feedback to the terminals of most bipolar cells (Lukasiewicz et al., 1994; Lukasiewicz and Werblin, 1994; Wässle et al., 1998), but $GABA_A$ receptors also play a role (e.g., Pan, 2001).

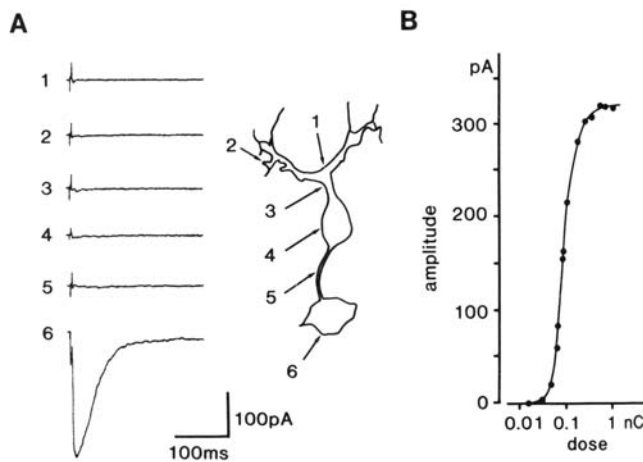

FIGURE 19.7. Currents recorded from a voltage-clamped, isolated Mb1 cell from the goldfish retina. A fine-tipped pipette containing GABA was moved around the cell to the positions indicated by numbers. At each position, an identical dose of GABA was applied iontophoretically. Only when the pipette was placed next to the synaptic terminal (6) was a large, inward Cl^- current seen. (From Tachibana and Kaneko [1987], with permission of the authors.)

The mammalian rod bipolar cell is the best-examined mammalian bipolar cell. Fast-acting GABAergic reciprocal feedback to this bipolar cell is provided by the A17 amacrine cell. This amacrine cell has a powerful ability to extend the dynamic range of the bipolar cell with respect to light intensity, as demonstrated by depressing $GABA_A$ and $GABA_C$ input pharmacologically, or alternatively, cutting off the axon terminal (Fig. 19.8) (Euler and Masland, 2000). $GABA_A$ and $GABA_C$ receptors, though both present on the terminals of rod bipolar cells, do not colocalize (Koulen et al., 1998), raising the question of which amacrine cell provides $GABA_A$ and which $GABA_C$ feedback. An alternative possibility is that A17 cells themselves form both $GABA_A$ -only and $GABA_C$ -only synapses. Is depolarization of a single rod bipolar cell sufficient to drive its own reciprocal inhibition? Direct voltage-clamp experiments on rat rod bipolar cells show that it is (Hartveit, 1999). This result is remarkable, as a single A17 cell, at least in the cat, contacts on the order of 1000 rod bipolar cell terminals (Nelson and Kolb, 1985), leading to the expectation that input from a single rod bipolar cell would generate a negligible signal in the amacrine cell. The fact that this expectation is not fulfilled might suggest that reciprocal synapses act locally. A version of this idea was proposed earlier (Ellias and Stevens, 1980), whereby amacrine cells were thought to act locally by virtue of a restricted spread of their electrical signal. Unfortunately, this idea is not easily consistent with the receptive field properties of amacrine cells (Bloomfield, 1992) and is not widely believed. It might be time to revisit the idea of local

FIGURE 19.8. Normalized peak responses of rod bipolar cells to flashes of different luminance, recorded in retinal slices of a rat. Intact rod bipolar cells have a significantly shallower response curve than those in which the axon terminal has been removed. The implication of this difference is that the feedback at the axon terminal of bipolar cells can extend the sensitivity of these cells. (From Euler and Masland [2000], copyright 2000, The American Physiological Society.)

interactions, this time with the idea that they might be based on local cytoplasmic Ca^{2+} concentration, as it is now well established that this ubiquitous messenger can be locally controlled. In this context an important recent finding has been revealed by 2-photon Ca^{2+} imaging applied to starburst amacrine cells while moving patterns of light were applied to the retina (Euler et al., 2002). Voltage recordings from the somata of these neurons showed no directional preference but the Ca^{2+} signals in individual dendrites were strongly selective for patterns moving centrifugally relative to the soma.

The relative importance of different GABA receptors in generating feedback to bipolar cells other than mammalian rod bipolar cells is somewhat controversial. A confusing factor in untangling this problem is that the pharmacology of GABA_C receptors has not been completely described and differs between preparations. The hallmark insensitivity to bicuculline is consistent, but picrotoxin, which inhibits these channels in ferrets (Lukasiewicz and Wong, 1997) and amphibians (Lukasiewicz et al., 1994), fails to block the channel in the rat (Feigenspan et al., 1993). As described by Shen and Slaughter (2001), there are two pharmacologically distinct GABA_C receptors, one blocked by picrotoxin and the other blocked by I4AA (imidazole-4-acetic acid).

In the salamander retina, Shen and Slaughter (2001) claim that GABA_A input to bipolar cells is small and that the metabotropic GABA_B receptors and the ionotropic GABA_C receptors contribute approximately equally to inhibitory feedback. Lukasiewicz and Werblin (1994), however, failed to confirm an earlier report (Maguire et al., 1989) that GABA_B receptors in bipolar terminals controlled Ca^{2+} current and hence, transmitter release. In addition to uncertainties in the pharmacology of the various GABA receptors, another possible reason for differences in interpretation is that the GABA_B pathway may not be driven strongly by brief step of light, the conventional stimulus (Shen and Slaughter, 2001).

Amacrine cell to ganglion cell. Inhibitory feedforward from amacrine cells to ganglion cells, like feedback to bipolar cells, is an area of pharmacological controversy. There is general agreement that inhibitory feedforward is a powerful mechanism, but disagreement concerns the receptors that mediate this. GABA_A receptor subunits are found expressed on ganglion cells with different subunits at different synapses on the same cell (Wässle et al., 1998), where they mediate transient inhibition (Lukasiewicz and Shields, 1998). Lukasiewicz and Shields (1998) report that GABA_A receptors alone mediate inhibition to ganglion cells of the amphibian retina, but other work suggests there is also GABA_C (Zhang and Slaughter, 1995) and GABA_B input to ganglion cells (Shen and Slaughter, 2001).

As described by Zhang et al. (1997b), there are two separate GABA_B receptors on salamander ganglion cells. For one of these, baclofen is an agonist; for the other, *cis*-aminocrotonic acid (CACA) is an agonist. Both GABA_B receptors reduce Ca^{2+} currents, but the baclofen-sensitive receptor seems to work through a G protein that directly interacts with an N-type Ca^{2+} channel, whereas the CACA-sensitive pathway affects Ca^{2+} entry through L-type Ca^{2+} channels. The regulation of the CACA-sensitive pathway involves cGMP that can be stimulated through the effect of nitric oxide on G cyclase, whereas regulation of the baclofen-sensitive pathway involves calmodulin, which, in turn, can apparently produce both upregulation and downregulation at the receptor.

Already, this is a very complicated picture implying several levels of inhibition under different control mechanisms. Calcium entry clearly plays a significant role in the control of this inhibition, and it is apparent that Ca^{2+} can enter not only through the N- and L-type Ca^{2+} channels of ganglion cells, but possibly, also through NMDA receptors and Ca^{2+} -permeable AMPA receptors. As already described, glutamate seems to regulate L- and N-type Ca^{2+} channels (Shen and Slaughter, 1998), thus allowing an interaction of the two transmitters—GABA and glutamate—at the level of the ganglion cell second-messenger pathways and dendritic Ca^{2+} concentration. Working out how this level of control is regulated normally will be a difficult task since we presently have no good picture of which amacrine cells provide input to which ganglion cells. Conceivably, the complex situation described here for the amphibian retina will turn out to be less complicated in the mammalian retina, as the evidence for GABA_B receptors in the latter is presently not strong.

Amacrine cell to amacrine cell. Electron microscopic anatomy has shown that amacrine cells are extensively interconnected by conventional synapses. In some retinas, such as those of the frog and pigeon, synapses in the inner plexiform layer at which amacrine cells are presynaptic outnumber those at which bipolar cells are presynaptic, by a factor of almost 11 to 1 (Dubin, 1970). As already pointed out, the patterns of amacrine to amacrine connections are clearly complex, involving loops of synapses in addition to presumed electrical connections mediated by gap junctions (Vaney, 1999).

Like reciprocal synapses, “serial synapses” are defined anatomically and describe the common situation in which one amacrine cell process is seen to be presynaptic to another, which is presynaptic to another, and so on. Identifying these chains depends on lucky electron microscopic sections, so it can be assumed that chains of amacrine cell synapses are even more common than they appear. A simple

physiological experiment involving the application of a glycinergic antagonist to the retina (Zhang et al., 1997a) shows that serial synapses are important. With this treatment, inhibition was decreased in most ganglion cells, but was increased in one-third of the ganglion cells examined. The explanation for this is that blockade of glycinergic amacrine cell synapses is disinhibitory for some GABAergic amacrine cells, and for about one-third of ganglion cells, these disinhibited GABAergic amacrine cells provide the bulk of the inhibitory input. A similar result was obtained when GABAergic input was blocked, and in an analogous way, this implies that, for some ganglion cells, disinhibited glycinergic amacrine cells provide the chief inhibitory input. Clearly, if the pattern of connectivity is complex and contains nested loops (Marc and Liu, 2000), the outcome of blocking a whole class of transmission will be hard to predict without knowing the relative synaptic strengths and dynamics of the synapses. Needless to say, this knowledge is not imminent.

Although most amacrine cells are GABAergic, some of these cells may release other fast transmitters in addition to GABA. The best-known example of this is the starburst amacrine cell, which is thought to release both GABA and acetylcholine (ACh). Studies examining the release of radioactively labeled GABA and ACh (O'Malley et al., 1992) provide convincing evidence that ACh is released by depolarization and light stimuli in a Ca^{2+} -dependent way, consistent with conventional vesicular transmitter release. The results concerning the release of ^3H -GABA are less easy to interpret, but point to a Ca^{2+} -independent exchange mechanism like that described in horizontal cells (Schwartz, 1987). Because these studies were carried out in intact retinas, ^3H -GABA efflux is the sum of efflux from all GABAergic cells in the retina, including horizontal cells, of course. Since GABAergic amacrine cells have conventional synapses with clear vesicles, it seems dubious that GABA transport would be the only mode of release in these cells. More recent studies using cultures of amacrine cells that accumulate both GABA and ACh suggest that, in addition to some GABA release via a transporter, both transmitters are released in a Ca^{2+} -dependent manner. Release of the two transmitters is, nevertheless, slightly different in that GABA release prefers Ca^{2+} entry through L-type Ca^{2+} channels, whereas ACh release seems to prefer entry of Ca^{2+} through N-type channels (Santos et al., 1998). If true, many intriguing questions follow from the implication that a single amacrine cell can release two transmitters. Are the two transmitters released by different patterns of input? Are the two transmitters located at different synapses, and if so, what are the postsynaptic cells at those synapses? These questions have rich implications, as the starburst amacrine cell is a key element in the establishment of directional cell activity in ganglion cells (Yoshida et al., 2001), and the differential

release of the two transmitters might well play a central role in this.

Much has been learned about the release of GABA from amacrine cells by the application of electrophysiological techniques to transmission between synaptically connected pairs of cultured chick amacrine cells. Consistent with the anatomy, which shows vesicles in presynaptic locations (Gleason and Wilson, 1989), transmission is quantal when examined with brief depolarizations (Fig. 19.9). Depolarization to about -45 mV is required to evoke transmission, and Ca^{2+} entry is chiefly through L-type Ca^{2+} channels, though another unidentified high voltage activated (HVA) Ca^{2+} channel plays a minor role in promoting release (Gleason et al., 1993). An important feature of these synapses is that, although buffering cytoplasmic Ca^{2+} to zero abolishes all release, these synapses release transmitter, albeit at a low rate, even at resting cytoplasmic levels of Ca^{2+} (around 100 nM) (Frerking et al., 1997). This is a little surprising, as these are conventional synapses for which the expectation is that about $100\text{ }\mu\text{M}$ of Ca^{2+} is required to activate release; in this regard, these synapses are similar to the ribbon synapses in photoreceptor and bipolar cells. Recordings from goldfish amacrine cells in slices show a continuous barrage of quantal input from other GABAergic amacrine cells, even in the absence of all glutamatergic input (Watanabe et al., 2000). It is not clear how this input is maintained, but it seems plausible that it represents the collective input from several amacrine cells releasing quanta at a basal rate.

Strong depolarizations of chick amacrine cells elicit an initial burst of transmitter release, followed by sustained release at a much lower rate (Fig. 19.10) (Borges et al., 1995). This result supports a "fire and reload" model in which vesicles already docked and primed at release sites are discharged soon after Ca^{2+} entry, but once these have fused with the plasma membrane, the release rate slows down considerably as the docking or priming of fresh vesicles becomes the rate-limiting step. Once again, this is qualitatively similar to the situation with the bipolar cell ribbon, except that only a single vesicle is capable of immediate release at the amacrine cell active zone, as opposed to the 22 at the bipolar cell ribbon. Like bipolar cell synapses, cessation of Ca^{2+} influx does not result in immediate termination of transmitter release because the low residual concentrations of Ca^{2+} are sufficient to promote transmitter release. This observation in cultured cells has a counterpart in retinal slices, where depolarization of a rat rod bipolar cell results in a long-lasting inhibitory input presumed to be from an A-17 amacrine cell (Hartveit, 1999).

Because low concentrations of cytoplasmic Ca^{2+} are sufficient to promote transmitter release, the removal of Ca^{2+} plays a role in the kinetics of transmitter release. At synapses that require a high concentration of Ca^{2+} , diffusion alone is

FIGURE 19.9. The Ca^{2+} requirement for transmitter release from amacrine cells. *A*, Postsynaptic currents recorded from a cultured chick amacrine cell held in voltage clamp while the presynaptic cell is depolarized from -70 mV to the voltages indicated to the left of each record. The presynaptic voltage step to -40 mV elicits a single, discrete, outward current corresponding to the release of a single vesicle of transmitter. As the voltage is made increasingly positive, the numbers of vesicles released increases, and transmitter release clearly continues after the presynaptic cell has been repolarized. *B*, The normalized peak Ca^{2+} currents, elicited from a voltage-clamped, isolated amacrine cell. Current begins to activate at about -40 mV , the voltage at which transmission begins in *A*. Pharmacological data show that this inward current is chiefly, but not exclusively, an L-type Ca^{2+} current. *C*, Dependence of the rate of transmitter release on cytoplasmic Ca^{2+} concentration. Buffered Ca^{2+} was internally perfused in 49 amacrine cells while the maximum rate of their transmitter release was recorded. The most important feature of this plot is that, while the release rate is zero at 1 nM Ca^{2+} , 50 and 200 nM Ca^{2+} clearly produces continuous release of transmitter at a low rate. (*A*, From Gleason et al. [1993], copyright 1993, the Society for Neuroscience. *B* and *C*, From Wilson, M. Synaptic transmission between retinal neurons, in Chalupa and Finlay [1998], Copyright 1998, Plenum Press, New York.)

sufficient to clear Ca^{2+} very quickly once Ca^{2+} channels close. The ribbon synapses of photoreceptors and bipolar cells apparently rely on the plasma membrane Ca^{2+} ATPase, the Ca^{2+} pump, for Ca^{2+} clearance (Krizaj and Copenhagen, 1998; Zenisek and Matthews, 2000), but at chick amacrine cell synapses, the $\text{Na}^+-\text{Ca}^{2+}$ exchanger is important (Fig. 19.11) (Gleason et al., 1994). Disabling exchange by removing external Na^+ can enormously extend synaptic transmission in these cells, but the mechanism by which this works is indirect. The seemingly obvious interpretation, that Ca^{2+} entering through Ca^{2+} channels remains longer when the $\text{Na}^+-\text{Ca}^{2+}$ exchanger is unable to function, is wrong. Instead, even when the exchanger is working normally, a large fraction of the Ca^{2+} responsible for synaptic transmission comes, not from Ca^{2+} entry from the outside, but rather from internal Ca^{2+} stores triggered to release by the Ca^{2+} entering

through Ca^{2+} channels (Hurtado et al., 2002). Calcium increases in amacrine cell dendrites can be very local and “spontaneous.” Using two-photon microscopy, Denk and Detwiler (1999) have observed local Ca^{2+} variations in dendrites and spontaneous Ca^{2+} increases, even in the absence of light stimulation.

Synaptic plasticity

Because the retina has to operate efficiently over a huge range of light intensities, it has the ability to tune its configuration to suit the prevailing lighting. The processes of dark and light adaptation are the transitions from one state to another and represent changes in many aspects of retinal organization, including functional changes to synapses. One of the most striking forms of plasticity is the change in

FIGURE 19.10. The kinetics of transmitter release from cultured chick amacrine cells. *A*, The average postsynaptic current elicited by repeatedly stepping the presynaptic voltage from -70 to 0 mV during the period indicated by the bar. The postsynaptic current shown here is the sum of responses to many individual quanta of transmitter. *B*, Using the measured average response to a single quantum of transmitter, a mathematical deconvolution has been used to generate the instantaneous release rate, given in number of quanta released per release site per millisecond. What is revealed

here is that depolarization brings about a sharp, transient increase in release rate, followed by a much slower rate that continues even after presynaptic Ca^{2+} channels close. The initial spike of release probably corresponds to the fusion of vesicles already docked at the release site, whereas the slower, continuous rate is limited by some other process, such as the docking of fresh vesicles. (From Borges et al. [1995], Copyright 1987, National Academy of Sciences, USA.)

synaptic anatomy that takes place in teleost fish retinas (reviewed in Wagner and Djamgoz, 1993).

SPINULES Exposure of a dark-adapted teleost retina to light brings about dramatic physiological (Mangel et al., 1994) as well as morphological changes at cone terminals, on a time scale of minutes. As already described, horizontal cells typically form the two lateral elements of invaginating synapses in which the postsynaptic elements push deeply into the presynaptic terminal, assuming a position opposite the synaptic ribbon. The major morphological change produced by light is that horizontal cell dendrites push out new finger-like processes called spinules, the tips of which are lined with electron-dense material, which further invade the synaptic terminal of cones (Fig. 19.12). The prevailing view has been that spinules are the site of feedback to cones from horizontal cells; in support of this idea is the finding that some changes in horizontal cell physiological properties exactly parallel spinule formation. For example, one sort of horizontal cell, the C-type H2 cell, changes its spectral responses in parallel with spinule formation. When light adapted, it shows depolarization to red light but hyperpolarization to all other wavelengths, whereas when dark adapted, it hyperpolarizes regardless of wavelength (Weiler and Wagner, 1984). A popular theory of the way in which color opponency is generated in light-adapted cones and horizontal cells implicates feedback to cones from horizontal cells as a critical component (Stell et al., 1975), consistent with the “spinules as feedback sites” idea. Further support for this comes from the finding that cytochalasin, which inhibits spinule formation, also prevents the development of spectral opponency in H2 cells (Ter-Margarian and Djamgoz, 1992).

The notion that spinules serve to mediate feedback is an attractive idea, but one based chiefly on correlation, rather than demonstrated causation, and this interpretation has recently been questioned (Weiler et al., 1996). One objection to the concept of spinules as feedback sites is that no GABA_A receptors have been identified immunocytochemically on the cone terminal membranes surrounding the spinule (Yazulla et al., 1989). However, as discussed earlier, it is possible that feedback might be ephaptic (Kamermans et al., 2001), with no need of GABA receptors. The fact that spinules are generally without vesicles is not a strong objection since horizontal cells are thought to release GABA in a non-vesicular fashion (Schwartz, 1987). However, under some circumstances, vesicles in the cone align themselves with the tips of spinules, suggesting that horizontal cell spinules might actually be postsynaptic, rather than presynaptic, structures (Weiler et al., 1996).

The mechanisms involved in the formation and retraction of spinules have been widely investigated. Separate mechanisms seem to be involved in the formation, retraction, and, perhaps, maintenance of spinules, and though none of these pathways have been fully worked out, progress has been made in identifying the likely initial steps. Retinoic acid, a by-product of phototransduction, may well be the main signal for spinule formation, as it is potentially effective at this task (Weiler et al., 1998). Activation of protein kinase C is also very effective and is a likely early step (Kohler et al., 1990). Dopamine, which has multiple actions in mediating light adaptation, is also, to a lesser extent, capable of spinule induction (Kirsch et al., 1991), but may be working through a parallel pathway.

FIGURE 19.11. Simultaneous presynaptic and postsynaptic recordings from a synaptically connected pair of cultured chick amacrine cells. These records show the importance of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger in controlling the release of transmitter. When the presynaptic cell is depolarized for 100 msec, an inward Ca^{2+} current is elicited, followed by a slowly decaying, inward current that is the signature current of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger. During presynaptic depolarization, and for some time afterward, the postsynaptic cell shows a noisy, outward current generated by the release of GABA quanta. When Li^+ replaces external Na^+ , the $\text{Na}^+\text{-Ca}^{2+}$ exchanger is disabled, and the exchanger's signature current is abolished. Under these conditions, the release of GABA quanta is greatly prolonged. Restoring normal external Na^+ restores the normal kinetics of transmitter release. (Modified from Gleason et al. [1994], copyright 1994, with permission from Elsevier Science.)

The dark-adaptation signal for spinule retraction probably operates via AMPA receptors in the horizontal cell membrane. This seems reasonable because darkness would be expected to increase glutamate release from photoreceptors and could, therefore, open AMPA channels. The spinule retraction signal requires external Ca^{2+} to be admitted to horizontal cells, but not through NMDA receptors or voltage-gated Ca^{2+} channels. Only AMPA receptors, presumably without the GluR2 subunit and probably homomeric GluR3 (Schultz et al., 2001), seem to be involved (Okada et al., 1999). Several pieces of evidence contribute to this conclusion, including the finding that a selective

FIGURE 19.12. A cut-away schematic view of a cone terminal shown in its light-adapted state (*left*) and dark-adapted state (*right*). In the light-adapted state, the horizontal cell dendrites that form the lateral elements of triads push out finger-like spinules that are retracted during dark adaptation. (From Wagner and Djamgoz [1993], copyright 1993, with permission from Elsevier Science.)

antagonist for AMPA receptors inhibits spinule retraction. The Ca^{2+} that is admitted through these channels probably activates CaM KII, as inhibition of this kinase or calmodulin also prevents spinule retraction.

The terminals of bipolar cells also show spinule formation, though less is known about this process. The transition between light and dark adaptation produces substantial changes in membrane area in bipolar cell terminals, and spinule formation is one part of this more general rearrangement. ON bipolar cells show spinule formation during dark adaptation (Yazulla and Studholme, 1992), whereas OFF bipolar cells form spinules in light adaptation (Behrens and Wagner, 1996), like horizontal cells. In both cases, the spinules of the inner retina are finger- or mushroom-shaped projections of the bipolar terminal that invaginate an amacrine cell process. The cytoplasm in the tip of the spinule contains vesicles and is lined with membrane densities, as is the apposing amacrine cell membrane.

The isolated Mb1 cell from the goldfish that has proved so useful in the examination of vesicle cycling, has recently become the subject of studies on spinule formation. Depolarization of isolated Mb1 cells from the goldfish, mimicking the effect of light, has been shown to increase the amount of F actin in the terminal in a way that requires Ca^{2+} influx through L-type channels, as well as the stimulation of protein kinase C (PKC) (Job and Lagnado, 1998). Disappointingly, though, this study finds that the cytoskeletal change does not affect the continuous cycling of vesicles.

Using slightly different methods, however, Minami et al. (1998) found that activation of PKC could augment transmitter release. This seems to be accomplished by increasing the size of the available vesicle pool (Tachibana, 1999).

As is true for horizontal cell spinules, the function of spinules in bipolar cells has not been elucidated convincingly. However, Yazulla and Studholme (1992) have proposed that, in the case of the Mb cells, spinules are the sites of GABAergic input to bipolar cells from amacrine cells since the amacrine cell processes that host spinules stain positive for glutamic acid decarboxylase (GAD), the GABA-synthesizing enzyme (Yazulla and Studholme, 1991). This simple proposal is complicated, though, by the finding that, instead of GABA receptors, glycine receptors are found on the bipolar cell spinule membrane.

Summary and future directions

It will, I hope, be clear from this brief review that the field of retinal synapses offers the neuroscientist a rare opportunity to understand the mechanism of a neural machine in a way that can be related to the function and overall design of the machine. There is an abundance of first-rate questions, and because the field is in its early growth phase, the answers to these questions tend to generate still more questions.

In the outer retina, the working of the synaptic complex of cones remains a puzzle, but one that might be addressable in the near future. There are very particular questions associated with this issue. For example, does all the glutamate come from the release sites adjacent to the ribbon, or is glutamate also released at the base of the cone terminal? The overarching question, though, is what engineering problem is solved by this baroque structure?

In the inner retina, there are many pressing questions. The presence of multiple metabotropic receptors in the inner retina has brought the modulation of synapses high up the agenda. Quite apart from modulation of synapses by the metabotropic receptors already discussed is the action of the many peptides found in amacrine cells. Extremely little is known about what these peptides do, and almost nothing is known about how they are released and where their target receptors lie. Because the retina contains dozens of neuropeptides, it seems implausible that they are all involved in light/dark adaptation, the only form of modulation about which we have some understanding.

Release of transmitter from amacrine cells probably has some novel mechanisms. The release of more than one transmitter from a single cell is clearly an important problem, as is the possibility of local control of release. In approaching these issues, a confounding factor is that much of the connectivity of amacrine cells is unexplored territory. A practical approach would be to concentrate on the best-known amacrine cells and to examine closely their synaptic

physiology. The obvious choice would be the AII and the A17 cells postsynaptic to rod bipolar cells in the mammalian retina.

20 Retinal Neurotransmitters

ROBERT E. MARC

FAST SYNAPTIC SIGNALING in the vertebrate retina encodes presynaptic voltages as time-varying modulations in extracellular neurotransmitter concentrations and decodes neurotransmitter signals with postsynaptic transmembrane ionotropic or heptahelical receptor arrays. Additional heptahelical receptor pathways conditionally modulate synaptic signaling, often on lower temporal and spatial frequency scales. The six major retinal neurotransmitters—glutamate, gamma-aminobutyric acid (GABA), glycine, acetylcholine, dopamine, and serotonin—are synthesized in group-transfer reactions associated with distinctive cells. The sources and targets of less circumscribed, small-molecule modulators are mentioned only briefly, and peptides are treated elsewhere. Vertical channels deploy fast, high-gain glutamatergic synapses between photoreceptors (PRs) and their bipolar cell (BC) and horizontal cell (HC) targets, and between bipolar cells and their amacrine cell (AC) and ganglion cell (GC) targets. Lateral channels composed of horizontal cells and amacrine cells primarily use fast, low-gain, sign-inverting GABAergic and glycinergic synapses, with specialized circuits employing high-gain, sign-conserving cholinergic signaling. Four modes of fast synaptic transfer dominate neuronal receptive field circuits: high-gain, sign-conserving (\Rightarrow) or sign-inverting ($i\Rightarrow$) transfers, and low-gain, sign-conserving (\rightarrow) or sign-inverting ($i\rightarrow$) transfers. The following sections summarize metabolic networks, transporters, receptors, and circuitries for each neurotransmitter species, concluding with a summary of future directions. Figures 20.1 to 20.6 encapsulate metabolic network diagrams, Enzyme Commission (EC) and Transport Commission (TC) codes, localizations of macromolecules associated with a neurotransmitter phenotype, and other data. References are restricted to reviews or recent exemplars of concepts from which original literature may be traced.

The vertical channel neurotransmitter: L-glutamate

GLUTAMATE METABOLIC NETWORKS L-glutamate is a net anion at physiological pH and the central amino acid in a vast network of group transfers in all cells. No enzyme exclusively controls intracellular glutamate levels and no enzyme cluster yet defines a glutamatergic phenotype. Cellular contents of glutamate and other small molecules reflect group transfer, energetic, redox, osmoregulatory, and signaling demands that require supramillimolar concentrations

≈ 10 to 100 times greater than those required to charge transfer RNAs (tRNAs) for protein synthesis. Many transport epithelia and other somatic cells maintain 1 to 10 mM of glutamate, levels as high as photoreceptors, bipolar cells, and ganglion cells; neurons are not unique in this regard. Neuronal glutamate is predominantly derived from glutamine produced in Müller cells (MCs), but the retinal pigmented epithelium (RPE) maintains 2 to 10 mM glutamine and could be a source for photoreceptors. Normal Müller cells display avid glutamate transport but contain less glutamate than neurons (50 to 500 μ M) owing to robust conversion by glutamine synthetase (glutamate-ammonia ligase, Fig. 20.1). Glial glutamine export appears driven by transactivated System N (SN1) transporters (Chaudhry et al., 1999) and neuronal glutamine import by the Na^+ -dependent Glt1 transporter (Varoqui et al., 2000). Glutaminase on the inner mitochondrial membrane exterior deamidates glutamine to glutamate within the intermembrane space, from whence glutamate may either be transported to the mitochondrial matrix to drive 2-oxoglutarate synthesis or escape to the cytosol via porin channels.

GLUTAMATE TRANSPORTERS Vesicular glutamate import is mediated by VGluT1 and VGluT2 transporters, members of the Na^+ -dependent plasma membrane PO_4^- symporter family (e.g., Takamori et al., 2000). VGluT1 is strongly expressed in both the outer and inner plexiform layers (Stobrawa et al., 2001), and VGluT2 has yet to be mapped, although it is differentially distributed in brain (Varoqui et al., 2002). Anionic glutamate import ($K_m \approx 1$ to 3 mM) is strongly coupled to $\Delta\psi$ generated by vacuolar ATPase (vATPase)-mediated proton accumulation. The number of VGluTs per vesicle, their transfer numbers, and resultant vesicular glutamate concentrations are all undetermined. Electron microscopic immunocytochemical data in lamprey spinal cord have yielded estimates of vesicular glutamate levels of ≈ 60 mM, but true levels could be up to 10-fold lower.

Plasma membrane high-affinity glutamate transporters ($K_m \approx 5$ to 50 μ M) are single, 10-transmembrane domain (TMD), 1-reentrant loop polypeptides and members of the widely distributed Na^+ -dependent acidic and neutral amino acid transporter superfamily (Seal and Amara, 1999). Import is coupled to the sodium gradient ($\Delta p\text{Na}$) and $\Delta\psi$ (increased transport at negative potentials), and

FIGURE 20.1.

experimental collapse of these gradients activates transporter export sufficient to empty a neuron of glutamate in minutes. Physiologically, export is gradually activated by increasingly positive potentials, although the net import/export balance is not known. Import is weakly electrogenic owing to Na^+/H^+ symport, but it can be strongly electrogenic by activating nonstoichiometric Cl^- channel conductance increases ($\uparrow\text{gCl}$). Four glutamate transporters are expressed in the mammalian retina: predominantly EAAT1 in Müller cells; EAAT2 in cones and bipolar cells; EAAT3 in horizontal cells, amacrine cells, and ganglion cells; EAAT5 in nonmammalian Müller cells and mammalian rods (Pow et al., 2000).

Plasma membrane glutamate transporters likely shape synaptic kinetics, control glutamate overflow, and recycle carbon skeletons. Horizontal cell response kinetics are shaped by cone glutamate transporters (Gaal et al., 1998; Vandenbranden et al., 1996), and EAAT2 should act similarly at $\text{BC} \Rightarrow \text{AC}$ and $\text{BC} \Rightarrow \text{GC}$ synapses. The relative roles of intrasynaptic neuronal and extrasynaptic glial transport are unresolved. Neuronal transport may couple intrasynaptic glutamate levels to cone voltage via transporter $\Delta\psi$ dependence (Gaal et al., 1998) when Ca^{2+} flux through voltage-independent cone inner segment cation channels drives vesicle fusion at potentials below Ca^{2+} channel activation (Rieke and Schwartz, 1994).

EAATs on bipolar cell dendrites could have novel, receptor-like activity by activating $\uparrow\text{gCl}$, but ON-center bipolar cell responses are abolished in mGluR6 knockout mice (Masu et al., 1995), and all bipolar cell responses can be blocked with glutamate receptor-specific agents. EAAT-like involvement in $\text{PR} \Rightarrow \text{ON-center BC}$ signaling is more compelling in fishes where hyperpolarizations arise from glutamate-activated $\uparrow\text{gCl}$ (Grant and Dowling, 1996).

IONOTROPIC GLUTAMATE RECEPTORS (iGluRs) Vertebrate iGluRs are a diverse group (Dingledine et al., 1999), decoding glutamate signals as cation currents via ionotropic KA and AMPA receptors: apparently nonordered tetramers of 3-transmembrane domain/1-reentrant loop subunits with mid-to-high micromolar glutamate thresholds, separable pharmacologies, and transient channel-opening properties. AMPA receptor GluR1–4 subunits are produced by a single gene family, with a large number of alternatively spliced and RNA edited forms, whereas KA receptor GluR5–7 and KA1, two subunits arise from two gene families, also with posttranslational modifications. The *orphan* receptor subunits $\delta 1,2$ are yet another family of likely iGluR subunits. This diversity potentially yields iGluR assemblies with varied unitary conductances, ionic selectivities, kinetics, and affinities, as well as protein kinase A and C (PKA, PKC) modulation, and postsynaptic aggregation control through specialized “PDZ”-like domains. Receptor diversity is

further enhanced by mixed iGluR expression (e.g., Ghosh et al., 2001) and the coexistence of different functional AMPA assemblies in one cell (Zhang et al., 1995). AMPA and KA receptors tend to activate brief conductances in the 1 pS to 20 pS range, although some KA receptors can activate larger conductances, whereas AMPA receptors containing GluR2(R) subunits have substantially smaller unitary conductances.

Functional NMDA receptors are obligate heteromeric 3-transmembrane domain/1-reentrant loop tetramers or pentamers of NR1 and NR2 subunits. They require concurrent glutamate and glycine binding and depolarization relief of uncompetitive Mg^{2+} channel block, and gate unitary conductances two to three times larger than those of AMPA/KA receptors. NMDA receptor currents activate/deactivate more slowly, with less desensitization than AMPA/KA receptor currents, and they are more glutamate sensitive. Coactivated with AMPA receptors in retina (Diamond and Copenhagen, 1995), functional NMDA-activated pathways appear restricted to amacrine cell and ganglion cell subsets (Fletcher et al., 2000; Marc, 1999).

Heptahelical glutamate receptors. Heptahelical glutamate receptors are G-protein coupled receptor (GPCR) group C members requiring homodimer formation for signaling. The only heptahelical receptor that completely regulates a synaptic pathway is the mGluR group III mGluR6 localized to ON-center bipolar cell dendrites (Vardi, et al., 2000a). How mGluR6 activation effects closure of ON-center bipolar cell cation channels is unknown, and, because all ON-center bipolar cells in mammals express a single isoform of mGluR6, any filtering differences must arise within or after the G-protein signaling path, where $\text{G}\alpha_o$ appears to be the coupler (Dhingra et al., 2000). ON-center bipolar cells in tetrapods, but perhaps not fishes, appear to be under the complete control of mGluR6 signaling.

Other mGluRs have been localized to the retina, but specific pathway functions have not been delineated. Group I-like systems generally mediate intracellular Ca^{2+} modulations, and isoforms of both mGluR1 and mGluR5 have been localized to the inner retina (Koulen, et al., 1997b). Group II mGluR2 isoforms may inhibit synaptic release, and the most distinctive, but likely not exclusive, localization is the expression of mGluR2 by starburst amacrine cells (Koulen et al., 1996). Group III mGluRs (4,7,8) are widely expressed in the inner retina, but their functional roles await analysis. However, there is a striking localization of mGluR8 in rod and cone synaptic terminals and evidence that mGluR8 activation decreases presynaptic calcium levels, acting as a negative feedback process (Koulen et al., 1999). The kinetics, sensitivity, and desensitization of this process are uncertain, and it is not known how steady-state release rates are maintained. In cones, at least,

constitutive Ca^{2+} leaks could override the mGluR8 feedback signal. mGluR1 α receptors have also been localized in rod terminals and could play a similar role (Cai and Pourcho, 1999).

GLUTAMATERGIC SIGNAL PROCESSING AMPA receptors dominate physiological PR \Rightarrow HC signaling (Blanco and de la Villa, 1999), although horizontal cells may coexpress AMPA GluR2,3,4 (Haverkamp et al., 2001; Morigiwa and Vardi, 1999) and KA GluR6,7 receptors (Brändstatter et al., 1997). Cone \rightarrow OFF BC signaling in mammals is decoded by KA receptors in two classes of OFF-center bipolar cells and AMPA receptors in a third (DeVries, 2000), generating fast AMPA-driven and slower KA-driven bipolar cell classes, perhaps initiating transient and sustained OFF channels, analogous to the ON-center bipolar cell shaping of transient and sustained ON channels described by Awatramani and Slaughter (2000). OFF-center bipolar cells of nonmammals may be dominated by AMPA receptors. Signaling via mGluR6 appears to be the sole process controlling ON-center bipolar cells in mammals. Rod bipolar cells have been shown to express GluR2 AMPA subunits, but their role is yet unknown.

BC \Rightarrow AC and GC signaling in all vertebrates is dominated by AMPA receptors (Marc, 1999), although KA receptors may shape some responses. Amacrine cells and ganglion cells display cell-specific responses to glutamate agonists, and responsivity fractionation suggests that physiological attributes, such as “sluggish” or “brisk” responses, may be determined, in part, by different AMPA receptor assemblies (Marc and Jones, 2002). NMDA receptor expression varies across amacrine cells and ganglion cells, and both immunocytochemical and physiological mappings reveal that specific inner plexiform layer strata driven by cone bipolar cells are enriched with amacrine cell and ganglion cell dendrites bearing NMDA receptors (Fletcher et al., 2000; Marc, 1999). Conversely, rod bipolar cell sublayer amacrine cell targets lack NMDA receptors (Ghosh et al., 2001; Marc, 1999).

GLUTAMATE: FUTURE DIRECTIONS Is there a macromolecular signature for a glutamatergic neuron phenotype? VGluT is currently the sole identifier of a glutamatergic phenotype (Eiden, 2000), but other gene products, such as EAAT2, may be coordinately regulated with VGluT, and transcription factor clusters may ultimately define the glutamatergic phenotype. Detailed spatial mapping and biophysics will be required to resolve the contributions of glial and neuronal EAAT transporters to synaptic kinetics. The mGluR6 transduction pathway and its target channel remain major puzzles. Do adapter proteins modify their properties, and does receptor oligomerization influence signaling? What are the consequences of expressing mixed AMPA, KA, and δ

receptors? Do mGluRs shape specific networks, or are they diffuse, subtle, adaptive elements? Why are NMDA receptors relegated to subsets of amacrine cells and ganglion cells and absent from rod bipolar cell targets?

The dominant lateral channel fast inhibitory neurotransmitter: GABA

GABA METABOLIC NETWORKS GABA, an achiral, zwitterionic, nonprotein amino acid, evolved into a signaling molecule from its ancestral metabolic role. Vertebrate GABA synthesis from glutamate is driven by two glutamic acid decarboxylases (GAD1/GAD67 and GAD2/GAD65; Fig. 20.2) that differ in targeting and regulation. GABA catabolism is aerobic, largely driven by mitochondrial matrix GABA transaminase serial oxidation of GABA to succinate semialdehyde and succinate, driving the citrate cycle (Kalloniatis and Tomisich, 1999). Most GAD-containing retinal neurons are likely GABAergic, although some somatic tissues synthesize GAD and GABA, and developing glutamatergic motor neurons in *Drosophila* require GAD expression (Featherstone et al., 2000). Supramillimolar GABA content remains a strong marker of GABAergic function, and neuronal GABA signals span the inner plexiform layer in all species.

Subsets of horizontal cells and amacrine cells have been shown to express GABA signals, GABA transport, and GAD content (reviewed by Marc, 1992). Most amacrine cells are GABA-positive and GAD-positive, although a total match has yet to be achieved. GABA signal strengths vary widely across amacrine cell classes (≈ 1 to 10+ mM), forming characteristic, quantitative, GABAergic signatures. All cholinergic, serotonergic, and many peptidergic amacrine cells express GABAergic signatures and are, thus, multi-neurotransmitter neurons. Interplexiform cells (IPCs) are amacrine cell variants whose processes target the outer retina, and several IPC classes may contain GABA (Marc, 1995).

Vertebrate horizontal cells remain neurochemically recalcitrant despite a long history of physiological analysis. GABA content, GABA transport, and GAD are expressed by subsets of horizontal cells in many species, but many horizontal cells express no known neurotransmitter signature. A neurotransmitter-free model of feedback signaling via connexin currents has been proposed by Kamermans et al. (2001), although not all problems are thereby solved. Why do any horizontal cells contain GABA if they use connexins for feedback? Some nonmammalian horizontal cells form conventional synapses onto glycinergic IPCs and other targets in fishes (reviewed in Marc, 1992; Marc, 1995), but may use connexin signaling for cone feedback. Horizontal cells in mammals are equally challenging. Rodent horizontal cells are GABA-negative but express GABA in develop-

FIGURE 20.2.

ment; macular primate horizontal cells are GABA-positive but become GABA-negative in the periphery; rabbit type B horizontal cells are all GABA-negative, whereas type A horizontal cells are GABA-positive in the streak and GABA-negative in the periphery. Even so, all rabbit horizontal cells are GAD67-immunoreactive at their dendritic tips, suggesting fine regulation of signaling (Johnson and Vardi, 1998). All feline, canine, and porcine horizontal cells express GABA (Kalloniatis and Tomisich, 1999; Marc, 1992).

Many species display weak GABA signals in small subsets of the bipolar cell cohort, and some have been shown to contain GAD. Some may acquire GABA through heterocellular coupling, whereas others may be true sign-inverting elements. The ganglion cell layer in many species contains many GABA-positive cells, mostly displaced starburst

amacrine cells, whereas the remainder are ganglion cells coupled to GABAergic amacrine cells (Marc and Jones, 2002).

GABA TRANSPORTERS The vesicular transporter VGAT is a 10-transmembrane domain polypeptide related to the plant amino acid permease family. It is two- to threefold selective for GABA ($K_m \approx 5$ mM) over glycine (McIntire et al., 1997), and it is widely distributed in the inner plexiform layer and in mammalian horizontal cells (Haverkamp et al., 2000).

Most nonmammals express only neuronal amacrine cell and horizontal cell GABA transport, whereas mammals express neuronal amacrine cell and glial Müller cell transport. Three single-polypeptide, 12-transmembrane domain,

Na⁺-coupled GABA transporters (GAT1,2,3) are present in mammals (Johnson et al., 1996), although GAT2 is more closely related to the epithelial osmoregulatory GABA/betaine transporter and is expressed in the retinal pigmented epithelium, which contains no detectable GABA. GAT1 is widely expressed in some, but not all, GABAergic amacrine cells, whereas Müller cells preferentially display GAT3. No horizontal cell has been found to express these proteins, even those horizontal cells with robust GABA transport.

GATs may regulate synaptic kinetics as they are localized on presynaptic GABAergic neurons and neuronal transporter blockade can dramatically slow inhibitory postsynaptic potential (IPSP) kinetics (Cherubini and Conti, 2001). GAT3-mediated GABA transport by Müller cells is avid in mammals, buffering any additional synaptic overflow, although nonmammals do not require glial support.

Is GABA export a surrogate for or an adjunct to vesicular GABAergic synaptic transmission (O'Malley et al., 1992; Schwartz, 1999; Yazulla, 1995)? GABA import is ΔpNa - and $\Delta\psi$ -coupled, with greater import at negative potentials. Collapse of ΔpNa or decreasing $\Delta\psi$ activates ligand export, but is it physiologically significant? Isolated fish horizontal cells can export physiologically detectable GABA in vitro upon depolarization (Schwartz, 1999), suggesting that transport can mediate feedback or feedforward. However, neither GABA transport nor GATs have been detected in mammalian horizontal cells, and reconciliation of these observations awaits new research.

IONOTROPIC GABA RECEPTORS GABA_A and GABA_C receptors, members of the ligand-gated channel superfamily, are partially ordered pentameric assemblies of four-transmembrane domain α (1–6), 2β (1–3), γ (1–4), δ , ϵ , θ , and π subunits, some with splice variants. Coassembly of 2α and 2β subunits, at least, is required to form functional surface-expressed GABA_A receptors (Connor et al., 1998). GABA_A receptors gate large, rapidly desensitizing $\uparrow gCl$ with GABA thresholds in the 10- μ M range. GABA_C receptors are homomeric assemblies of ρ (1–3) subunits, are more GABA-sensitive than GABA_A receptors, and activate weaker but relatively nondesensitizing $\uparrow gCl$. Cones, bipolar cells, and ganglion cells are known to express functional GABA_A and GABA_C receptors concurrently (Feigenspan and Bormann, 1994; Picaud et al., 1998; Zhang, et al., 1997b).

HEPTAHELICAL GABA RECEPTORS Functional GABA_B receptors (group C GPCRs) are R1–R2 isoform heterodimers (Jones et al., 1998; Sullivan et al., 2000). R1a and R1b versions have been mapped to horizontal cells, amacrine cells, and ganglion cells (Koulen et al., 1998; Zhang, et al., 1998a), and physiological data have shown ganglion cells and bipolar cells to bear functional, pharma-

cologically defined GABA_B receptors, in some cases exhibiting complex switching behavior (Zhang, et al., 1997b; Zhang, et al., 1998b). GPCR coupling of GABA_B receptors can activate $\uparrow gK$, hyperpolarizing target neurons, whereas others gate increases in $[Ca^{2+}]_i$ (Zhang, et al., 1997b) or inhibit presynaptic Ca^{2+} currents (Matthews et al., 1994).

GABAERGIC SIGNAL PROCESSING GABAergic signaling is primarily inhibitory, effected through ionotropic hyperpolarizations/shunts or GPCR pathways. The HC $i \rightarrow$ cone GABAergic pathway has been difficult to validate owing to its varied expression. HC $i \rightarrow$ cone feedback in amphibians clearly involves ionotropic GABA receptors (Wu, 1994), and most of the components of the pathway are expressed in most vertebrates. Unconventional feedback mechanisms, such as connexin-based feedback currents and $\Delta\psi$ -coupled GABA transporter export, enrich signaling possibilities but do not reduce uncertainty. Mammalian horizontal cells lack GABA transport, whereas the presence of VGAT provokes the idea that vesicular transmission can occur from horizontal cell dendrites. Horizontal cells do display presynaptic vesicle clusters within photoreceptor synaptic terminals, but these have been documented infrequently (e.g., Linberg and Fisher, 1988).

The existence of a functional horizontal cell to bipolar cell path has been posited from anatomical data, but the relative horizontal cell- and amacrine cell-driven surround strengths remain unclear. Bipolar cells express dendritic GABA_A and GABA_C receptors (Greferath et al., 1994; Haverkamp et al., 2000; Koulen, et al., 1997a) consistent with GABAergic HC $i \rightarrow$ OFF bipolar cell signaling through $\uparrow gCl$, forming a proper surround polarity. GABAergic HC \rightarrow ON BC signaling through $\uparrow gCl$ must be *sign-conserving* for proper surround polarity, and specialized chloride importers likely shift ON-center bipolar cell dendritic E_{Cl} to positive levels to achieve polarity reversal, while preserving a proper negative E_{Cl} at the axon terminal (Vardi, et al., 2000b).

The AC $i \rightarrow$ BC signaling is supported by abundant evidence in all vertebrates. How GABA_A and GABA_C receptors differentially shape bipolar cell responses is just now emerging. GABA-sensitive, comparatively slower GABA_C receptors may initiate feedback control at low contrasts, with less sensitive, faster GABA_A receptors dominating at high contrast. The involvements of GABA_B receptors appear complex and may vary over bipolar cell types. GABAergic AC $i \rightarrow$ AC signaling numerically dominates retinal circuitry and is largely GABA_A mediated (Lukasiewicz and Shields, 1998), with concatenated inhibitory chains enriching the network assembly (Marc and Liu, 2000). All ganglion cells show significant GABAergic inputs, much of it driven by receptors with GABA_A-like pharmacologies (Akopian et al.,

1998), although some clearly use concurrent GABA_A/GABA_B/GABA_C signaling (Zhang, et al., 1997).

GABA: FUTURE DIRECTIONS Diverse data support GABAergic signaling by some horizontal cells, but inconsistencies persist, and many horizontal cells lack detectable GABA. How do these cells function? Where are the synapses and GABA transporters in mammalian horizontal cells? The mysteries involving AC $i \rightarrow$ BC, AC, GC signaling events are more straightforward. The functional consequences of GABA receptor types and subtype mixtures must be understood. What are the contributions of glial and neuronal GATs to synaptic kinetics, and do amacrine cells use GABA export to supplant or augment vesicular release?

The minor lateral channel fast inhibitory neurotransmitter: glycine

GLYCINE METABOLIC NETWORKS Glycine is an achiral zwitterion at physiological pH with limited conformers (Fig. 20.3). Glycine content is elevated in specific amacrine cells with sparse, varicose dendrites (e.g., AII and DAPI-3 amacrine cells of mammals). Lower glycine levels are found in ON-center bipolar cells that acquire glycine by coupling leakage from AII amacrine cells. Amacrine cells with high glycine levels may also contain low GABA levels in many species, perhaps as a result of heterocellular coupling. Retinal glycine synthesis is still an unresolved process. Although glycine hydroxymethyltransferase is reportedly

FIGURE 20.3.

elevated in retina and spinal cord, and converts precursor serine to glycine, glycinergic amacrine cells contain no significant precursor serine (Kalloniatis and Tomisich, 1999). Of course, many GABAergic amacrine cells contain little glutamate, so precursors are not proven indices of phenotype. Conversely, somatic cells also use alanine-glyoxylate transferase to produce glycine, and precursor L-alanine is elevated in retina and perhaps in glycinergic amacrine cells. Glycine transport has been proposed as a novel mechanism for elevating amacrine cell glycine levels based on the depletion of amacrine cell glycine by sarcosine (methylglycine), a glycine transport agonist (Pow, 1998), although this effect may have been complicated by transactivated glycine export.

GLYCINE TRANSPORTERS No glycine-selective vesicular transporter has been identified, and the nominal inhibitory amino acid vesicle transporter, VIAAT, transports GABA and glycine with similar efficacy, whereas VGAT is only two- to threefold selective for GABA over glycine. Either might serve a neuron with elevated levels of glycine and no GABA.

Plasma membrane amacrine cell glycine transport is mediated by GlyT1, a member of the sodium-coupled solute symporter family and the signature macromolecule of the retinal glycinergic phenotype. As with EAATs and GATs, collapse of $\Delta\psi$ or ΔpNa can evoke complete glycine export in minutes, but under normal conditions, GlyT1 likely regulates synaptic kinetics.

IONOTROPIC GLYCINE RECEPTORS Glycinergic signaling is exclusively mediated by ionotropic glycine receptors (GlyRs), apparently nonordered multimers of $\alpha 1$ –4 and β subunits. Subunit $\alpha 1$ is abundant in the mammalian inner plexiform layer and is expressed on bipolar cells and ganglion cells (Wässle et al., 1998), although amacrine cells with well-documented anatomical glycinergic inputs must certainly express GlyRs as well. Glycine activates a large, rapidly desensitizing $\uparrow gCl$, especially in ganglion cells. Because glycine activates gCl in parallel with GABA_A and GABA_C receptors, often on adjacent synapses (Marc and Liu, 2000), glycinergic signaling may avoid inhibitory *occlusion*, that is, subadditivity due to GABA spillover at adjacent synapses.

GLYCINERGIC SIGNAL PROCESSING The best-known glycinergic circuit is the rod $i \Rightarrow$ rod BC \Rightarrow AII AC $i \Rightarrow$ cone OFF BC pathway, where OFF bipolar cell glycine receptors render the pathway net sign-conserving, as is appropriate for OFF-center channels. This arcane evolutionary capture of cone pathways to serve scotopic signaling is absent in advanced nonmammalian retinas expressing complete, separable rod and cone ON and OFF pathways to ganglion cells. Most ganglion cells receive glycinergic input, and the

distributions of glycine receptors on identified ganglion cells match relative GABAergic and glycinergic presynaptic process densities in specific inner plexiform layer strata. Although their processes are sparse, glycinergic amacrine cells are potent and mediate complex behavior via local and wide-field systems, intercalating in sign-inverting chains with GABAergic amacrine cells (Cook et al., 2000; Marc and Liu, 2000; Zhang, et al., 1997a).

The glycinergic IPC of nonmammals is best characterized in teleosts (Marc, 1995). It is presynaptic and postsynaptic in both plexiform layers, and part of its role may be to transfer H1 horizontal cell signals to the inner plexiform layer, bypassing the bipolar cell spatial filter.

GLYCINE: FUTURE DIRECTIONS The vesicle transporter of glycinergic amacrine cells and the mechanism that elevates glycine content remain unknown. Does glycine transport shape synaptic kinetics in the retina? Does glycinergic transmission prevent synaptic occlusion? Why are glycinergic amacrine cells of mammals and ectotherms structurally similar but involved in such different networks?

The lateral channel fast excitatory neurotransmitter: acetylcholine

ACETYLCHOLINE METABOLIC NETWORKS Acetylcholine (ACh) is a small quaternary cation synthesized by cholineacetyl transferase (ChAT), a cholinergic phenotype signature macromolecule (Fig. 20.4). Attempts to localize retinal acetylcholine by immunocytochemistry have not succeeded. Conversely, 3H choline uptake autoradiography and ChAT immunocytochemistry label the same amacrine cells. Extracellular retinal acetylcholinesterase (AChE) terminates synaptic acetylcholine signaling.

ACETYLCHOLINE AND CHOLINE TRANSPORTERS Acetylcholine is transported into amacrine cell vesicles by vesicular acetylcholine transporter (VACHT) (Koulen, 1997), a member of the toxin-extruding, proton-translocating, antiporter family, under coordinate regulation with ChAT expression. The ligands for these transporters are cations, so proton antiport and ΔpH dominate vesicle loading.

Synaptic or overflow acetylcholine is cleared by AChE with a transfer rate of $\approx 10^4$, effecting rapid hydrolysis of acetylcholine into choline and acetate. Choline is a significant agonist at some acetylcholine receptors, and Na^+ -coupled choline transport via ChT1 may be essential to prevent adventitious receptor desensitization, as well as to allow for choline recovery.

IONOTROPIC ACETYLCHOLINE RECEPTORS Ionotropic cholinergic transmission is mediated by nicotinic acetylcholine receptors (nAChRs), ordered pentameric assemblies

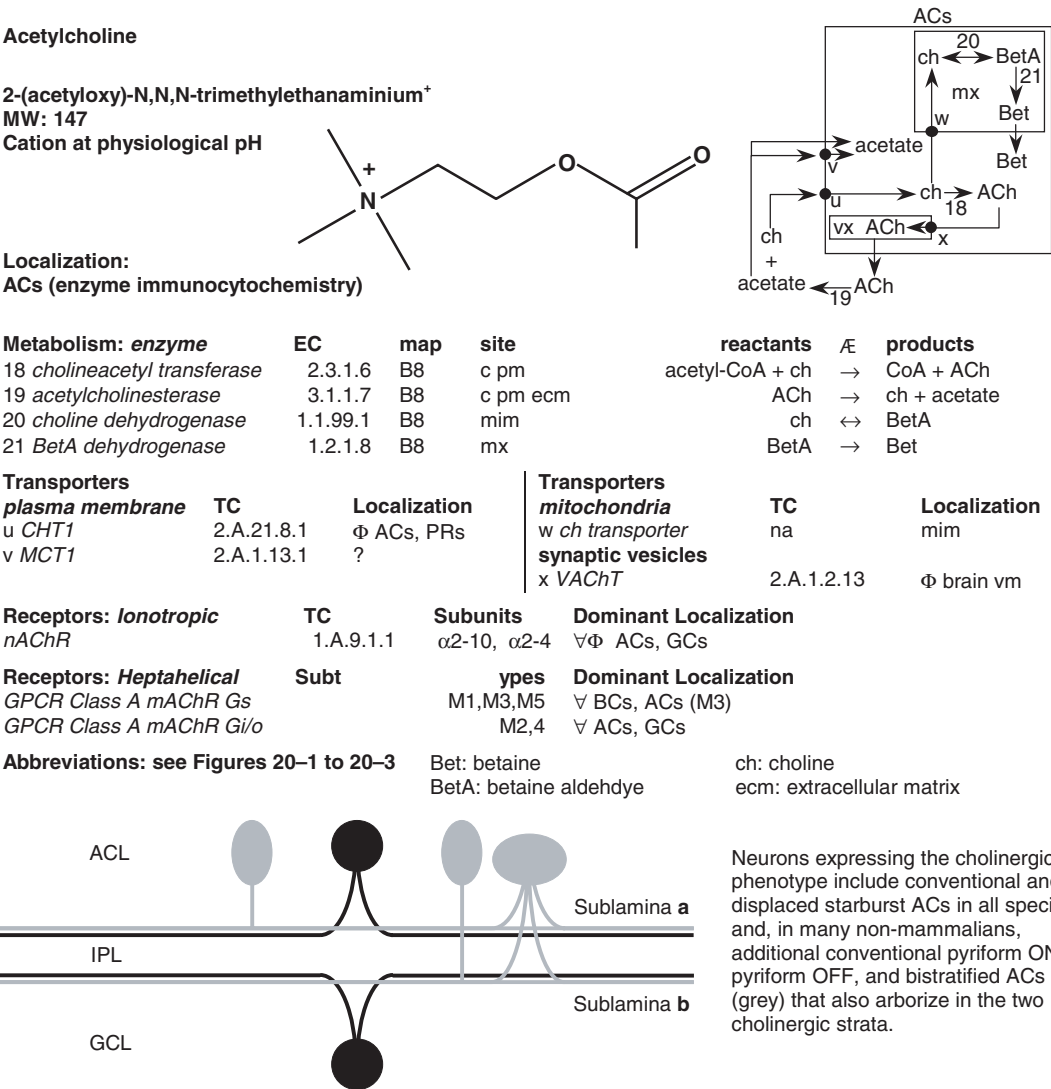

FIGURE 20.4.

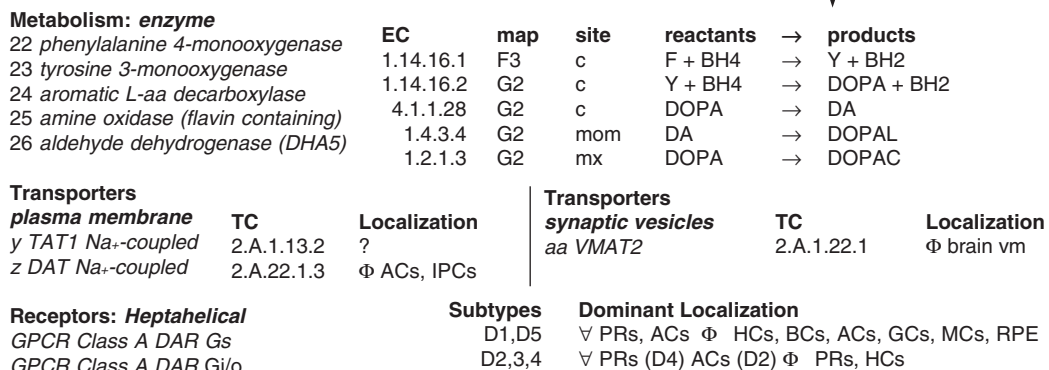

of four-transmembrane domain α , β , and γ subunits. Nine neuronal α subunits are known, imparting distinctive properties to channels; for example, $\alpha 7$ subunits are thought to form homomers with high Ca^{2+} permeability and are expressed widely in the inner plexiform layer. The $\beta 2$ subunit is also abundant in amacrine cells and ganglion cells (Keyser et al., 2000), and $\alpha 3\beta 2$ assemblies are apparently involved in developmental excitatory periodicity linked to retinothalamic patterning (Bansal et al., 2000).

HEPTAHELICAL ACETYLCHOLINE RECEPTORS The muscarinic acetylcholine receptors (mAChRs) are group A GPCRs. Subtypes M_2 , M_3 , and M_4 have been immunolocalized in avian retinas and are expressed by ganglion cells, amacrine cells, and bipolar cells (Fischer et al., 1998). Cholinergic starburst amacrine cells express type M_2 receptors consistent with autoreceptor regulation of acetylcholine release.

CHOLINERGIC SIGNAL PROCESSING Every vertebrate displays displaced ON and conventional OFF cholinergic starburst amacrine cell homologues and bistratification of cholinergic signatures in the inner plexiform layer. Non-mammals express two or three additional cholinergic amacrine cells, although the functions of the additional cells are unknown. All cholinergic amacrine cells are also GABAergic, confounding simple circuitry analysis. Only starburst amacrine cell circuits have been properly analyzed (Famiglietti, 1991), and they are driven by cone bipolar cells through a high-sensitivity AMPA receptor (Marc, 1999), primarily targeting ganglion cells. Unclassified GABAergic amacrine cells may be excited by starburst amacrine cells through nAChRs (Dmitrieva et al., 2001), perhaps amplifying surround inhibition of ganglion cells in dim photopic conditions. Any direct signaling between starburst amacrine cells is likely GABAergic and sign-inverting, as starburst

ACETYLCHOLINE: FUTURE DIRECTIONS Understanding cholinergic function requires more physiological data in light-driven preparations, discrimination of cholinergic and GABAergic synapses, and pharmacological dissection of nAChRs and mAChRs. Although starburst amacrine cells can be driven to release GABA by export (O'Malley et al., 1992), they lack the neuronal GABA transporter GAT1 (Dmitrieva et al., 2001): which do they use? Does ChT1 play any role in signal termination?

DOPAMINE METABOLIC NETWORKS Dopaminergic retinal neurons are amacrine cells or IPCs (reviewed by Witkovsky and Dearry, 1991) that express tyrosine 3-mono-oxygenase (tyrosine hydroxylase, TH) and lack conversion of dopamine (Fig. 20.5) to norepinephrine and epinephrine. Their sparse processes facilitate global signaling, and dopamine is not spatially buffered, effectively reaching sites tens of microns from the inner plexiform layer (Witkovsky et al., 1993). Tyrosine is an essential amino acid acquired exogenously and accumulated through TAT1 aromatic amino acid transport. In dopaminergic neurons, it is converted to dihydroxyphenylalanine (DOPA) by tyrosine hydroxylase and DOPA to dopamine by aromatic L-amino acid decarboxylase.

GCL

Neurons expressing a dopaminergic phenotype are conventional ACs in most species (black) and arborize in the distal inner plexiform layer with dendritic (heavy lines) and dense axonal fields (fine mesh). Additional sparse dopaminergic bands may also appear in mid and proximal inner plexiform layer. Many species exhibit very sparse IPC-like processes targeting the outer plexiform layer. Advanced fishes (teleosts) possess a dopaminergic IPC (grey) with a, dense axonal field in the outer plexiform layer and dendritic arborizations largely in distal and proximal inner plexiform layer.

313

Aromatic amines are highly oxidizable, and rapid turnover is common in aminergic neurons. Mitochondrial monoamine oxidase converts dopamine to dihydroxyphenylacetaldehyde (DOPAL), a highly toxic intermediate, then converted to the acetate form for export, apparently by diffusion. As tyrosine hydroxylase is the first stage in tyrosine conversion to neuroactive monoamines, it is present in rare additional neurons that may synthesize norepinephrine or epinephrine, although little is known of their dispositions and roles.

DOPAMINE TRANSPORTERS Dopamine is loaded into synaptic vesicles by VMAT2, the neuronal form of the vesicle amine transporter family (Erickson and Varoqui, 2000). As with other cationic amines, loading is strongly coupled to ΔpH .

The 12-transmembrane domain dopamine transporter DAT is similar to most other Na^+ -coupled transporters, and is susceptible to transactivation of dopamine export via transporter agonists, such as amphetamines. Its involvement in spatial buffering is somewhat unclear, as diffusing dopamine is a potent signal. However, dopaminergic neurons form many synapse-like contacts and highly targeted axonal fields, suggesting that specific connective zones are more highly regulated than others.

HEPTAHELICAL DOPAMINE RECEPTORS All known dopamine receptors are heptahelical group A (rhodopsin-like) GPCRs, coupled through G_s (subtypes D1, D5) or $G_{i/o}$ (D2, D3, D4), and grouped as pharmacological D1/D2 adenylyl cyclase-activating/-suppressing cohorts, respectively. No retinal cell, including Müller cells and the retinal pigmented epithelium, lacks some form of dopamine receptor, and many express both.

DOPAMINERGIC SIGNAL PROCESSING Dopaminergic neurons apparently signal the onset of photopic epochs through vesicular release and dopaminergic effects emerge in seconds to minutes, rather than milliseconds. In teleosts, dopamine activates cone contraction, uncouples horizontal cells, and renders ganglion cells more transient through D1 mechanisms, mimicking light adaptation (Vaquero et al., 2001; Witkovsky and Dearry, 1991). Coupling control between horizontal cells in teleosts is effected by the axonal fields of dopaminergic IPCs, whereas that between A_{II} amacrine cells in mammals is effected by axonal fields of dopaminergic amacrine cells in the distal inner plexiform layer (Hampson et al., 1992). In amphibians, dopamine shifts the balance of $PR \Rightarrow HC$ signaling in favor of cones, in part by reducing rod I_h currents via D2 receptors (Akopian and Witkovsky, 1996). The actual patterning and control of dopamine release remains uncertain, but dopaminergic amacrine cells/IPCs appear to be under massive GABA_A receptor-

gated suppression, and relief from inhibition uncovers spontaneous dopamine release, perhaps generated by constitutive repetitive spiking (Feigenspan et al., 1998). Nevertheless, many dopaminergic neurons also receive explicit bipolar cell inputs and express iGluRs, so the situation is far from clear. Mammalian, reptilian, and avian dopaminergic amacrine cells have also been reported to contain GABA, complicating interpretations further.

DOPAMINE: FUTURE DIRECTIONS A tremendous amount of analysis of dopamine receptor pharmacology has already been done, but how those signaling pathways are themselves regulated and how adaptation state controls, and is controlled by, dopaminergic neurons demands further exploration.

The mystery neurotransmitter: serotonin

SEROTONIN METABOLIC NETWORKS Serotonin is present at high levels in specific nonmammalian amacrine cell subsets (Fig. 20.6). The retinas of mammals contain, at most, 10-fold less serotonin than dopamine, much of that attributable to platelets and photoreceptor synthesis of melatonin. In the central nervous system, the phenotype-defining enzyme tryptophan hydroxylase (TrpH) converts TAT1-imported tryptophan to 5-hydroxytryptophan, but thereafter, the same enzymes expressed in all other aminergic neurons control serotonin production. There is yet no evidence that any mammalian amacrine cell expresses TrpH.

SEROTONIN TRANSPORTERS As for dopaminergic neurons in brain, VMAT2 is the obligatory vesicular serotonin transporter, although its intraretinal distribution is yet unknown. The content of VMAT2-expressing vesicles thus tracks the substrate amine content of cytosol, and VMAT2 expression is not a phenotype signature. All known and suspected serotonergic amacrine cells are also GABAergic neurons, perhaps expressing both VMAT2 and VGAT.

High-affinity serotonin transport is mediated by SERT, a classic Na^+ -coupled single polypeptide, 12-transmembrane domain transporter susceptible to inhibition by numerous agents, such as fluoxetine. In many vertebrates, more neurons express serotonin transport (photoreceptors, bipolar cell subsets, amacrine cell subsets) than are immunoreactive for serotonin, including the GABAergic mammalian A17/S1/S2 amacrine cells. No satisfactory explanation for this has emerged; some of these cells may truly express SERT, whereas others (e.g., some bipolar cells) may have a coupling leak with a bona fide serotonergic amacrine cell.

IONOTROPIC SEROTONIN RECEPTORS The 5HT3 serotonin receptor is an assembly of unknown stoichiometry of

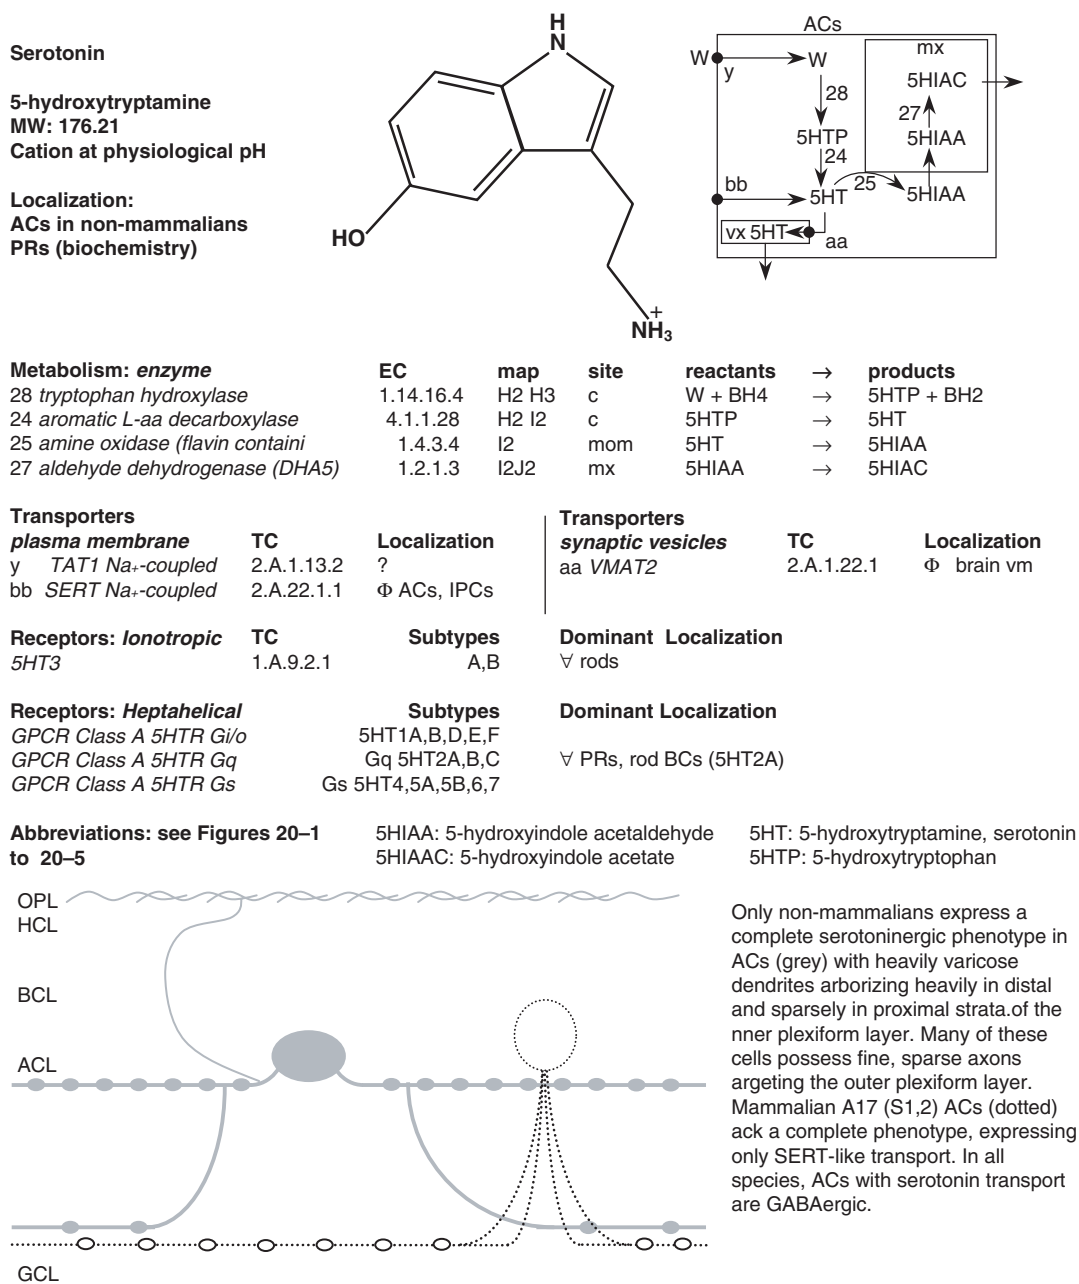

FIGURE 20.6.

presumed four-transmembrane domain subunits. 5HT3A and B variants have been described, and both must apparently be expressed to mimic conductances and pharmacological profiles of native 5HT3 receptors (Davies et al., 1999). 5HT3A subunits have been localized to rods in mammals, suggesting potential presynaptic control of rod signaling by endogenous serotonin of unknown provenance (Pootanakit and Brunken, 2001).

HEPTAHELICAL SEROTONIN RECEPTORS The GPCR group A serotonin receptors comprise a complex array of response element receptors, with 15 subtypes in seven families.

Among this cohort, 5HT2A receptors are known to be expressed on photoreceptors and rod bipolar cells in mammals (Pootanakit et al., 1999). Some controversy exists as to whether phospholipase C coupling is activated through Gq or Gi signaling, but the potential for generating IP3 or diacylglycerol signals near the membrane raises the possibility that serotonin could activate transient receptor potential (TRP), nonselective cation channels, some of which (TRP7) are expressed in retina.

SEROTONINERGIC SIGNAL PROCESSING Little is known of the functions of serotonin in the retina, owing to the pharma-

cological complexities of serotonin receptors, the fact that many GPCRs have constitutive activity, and that many agents act as inverse agonists, capable of generating effects in the absence of signaling. Serotonergic amacrine cells may be a central switch in controlling retinal function, although these amacrine cells must also serve GABAergic roles. Nonmammalian serotonergic amacrine cells are directly driven by mixed rod-cone OFF-center bipolar cells, form feedback synapses to bipolar cells, and target ganglion cells and amacrine cells with feedforward synapses (Marc et al., 1988). However, no data exist to discriminate GABAergic versus serotonergic signaling at these sites, and serotonin may act globally through diffusion. Serotonin reciprocally modulates ON and OFF channels: 5HT₃R activation suppresses scotopic mammalian OFF-center ganglion cell responses, whereas 5HT₃R antagonism inhibits ON-center ganglion cell responses, sparing cone-driven responses (Jin and Brunken, 1998). These complex reciprocal effects could act at photoreceptors or bipolar cells, and much remains to be resolved.

SEROTONIN: FUTURE DIRECTIONS The serotonin-transporting amacrine cell of mammals lacks histochemically and immunochemically detectable serotonin. Is an undiscovered monoamine involved, or are serotonergic synapses and vesicles rare, and serotonin synthesis restricted to small dendritic volumes? Is TrpH or VMAT2 expressed in mammalian amacrine cells? Does serotonergic signaling involve photoreceptor-derived serotonin, and are TRP receptors involved?

Other neuroactive molecules

Many nonpeptide species can target ionotropic receptors, GPCRs, tyrosine kinase receptors, and intracellular response elements, and more will likely be found. These additional signals emanate from multifarious sources and modulate signaling within diverse neuronal, glial, and epithelial targets, although none is known to be a primary fast signal.

Nitric oxide that is derived from Ca²⁺-coupled nitric oxide synthase arginine-citrulline cycling potentially arises from numerous vertical and lateral channel sources and can target an array of cells through guanyl cyclase activation (Eldred, 2001). The effects are potent and include cGMP modulation of cone synaptic Ca²⁺ channels and horizontal cell coupling. The involvement of *carbon monoxide signaling* in the retina is only now being explored.

Melatonin signaling, somewhat the inverse of dopamine signaling, initiates with melatonin production in scotophase photoreceptors. Melatonin diffuses to target melatonin receptors (Wiechmann and Smith, 2001), and activates dark-adapted states and suppresses light-adapted states. Melatonin signaling is coupled to intrinsic circadian oscilla-

tor pathways in photoreceptors, but such pathways are complex, and so simple assignment of photic states to melatonin-versus-dopamine signaling is certainly inaccurate.

The retina expresses a variety of adenosine triphosphate (ATP)-activated, ionotropic P2X receptors on neurons and Müller cells (Pannicke et al., 2000; Taschenberger et al., 1999). P2Y GPCRs are also expressed in retina (Deng et al., 1998), although the ATP sources and magnitudes of receptor-gated signaling have yet to be resolved.

One of the newest signal candidates in retina is *anandamide* (N-arachodonylethanolamine) or a related molecule that activates cannabinoid CB1 and CB2 GPCRs expressed on retinal neurons (Straiker et al., 1999; Yazulla et al., 1999). Retinal distributions of central nervous system anandamide transporters and potential interactions with vanilloid receptors are terra incognita.

Excitation in Retina: The Flow, Filtering, and Molecules of Visual Signaling in the Glutamatergic Pathways from Photoreceptors to Ganglion Cells

DAVID R. COPENHAGEN

Introduction

The neural retina serves both to transduce the visual scene into biologically relevant electrical signals and to “pre-process” the visual scene before transmission to the brain. The demands of the visual system require rapid and reliable signal transmission through the retinal synapses. Extraction and enhancement of salient features in the visual scene by the retina are motivated, in part, by the limited carrying capacity of the optic nerve exiting from the eye. In humans, only 1 million fibers are available to carry visual information to the brain. This section of the book discusses the anatomical and physiological processes underlying visual processing in the retina. This chapter focuses on the pathways, properties, and underlying mechanisms by which excitatory signals are conducted from rods and cones to bipolar cells to RGCs (retinal ganglion cells). This circuit is commonly referred to as the “vertical” or “radial” pathway. This chapter begins with the anatomical wiring of this vertical pathway, then discusses functional attributes of signal transfer, and finally ends with the cellular and molecular mechanisms that mediate signal transmission. Many of the topics discussed herein are covered in other previously published reviews (Dowling, 1987; Matthews, 1996; Thoreson and Witkovsky, 1999; Toyoda et al., 1999; Wilson, 1994; Wu, 1994).

Pathways

THE VERTICAL PATHWAY LINKS PHOTORECEPTORS TO BIPOLAR CELLS TO GANGLION CELLS A general template for the conduction of light-evoked excitatory signals encompasses photoreceptor to bipolar cell to ganglion cell synaptic transmission. This pathway utilizes the fast-acting neurotransmitter glutamate at both the photoreceptor–bipolar cell synapses and bipolar cell–ganglion cell synapses. Cone pathways in mammalian retina observe this basic template

pattern. Within the pattern there is some diversity. In primate retinas, midget bipolar cells in the high acuity foveal region of the retina usually contact a single cone. In the perifoveal and in the peripheral regions of the retina the midget bipolar cells contact a greater number of cones. Another class of bipolar cell has much more diffuse dendrites and contacts many more cones than the midget bipolar cells (Kolb et al., 1992). A third class, the blue-cone bipolar cells, contacts one or two blue cones exclusively (Kouyama and Marshak, 1992).

A rod pathway is “layered” onto the cone pathways in mammalian retinas. Rod ON bipolar cells are thought to be driven exclusively by synaptic inputs from rods. These rod ON bipolar cells do not activate RGCs but instead provide glutamatergic inputs to a class of amacrine cells classified as AII type. The processes of AII cells make chemical synaptic connections with the terminals of cone OFF bipolar cells. Other AII processes make gap junctions with cone ON bipolar cells. Thus, light-driven rod signals can reach both ON and OFF RGCs via the AII to cone bipolar cell connections. Light-induced depolarization of rod ON bipolar cells depolarizes AII cells via excitatory, sign preserving glutamate synapses. This depolarization evokes a depolarization in the cone ON bipolar cells via sign-converting transfer through the gap junctions. The depolarization in the AII cells evokes a hyperpolarization in the OFF cone bipolar cells via the inhibitory glycinergic synapse made at the AII–OFF cone bipolar synapses. Figure 21.1 illustrates these cone and rod pathways. Nonmammalian retinas are not thought to exhibit the same degree of pathway specializations observed in primate retina. It is generally observed that rod and cone signals are mixed in both bipolar and ganglion cells.

OTHER SYNAPTIC AND ELECTRICAL SYNAPSES ALLOW FOR SIGNAL CONDUCTION VIA ALTERNATIVE PATHWAYS Morphological, immunohistochemical, and electrophysiological

FIGURE 21.1. Vertical pathways from photoreceptors to ganglion cells. Cones connect to both ON and OFF bipolar cells. ON bipolar cells synaptically drive, via glutamatergic synapses, ON ganglion cells. OFF bipolar cells drive OFF ganglion cells, also via glutamatergic synapses localized in the distal half of the IPL (inner plexiform layer). ON-OFF ganglion cells (not shown) receive inputs from both ON and OFF bipolar cells and have dendritic processes in both halves of the IPL. Rods synaptically activate rod ON bipolar cells. These cells, in turn, synaptically drive the AII amacrine cells, whose output is onto cone ON and OFF bipolar cells. AII cells are coupled to ON bipolar cells via gap junctions and to OFF bipolar cells by glycinergic chemical synapses. Drawing is adapted from DeVries and Baylor (1995).

studies have revealed several alternative pathways by which photoresponses can be conducted to ganglion cells. Accumulating evidence demonstrates that light-evoked rod responses are not exclusively transmitted from rod ON bipolar cells through AII-type amacrine cells to couple into the cone ON and OFF pathways. Rod signals can be conducted directly by gap junctions to cones, and then transmitted through the vertical cone bipolar pathways. Evidence in support of this pathway includes the finding that light-evoked rod responses are observed in macaque monkey cones (Schneeweis and Schnapf, 1995). Also, rod-driven light responses in cat retina are seen in cones and in horizontal cells that are exclusively connected to cones (Nelson, 1977). Moreover, rod-driven light responses are observed in rabbit ganglion cells under conditions when the rod to rod ON bipolar cell synapses are blocked pharmacologically (DeVries and Baylor, 1995).

A second alternative pathway for rod signals is via rod synapses onto cone bipolar cells. Immunolocalization studies of the AMPA receptor subunits in rat retina showed GluR1 and GluR2 isoforms on OFF bipolar cell dendrites that contact rod photoreceptor synaptic terminals (Hack et al., 1999). Similarly in mouse retina, OFF bipolar cells make contacts with rod synaptic terminals (Tsukamoto et al., 2001). Electrophysiological recordings from the *coneless*

mouse strain reveal that rod signals can be observed in RGCs (Soucy et al., 1998). Because cones are nonfunctional in this mouse strain, these findings provided strong evidence for the functional transmission of rod signals through the OFF cone bipolar cells.

Human psychophysical and electroretinogram (ERG) measurements provide evidence that there are two alternative pathways for rod signals in retina (Stockman et al., 1995). The slower, higher gain rod pathway is thought to be mediated via the conventional rod bipolar to AII amacrine cells. The faster responding rod pathway is postulated to be mediated by rod signals coupled into the cone pathway at the outer retina.

IN YOUNGER ANIMALS EXCITATORY SYNAPTIC CIRCUITS REMAIN MODIFIABLE Although it is believed that the physical “wiring” of retinal pathways is fixed, it is now being appreciated that glutamatergic retinal synaptic pathways retain some degree of morphological and functional plasticity after eye opening. As discussed above, in mammalian retina, ON bipolar cells make exclusive synaptic contacts with rod photoreceptors. In retinas from transgenic pigs and *rd* mice with severe rod photoreceptor degeneration, ON rod bipolar cells develop ectopic synaptic contacts with cones. Analysis of light-evoked ERG from transgenic porcine retinas provides evidence that the newly formed cone to ON rod bipolar cell synapses are functional (Peng et al., 2000).

Pharmacological blockade of glutamatergic inputs to ON bipolar cells can modify the pattern of synaptic inputs to RGCs. At early postnatal ages a significant percentage of ganglion cell dendrites are bistratified. In cat retina, approximately 40% of the RGCs have dendrites in both the ON and OFF sublaminae of the inner plexiform layer (IPL). By eye opening less than 20% of the RGCs exhibit bistratified dendrites (Bodnarenko et al., 1999). Intravitreal injections of APB, a glutamate agonist for the mGluR6 receptor that drives ON bipolar cells, suppresses the loss of bistratified RGCs (Bodnarenko and Chalupa, 1993). The consequences of APB injections were reflected in the light responses from optic nerve and dorsal lateral geniculate. In normal adult cats, virtually all cells respond as either ON or OFF cells. In animals treated with the intravitreal injections of APB for their first postnatal month, 37% of the cells responded as ON-OFF cells (Bisti et al., 1998). This result suggests that the increased number of bistratified RGCs that remained in APB-treated retinas retained functional synaptic inputs from ON and OFF bipolar cells.

In a visual deprivation paradigm it was demonstrated that dark rearing can regulate the excitatory spontaneous synaptic inputs to mouse RGCs. In animals reared in cyclic light, there is a prolonged burst in the frequency of spontaneous EPSCs in RGCs that occurs approximately 2 weeks after eye

opening (Tian and Copenhagen, 2001). This burst is thought to reflect an increased probability of release from bipolar cell terminals. Interestingly, dark rearing reduces the magnitude of the increase in spontaneous EPSCs seen after eye opening (Tian and Copenhagen, 2001). Taken together, these findings show a degree of plasticity in the formation of the excitatory retinal pathways.

Gap junction coupling between photoreceptors can improve reliability of the transmission of light-evoked signals to bipolar cells David Vaney (Chapter 25) discusses gap junction coupling between many different classes of retinal neuron. Here, it is instructive to consider the functional advantages of coupling between photoreceptors in terms of how the light-evoked excitatory signals are transmitted to the second-order neurons. Gap junctions between photoreceptors exist in virtually every vertebrate species (Cook and Becker, 1995). These gap junctions are formed by pairs of connexons, which are made of connexin subunits arranged to form a pore that passes small molecules (<1 kD), including small ions that carry electrical current. Functional electrical coupling was first identified by studying the spread of light-evoked and injected electrical current between neighboring cones (Baylor et al., 1971) and rods (Copenhagen and Owen, 1976). Electrical coupling is found between rods and cones of mammals (including primates) and reptiles (Schneeweis and Schnapf, 1995; Schwartz, 1975). The gap junction-mediated mixing of rod and cone signals may at first appear disadvantageous since it blurs the spectral selectivity afforded by having separate classes of rod and cones. One functional advantage of the rod to cone coupling may be that it extends the rods' dynamic range by providing a pathway from rods to ganglion cells independent of the high-gain rod to ON bipolar cell pathway. This second pathway could increase the sensitivity of photon detection in the mesopic range of vision (DeVries and Baylor, 1995). Coupling signals between photoreceptors can serve to increase the signal-to-noise ratio for detection of dim lights. At low luminances where photon noise is significant relative to its signal power, coupling reduces the noisiness associated with fluctuations from the random absorption of photons by a factor of 10 or more (Lamb and Simon, 1976). Electrotonic coupling can also facilitate neurotransmission of light-evoked signals by limiting voltage excursions that would take the presynaptic potential into lower gain regions of the input/output relationship. Basically, by spreading light signals across many rod terminals, neurotransmission is accomplished in the linear region of the synapse (Tessier-Lavigne and Attwell, 1988). In summary, coupling is useful because it spreads the signal which might saturate a single synapse over many rods. The random noise intrinsic to individual rods and cones will be reduced by averaging through the coupled network. The coupling between rods and cones

can provide alternative pathways for signals from each of these types of photoreceptors to second- and third-order neurons in the retina.

Gain, filtering, and delay in the transmission of light-evoked signals

LIGHT-EVOKED VOLTAGES IN THE EXCITATORY PATHWAY TO RGCs ARE SLOW, NONSPIKING RESPONSES Luminance changes in the environment vary around a mean level. Rods, cones, and bipolar cells signal these luminance changes not as changes in the rate of action potentials, commonly used for signaling in the nervous system and in amacrine and RGCs, but as graded variations in membrane potential. These changes in membrane potential regulate the mean rate of glutamate release. The advantages of graded signaling are that small increments and decrements can be transmitted with comparable sensitivity and the synapses have a larger bandwidth, making it possible to transmit more information than spike-driven synapses (Juusola et al., 1996).

THE EXCITATORY PATHWAYS ARE CAPABLE OF RELIABLY TRANSMITTING VERY SMALL MEMBRANE POTENTIAL PERTURBATIONS That small-amplitude signals can be transmitted from photoreceptors to ganglion cells is made clear by considering rod-mediated vision at very low levels of light. The light levels present in starlight correspond to one or fewer photon absorptions within an integration time for each mammalian rod outer segment (Rao et al., 1994). At illumination levels that produce only 1 to 2 photons/s/100 rods, toads are capable of reliable visually guided prey-catching (Aho et al., 1993). Humans are capable of detecting the simultaneous absorption of 5 to 7 photons over an area covering several hundred rods. Thus light detection is accomplished with very minimal stimulation of the rods. In considering the relative reliability of transduction in rods versus signal transmission in the retina, it appears that signal conduction is quite noise-free. Behavioral studies of prey catch by toads shows that the limit on absolute visual sensitivity originates principally from thermally activated isomerizations of rhodopsin, which itself is very stable, having a half-life for thermal isomerization of greater than 500 years (Aho et al., 1988). Thus, the excitatory pathways are capable of transmitting very low amplitude signals.

The size of light-evoked hyperpolarizations in rods and cones that evoke action potentials in RGCs is on the order of 10 μ V (Copenhagen et al., 1990; Fain et al., 1977). Although these voltage estimates were derived from experiments with very defined and arbitrary background lights, it is becoming evident that such small signals may be used primarily for signaling the visual image at all ambient background intensities. Analysis of natural scenes shows that

FIGURE 21.2. Comparison of rod, horizontal cell, and ganglion cell responses to the same 5 flash intensities. All responses are shown at the same amplification. For clarity, the action potentials were truncated in the responses to higher flash intensities. All these responses were recorded by microelectrodes in dark-adapted toad retina. (Taken from Copenhagen et al., 1990.)

most of the reflected light from a scene has a contrast $<50\%$. Given that photoreceptors exhibit a maximum response range of $\sim 30\text{ mV}$ over intensity ranges of several orders of magnitude, this implies that most “seeing” originates from photoreceptor responses that are only a few millivolts in amplitude (Vu et al., 1997).

SYNAPTIC TRANSMISSION OF LIGHT-EVOKED SIGNALS IS ASSOCIATED WITH VOLTAGE GAIN Comparison of the light-evoked voltages in photoreceptor, bipolar, and ganglion cells reveals that each stage of synaptic transfer boosts the signal. Figure 21.2 demonstrates the gain in the light-evoked signals of the toad retina. Here, intracellular voltage responses of a rod, horizontal, and ganglion cell to light flashes are plotted in adjacent rows. The dimmest light, which produced 0.13 photoisomerizations per rod, depolarized the ganglion cell by 12 to 15 mV and consequently generated an action potential. The rod terminals were hyperpolarized by approximately $20\mu\text{V}$ by this same stimulus (Copenhagen et al., 1990). Defining gain as the ratio of the peak presynaptic voltage in rods to the peak depolarization in the RGC, one can estimate that the overall gain was ~ 60 in this example. Paired recordings from rods and bipolar cells in toads showed that voltage gain for dim flashes at this first synapse was ~ 10 (Belgium and Copenhagen, 1988). Using similar approaches, the gain from cones to bipolar cells in turtle retina was estimated to be around 10 (Copenhagen et al., 1983). In skate retina, voltage gains from rods to ON bipolar

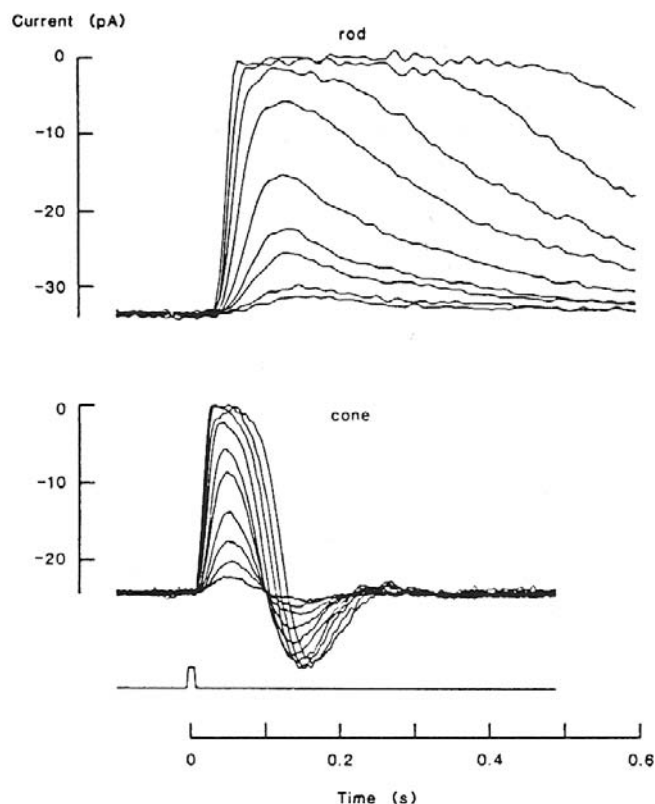

FIGURE 21.3. Photocurrents recorded from a rod and red cone of the monkey retina. Each series of tracings shows light-evoked responses to a sequence of flashes of increasing intensity. Rod responses are slower and more sensitive to light than cones. (Taken from Baylor, 1987.)

cells were seen to be as high as 200 (Ashmore and Falk, 1980).

DELAYS AND TEMPORAL FILTERING SHAPE THE SIGNALS AS THEY ARE TRANSMITTED THROUGH THE EXCITATORY PATHWAYS OF THE RETINA It is well known that responses of rods are much slower than those of cones. Figure 21.3 illustrates the kinetic differences between these two types of photoreceptors. One important question has been whether signal transmission in the retina is matched in any way to the kinetics of the rod and cone light responses. An elegant study in turtle retina demonstrated the differences in signal delay through the ON and OFF pathways and the slower conduction of rod signals versus cone signals. Single rods or cones, impaled with a microelectrode, were depolarized and hyperpolarized with current. RGC responses were simultaneously recorded (Baylor and Fettiplace, 1977a). The latency for the signal in the cone to OFF RGC pathway was on the order of 100 msec. Latencies for cone to ON RGCs and rod to RGCs were approximately 1.5-fold longer for comparable stimulus conditions. An analysis of the kinetics of

synaptic transfer in the OFF pathway showed that rod signals were slower by approximately fivefold, comparable to the differences in the kinetics of the rod and cone single-photon responses (Baylor and Fettiplace, 1977b). These findings reveal that signal transfer is faster in OFF pathways and that the conduction of rod signals is slower than that of cone signals.

Many studies have investigated the temporal properties of synaptic transmission at the photoreceptor and bipolar cell synapses. One important result is that the delays observed by electrical stimulation, discussed above, are not reflected in the speed of glutamate release from the synaptic terminals. Exocytosis of glutamate from photoreceptor and bipolar terminals can be very fast. In fish retina, pulses of transretinal currents were used to depolarize photoreceptors. Glutamate release was monitored by recording membrane potentials in horizontal cells. Evoked postsynaptic potentials were recorded within 2 msec of the stimulus (Kaneko and Shimazaki, 1976). In ground squirrel, single cones were depolarized with a patch pipette while recording the response of bipolar cells (DeVries and Schwartz, 1999). The synaptic currents were similarly evoked with delays of ~1 msec. Depolarization-evoked exocytosis in goldfish bipolar terminals occurred within 1 msec (Mennerick and Matthews, 1996). Electrical stimulation of single bipolar cells in newt retina evoked glutamatergic currents in simultaneously recorded ganglion cells with a delay on the order of just a few milliseconds (Matsui et al., 1998). In other experiments in which isolated catfish horizontal cells were used to detect stimulated release from goldfish bipolar cells, AMPA receptor-mediated currents in the horizontal cells were detected within 1 msec (von Gersdorff et al., 1998). These studies indicate that the glutamatergic synapses are inherently capable of releasing vesicles with a very short delay. Delays in the transmission of visual-evoked signals must be accounted for by other mechanisms.

No comprehensive kinetic model of signal transfer in the excitatory pathways has been formulated to date. However, experimental studies in the outer retina do show that some of the differences between ON and OFF pathways and between rod and cone signaling can be accounted for by temporal filtering in the transfer of signals from the photoreceptors. Dim light flashes were recorded simultaneously in rod-horizontal cell and cone-horizontal cell pairs. Analysis of synaptic transfer characteristics showed that signal transfer from the rods was slowed approximately 8- to 10-fold compared to transfer from cones (Schnapf and Copenhagen, 1982). A similar analysis estimated that cone to ON bipolar cell transfer was approximately 10-fold slower than the transfer from cones to OFF bipolar cells (Copenhagen et al., 1983). Figure 21.4 shows the impulse response function of synaptic transfer from rods and cones to the H1 type of horizontal cell in turtle retina. Also shown

FIGURE 21.4. Synaptic impulse responses of bipolar and horizontal cells. These functions represent the waveform produced in postsynaptic cells in response to a brief depolarization of the synaptic terminals of the rods or cones. The kinetics of the cone to horizontal cell transfer is approximately 10 times faster than the transfer to the same cell from rods. The transfer from cones to OFF bipolar cells (HBCs) is several-fold faster than the transfer to the ON bipolar cells (DBC). (Taken from Copenhagen et al., 1983.)

is the impulse response function for cone to ON and OFF bipolar cells in turtle retina.

A recent study in ground squirrels shows that synaptic transfer from cones to one type of cone-bipolar cell (b2-type) is mediated by kainate glutamate receptors. In contrast, synaptic transmission from cones to b3- and b7-type bipolar cells is mediated by AMPA-type receptors. The AMPA receptors remained desensitized longer than the kainate receptors in this retina. Temporally, this confers a much lower frequency response on signal transfer from the cone to b3 and b7 bipolar cells (DeVries, 2000). As cone to bipolar cell and bipolar cell to RGC synapses are studied in more detail, many variations in the kinetics of synapses between specific cell types will undoubtedly be revealed.

FIGURE 21.5. Stratification of transient and sustained responses in the IPL. ON and OFF responses are transmitted to postsynaptic cells in the proximal and distal halves, respectively, of the IPL. Sustained responses and rod signals are transferred closer to the inner and outer border of the IPL. Cone signals and transient responses are transmitted preferentially at the middle of the IPL. (Taken from Rodieck, 1998.)

TRANSIENT COMPONENTS OF LIGHT RESPONSES ARE ACCENTUATED IN SOME OF THE EXCITATORY RETINAL PATHWAYS In the outer retina, photoreceptors have sustained responses to light. In the inner retina, many amacrine and ganglion cells respond only to the onset and termination of stimuli. The responses of these transient cells encode light-dark transitions. In ganglion cells the form of light-evoked responses to steps of light ranges from brief transient burst of action potentials at the onset or termination of the light to a more sustained discharge either during or after light onset.

Several mechanisms work in coordination to generate the transient responses observed in the inner retinal neurons. Before discussing these alternatives, it is interesting to note that there is a morphological correlate of the sustained and transient response patterns. Several studies have revealed a functional lamination of response patterns across the IPL. As shown in Figure 21.5 (Rodieck, 1998), retinal neurons with synaptic processes at the distal and proximal margins of the IPL tend to have a greater sustained component in their light responses. Neurons with processes closer to the middle of the IPL tend to be more transient. A recent study in rabbit retina utilized a combination of electrophysiological recording and intracellular staining of RGCs to elegantly document this anatomical/physiological separation of transient and sustained responses across the IPL (Roska and Werblin, 2001).

Given that in response to a sustained depolarization, the spike discharge patterns of many neurons in the CNS decline, one must consider the possibility that a similar spike train adaptation accounts for the transience in the retina. By this mechanism, time-varying conductances intrinsic to these inner retinal neurons would truncate the more sustained light responses. This idea has received no experimental verification, as no difference has been observed in the membrane properties of transient versus sustained retinal cells. Currents injected into these different classes of cell gener-

ally produce sustained spiking. The transience must then be attributed to temporal modulation of synaptic inputs. This could result from either transient release of excitatory synaptic neurotransmitter from the bipolar terminals due to inherent ionic processes within these neurons, or from synaptic interactions between bipolar, amacrine, and RGCs that actively truncate the responses. Evidence exists for both mechanisms.

A recent study in salamander retina suggests that at least part of the mechanisms creating transient responses may reflect temporal differentiation at the inputs to bipolar cells in the outer plexiform layer (OPL). It was reported that ON bipolar cells can be classified into transient and sustained groups based on the waveform of their light responses. Pharmacological manipulations led to the suggestion that synaptic transduction in the dendrites of these two classes of cell conferred different degrees of transience (Awatramani and Slaughter, 2000). This hypothesis, while appealing, awaits confirmation. Surprisingly, no other studies examining bipolar cell responses have identified two groups of kinetically separable ON bipolar cell classes.

Amacrine cells are known to make synaptic contacts directly onto RGC dendrites and, via reciprocal synapses, onto the axon terminals of bipolar cells. Amacrine cells serve as inhibitory interneurons, releasing either GABA or glycine from their synapses. Synaptic inhibitory inputs could therefore modulate excitation, and hence the transience of responses, through feedforward or feedback pathways. Some experimental results support a feedforward component. Many ganglion cells are inhibited by GABA (Belgium et al., 1984), so it is plausible that amacrine cell inputs could shorten the excitatory response by offsetting the depolarization induced by the glutamatergic inputs. Evidence for this temporal truncation in RGCs was shown in salamanders (Bieda and Copenhagen, 2000). A large group of studies support a feedback mechanism for amacrine cell-mediated truncation of the responses. Functional GABA receptors are found on synaptic terminals of isolated bipolar cells (Tachibana and Kaneko, 1987) and GABA currents resulting from amacrine cell stimulation are recorded from bipolar cells in slice preparations (Lukasiewicz and Shields, 1998). Analysis of GABA receptor subtypes supports the idea that a majority of the feedback to bipolar cells is mediated by the slower decaying GABA_C-type receptors and feedforward is mediated by the GABA_A subunit (Lukasiewicz and Shields, 1998; Shields et al., 2000).

It is very likely that cellular processes in the bipolar cell terminals might contribute to transience. Support for the idea that amacrine cell synaptic interactions cannot account for all the transience is derived from experiments in which light responses are recorded from RGCs in the presence of GABA and glycine receptor antagonists. The light responses to a step of light are prolonged under these conditions;

however, they remain transient (Bieda and Copenhagen, 2000). Some of the inherent mechanisms within bipolar cell synaptic terminals that could truncate glutamate release include (1) depletion of vesicles in the bipolar cell synaptic terminals upon stimulation (von Gersdorff and Matthews, 1997) and (2) transient calcium currents that regulate exocytosis. In rodent bipolar cells, a rapidly inactivating calcium current has been identified (Kaneko et al., 1989; Pan, 2000). Calcium entry through this calcium channel has been shown to modulate exocytosis (Pan et al., 2001).

In summary it is evident that a number of processes and neuronal interactions in the excitatory pathways serve to transform light responses such that temporal changes are amplified.

Cellular mechanisms of excitatory transmission

SIGNAL TRANSFER RELIES ON VESICLE-MEDIATED SYNAPTIC TRANSMISSION Vesicle-mediated synaptic neurotransmission is the dominant mode at the glutamatergic synapses in retina. Immunocytochemical, electrophysiological, and morphological studies demonstrate the existence of the molecular machinery that underlies vesicle-mediated exocytosis and the existence of spontaneous quantal events in the postsynaptic retinal neurons.

Virtually every electronmicrograph ever published shows small clear vesicles filling the synaptic terminals of photoreceptor and bipolar cells. The size of these vesicles is comparable to synaptic vesicles in CNS neurons, but the quantity of vesicles is many orders of magnitude greater. Terminals of rod bipolar cells of goldfish retina contain 500,000 to 700,000 vesicles (von Gersdorff et al., 1996). Electron microscopy also reveals a dense ribbon-like structure in the terminals of both bipolar and photoreceptor cells. Often, vesicles are aligned along the edge of this ribbon, suggesting a mechanism to sequester vesicles for more efficient release near the “active site,” presumed to be at the juncture between the ribbon and the basal surface of the photoreceptors. Rod photoreceptors have fewer ribbons than cones. In macaque monkey retina, cones have 20 to 40 synaptic ribbons (Chun et al., 1996). MbI-type bipolar cell terminals of goldfish have upwards of 50 ribbons (von Gersdorff et al., 1996).

Photoreceptor and bipolar terminals generally express the full complement of synaptic proteins thought to be involved in vesicle-mediated synaptic transmission at glutamatergic synapses in the CNS (von Kriegstein et al., 1999; Morgans, 2000). However, there are some notable differences in which Synapsin I and rabphilin are absent in retina. Synapsin III is expressed and may substitute for Synapsin I. Vesicular glutamate transporters, proteins that catalyze the concentration of glutamate in vesicles, are richly expressed in both photoreceptor and bipolar terminals (Johnson et al., 2003).

Membrane capacitance changes provide evidence for vesicle-mediated quantal release of neurotransmitter from bipolar and photoreceptor cells. In these experiments, depolarization of presynaptic terminals using whole-cell patch pipettes produces a calcium-dependent increase in membrane capacitance that reflects the exocytosis-associated incorporation of vesicle membrane into the plasma membrane of the neurons (Lagnado et al., 1996; Rieke and Schwartz, 1996; von Gersdorff and Matthews, 1994). Simultaneous measurement of capacitance and glutamate release from MbI goldfish bipolar cells demonstrated that a calcium-dependent capacitance increase on depolarization was linked to glutamate release (Sakaba et al., 1997).

Postsynaptically recorded synaptic currents show glutamatergic “events” that result from exocytosis of single vesicles in the presynaptic terminals. AMPA receptor-mediated synaptic events typical of those observed in CNS neurons have been recorded in ganglion cells and bipolar cells (Maple et al., 1994; Taylor et al., 1995). Estimates of the rates of release in darkness range from 22 quanta/sec/synapse (cat bipolar cells; Freed, 2000) to ~30 quanta/sec/synapse (turtle cones; Ashmore and Copenhagen, 1983) to ~40 quanta/sec/synapse (cat rods; Rao et al., 1994).

The modest rate of tonic release is considerably below the rate that can be evoked by depolarization of individual bipolar cells. Analysis of the magnitude and kinetics of capacitance changes in MbI bipolar cells reveals rate on the order of 50,000 vesicles per second for voltage steps from -60 to 0 mV (von Gersdorff and Matthews, 1994; von Gersdorff et al., 1996). However, the rates estimated for in vivo tonic release are much lower, suggesting that the glutamatergic retinal neurons operate in the range in which vesicle turnover is much lower than can be evoked with artificial stimulation.

BOTH CALCIUM ENTRY AND EXTRUSION REGULATE TRANSMISSION OF EXCITATORY SIGNALS In common with all glutamatergic synapses, glutamate release from photoreceptors and bipolar cells is regulated by the depolarization-stimulated influx of calcium through voltage-activated calcium channels. These channels are so-called high voltage activated L-type channels. The relationship between presynaptic voltage, calcium channel activation, and glutamate release from photoreceptor terminals was derived from some elegant experiments measuring endogenous glutamate release from toad photoreceptors (Schmitz and Witkovsky, 1997). This relation is plotted in Figure 21.6. Interestingly, a novel subtype of the pore-forming α subunit of an L-type channel was isolated from human rods ($\alpha 1F$; Strom et al., 1998), suggesting that photoreceptor calcium channels are structurally distinct from other voltage-gated L-type calcium channels. It should be noted that in cones, an additional

FIGURE 21.6. Relationship between rod voltage and calcium current-mediated glutamate release. The separate relations between light and glutamate release and between light and membrane potential are combined in this figure. By parameterizing the data with respect to light, the dependence of glutamate release on membrane potential is derived. The solid curve shows the activation of the L-type calcium current of rods. This Boltzmann curve is well-fitted to the data points, supporting the hypothesis that L-type calcium channels play a major role in regulating glutamate release. (Taken from Witkovsky et al., 1997.)

component of Ca^{2+} flux may be contributed by a cGMP-gated Ca^{2+} -permeable channel (Rieke and Schwartz, 1994; Savchenko et al., 1997). In bipolar cells, glutamate release is modulated by L-type currents (Tachibana et al., 1993) and T-type calcium currents (Pan et al., 2001).

The direction of light-evoked membrane polarization in photoreceptors and OFF bipolar cells makes it important to consider the role of calcium extrusion in controlling the kinetics of these responses. Light hyperpolarizes these neurons with the resultant closing of calcium channels. Therefore, light-evoked signals transmitted to the postsynaptic neurons are carried by a net decrease in the rate of glutamate released from the terminals. Thus, the kinetics of these signals will depend on the rate at which calcium is extruded from the terminals. In photoreceptors, calcium extrusion is performed exclusively by PMCA (plasma membrane calcium ATPase) transporters (Krizaj and Copenhagen, 1998; Morgans et al., 1998). PMCA transporters are also expressed in bipolar cell terminals (Krizaj et al., 2002).

GLUTAMATE/GLUTAMINE RECYCLING REPLENISHES EXCITATORY GLUTAMATERGIC TERMINALS Glutamate/glutamine recycling plays an important role in maintaining a source of synaptic glutamate for transmission in the nervous system and in the retina, as well. In the basic recycling pathway, synaptically released glutamate is taken up by Na-dependent transporters located in the plasma membrane of nearby glial cells. The glutamate is amidated by glutamine synthetase (GS) to generate glutamine. Glutamine is then transported out of the glial cells to the extracellular space, where it is

transported back into presynaptic neuronal terminals to be converted into glutamate by mitochondrial-bound phosphate-activated glutaminase (PAG). A full description of the evidence supporting recycling is reviewed by Broer and Brookes (2001). Figure 21.7 illustrates glutamate/glutamine recycling.

Strong evidence supports the hypothesis that glutamate/glutamine recycling plays an important role in maintaining glutamatergic synaptic transmission in retina. Here, glutamate is taken up by Müller cells, the radial glia of retina. After conversion from glutamate, glutamine is “released” from these Müller cells to be taken up by photoreceptors and bipolar cells. Briefly, supportive evidence includes the findings that: (1) photoreceptor and bipolar cell synapses are enveloped by Müller cell processes (Sarantis and Mobbs, 1992); (2) Müller cells express GLAST or GLAST-like high-affinity plasmalemmal-bound glutamate transporters, which have been very well characterized electrophysiologically (Rauen and Weissner, 2000); (3) Müller cells express glutamine synthetase (Rieke and Norenberg, 1977); (4) inhibition of GS with MSO depletes photoreceptors and bipolar cells of glutamate and causes a buildup of glutamate in the Müller cells (Barnett et al., 2000; Pow and Robinson, 1994); (5) retinal incubation in MSO, an inhibitor of GS, reduces the b-wave of the ERG, an indicator of

FIGURE 21.7. Schematic diagram of glutamate/glutamine recycling at glutamatergic synapses in retina. Glutamate released from presynaptic neurons activates receptors on the postsynaptic cells and then is sequestered into Müller glial cells, where it is converted to glutamine. Glutamine is then shuttled back to the presynaptic neurons, where it is converted back to glutamate by a phosphate-activated glutaminase (PAG). Also shown in this diagram are glutamate transporters that sequester glutamate directly back into the presynaptic terminals. In addition, the PMCA extrusion pump and calcium channels are illustrated. (See color plate 8.)

photoreceptor to bipolar synaptic transmission (more importantly, the b-wave can be “rescued” in MSO by exogenous glutamine, consistent with the hypothesis that glutamine provides a substrate to restore glutamate [Barnett et al., 2000]); and (6) PAG, which converts glutamine to glutamate, has been immunolocalized to photoreceptors (Gebhard, 1992).

Other pathways exist by which glutamate used for synaptic transmission could be replenished without going through the glutamate/glutamine cycle. Because most of the glutamate taken into astrocytes is oxidized rather than being converted to glutamine, substrates such as lactate, malate, and alpha-ketoglutarate are proposed as precursors for glutamate in neurons (Schousboe et al., 1997). These suggestions are not consistent with in vivo nuclear magnetic resonance studies, which show that a large percentage of glutamine is incorporated into neuronal glutamate (Sibson et al., 2001). In retina inhibition of GS with MSO depleted neuronal glutamate pools, as shown with immunohistochemistry and electrophysiology. This occurred in spite of the availability of other potential substrates for glutamate synthesis (Barnett et al., 2000). Therefore, glutamate/glutamine recycling very likely plays a major role in replenishing synaptic glutamate in retinal neurons.

SYNAPTICALLY RELEASED GLUTAMATE CAN CONTROL THE TRANSMISSION OF LIGHT-EVOKED SIGNALS THROUGH FEEDBACK MECHANISMS There are examples at both excitatory and inhibitory synapses in the CNS that exocytosed neurotransmitter autoregulates further release by feeding back signals to the presynaptic terminals (e.g., Trombley and Westbrook, 1992). In the excitatory pathways of retina several such feedback mechanisms have been proposed. The metabotropic glutamate receptor mGlu-R8 has been immunolocalized to photoreceptors in rat retina (Koulen et al., 1999). Intracellular calcium levels in isolated photoreceptors are decreased by exogenous glutamate and by the class III metabotropic agonist APB (L-2-amino-4-phosphonobutyrate). This decrease in calcium is thought to reduce glutamate release.

Additionally, activation of a plasmalemmal glutamate transporter in synaptic terminals of salamander cones (see Fig. 21.7) is proposed to activate an anionic current that hyperpolarizes cones. Here synaptically released glutamate is proposed to inhibit further release as it is being taken back up into the terminals (Picaud et al., 1995).

A third separate feedback mechanism has also been proposed. It has recently been shown that protons released from synaptic vesicles inhibit the calcium current of ground squirrel cones (DeVries, 2001). Sequestration of glutamate into synaptic vesicles is known to require a proton gradient that acidifies the inside of the vesicles. When glutamate is released, the sequestered protons are also released. Inhibi-

tion of adjacent calcium channels serves to inhibit subsequent calcium-triggered release of glutamate (DeVries, 2001).

In the inner retina, it is proposed that activation of an APB-sensitive metabotropic glutamate receptor on bipolar synaptic terminals can attenuate release of glutamate from these terminals (Awatramani and Slaughter, 2001). The magnitudes of light- and potassium-evoked EPSCs and the rates of spontaneous EPSCs in salamander ganglion cells were reduced in APB, which is thought to be acting presynaptically on the axon terminals of bipolar cells. Functionally, all of the above autofeedback mechanisms would help to extend the dynamic range of the each synapse. Part of this action would be to prevent the synapse from saturating.

EXCITATION IS SIGNED BY BOTH IONOTROPIC AND METABOTROPIC GLUTAMATE RECEPTORS AND GLUTAMATE TRANSPORTERS Most of the currently cloned glutamate neurotransmitter receptors are expressed in retina. Little is known about what specific functional attributes are conferred upon signal transmission by the differential expression patterns of the receptor subunits. Clear evidence, however, shows that the dichotomy between the response properties of ON and OFF bipolar cells derives directly from the expression of the metabotropic (G-protein linked) mGlu-R6 receptor in ON bipolar cells versus the ionotropic (AMPA and kainate-type) receptors, which mediate the responses of OFF bipolar cells. It is also becoming a truism that RGC light responses are mediated by the simultaneous activation of NMDA- and AMPA-type ionotropic glutamate receptors.

ON bipolar cells are hyperpolarized by exogenous glutamate and the class III metabotropic receptor agonist L-AP4. Light, by decreasing glutamate release from photoreceptors, depolarizes the ON bipolar cells. Much evidence verifies that the action of glutamate at the photoreceptor–ON bipolar synapses is mediated by the mGlu-R6 receptor. Antibodies to mGlu-R6 localize to the dendrites of ON bipolar cells. The product of the reporter gene (*LacZ*) attached to mGluR6 is localized similarly to the dendrites of these cells (Nomura et al., 1994; Vardi et al., 2000). A mouse strain in which the *mGluR6* gene has been deleted has a very much reduced light-evoked b-wave in the ERG and ON responses recorded in the superior colliculus (Masu et al., 1995; Sugihara et al., 1997).

The slowness of the light response in ON bipolar cells, compared to OFF bipolar cells, can be attributed in part to the fact that mGlu-R6 modulation of the ionic conductances in the cell requires activation of a G-protein and subsequent regulation of one or more enzymatic steps. In contrast, activation of OFF bipolar cells is mediated by the rapid opening of an ionic channel that is part of the ionotropic glutamate receptors on these cells. Figure 21.8 illustrates glutamate activation of ON and OFF bipolar cells.

FIGURE 21.8. Schematic diagram of proposed glutamate-mediated transduction mechanisms in ON and OFF bipolar cells. In ON cells, glutamate activates an mGluR6 metabotropic receptor, which triggers an enzymatic cascade consisting of GTP-binding protein and phosphodiesterase (PDE). PDE activity controls the level of cyclic GMP in the cells. cGMP-gated channels regulate current flow through cationic channels in the plasma membrane of

these cells. In OFF cells, glutamate activates an ionotropic receptor that directly opens a nonselective cationic channel. In darkness glutamate release is maximal. Light, by reducing activation of post-synaptic glutamate receptors, produces a depolarization in the ON cells and a hyperpolarization in the OFF bipolar cells. (Taken from Kaneko, 1999.)

One unresolved functional question regarding glutamatergic activation of ON bipolar cells is the role of ionotropic glutamate receptor subunits found on the ON bipolar cell dendrites. In different species various NMDA receptor (NRI, NR2D) and AMPA receptor subunits (GluR2, GluR2/3, and GluR4) are immunolocalized to ON bipolar cells (Hughes, 1997; Hughes et al., 1992; Peng et al., 1995). The role of these ionotropic receptors remains unknown.

OFF bipolar cells can be potentially driven by one or more ionotropic glutamate receptors. In situ hybridization studies reveal mRNA expression of GluR1-7 and KA1-2 subunits in mammalian OFF bipolar cells (reviewed in Thoreson and Witkovsky, 1999; Hamassaki-Britto et al., 1993). Antibody staining suggests the expression of GluR4, GluR6/7, and KA2 in presumed OFF bipolar cells (reviewed in Thoreson and Witkovsky, 1999; Hack et al., 2001). Electrophysiological recordings of OFF bipolar cells reveal that light responses and glutamate currents are abolished almost entirely by CNQX, an AMPA/kainate receptor antagonist (cat: Sasaki and Kaneko, 1996; rat: Euler et al., 1996; zebra fish: Connaughton and Nelson, 2000). Moreover, spontaneous EPSCs recorded in OFF bipolar cells of newt and salamander are blocked by CNQX (Kawai, 1999; Maple et al., 1994). In newt these spontaneous EPSCs were prolonged by cyclothiazide, an AMPA receptor-specific drug that reduces desensitization (Kawai, 1999). In ground squirrel, one type

of OFF bipolar cell is driven by kainate receptors and two other classes are driven by AMPA receptors (DeVries, 2000). These findings strongly support a functional role for AMPA and kainate receptors in the transmission of signals from photoreceptors to OFF bipolar cells.

In fish retina, cone and rod inputs to ON bipolar cells activate two different synaptic mechanisms (Saito et al., 1978; Nawy and Copenhagen, 1987). Rod inputs are mediated by the mGlu-R6 receptor. The cone inputs may be mediated by an anionic current that is produced when glutamate is transported into the bipolar cell. In zebra fish ON bipolar cells, glutamate activates a chloride conductance that is reduced by lithium substitution for sodium (Connaughton and Nelson, 2000). In white perch, glutamate evokes a chloride current that is insensitive to ionotropic glutamate receptor antagonists, CNQX and DNQX, and is not activated by APB or quisqualate, metabotropic glutamate receptor agonists (Grant and Dowling, 1995). Taken together, these results suggest a glutamate transporter-activated current mediates cone inputs. In contrast, other findings suggest that the cone inputs are mediated by modulation of a potassium conductance. Goldfish ON bipolar cells exhibit a glutamate-activated current that is cesium sensitive and has a negative reversal potential (Nawy and Copenhagen, 1990). Because cesium blocks potassium conductances, these findings are taken as evidence that glutamate regulates a potassium conductance in these ON bipolar cells.

In the inner retina, bipolar-RGC synapses appear to be somewhat more straightforward than the photoreceptor-bipolar synapses of the OPL. Light-evoked glutamatergic excitation of RGCs by bipolar cells relies solely on the concomitant activation of both NMDA and non-NMDA ionotropic receptors. Light-evoked synaptic currents and spiking is blocked when both NMDA and NMDA glutamate receptors are antagonized pharmacologically. However, separate activation of either NMDA or non-NMDA receptors will support light responses in the RGCs (Diamond and Copenhagen, 1993; Mittman et al., 1990). The non-NMDA receptors are most likely AMPA-type, as cyclothiazide enhances the light responses and AMPA-receptor antagonists, including NBQX, GYKI52466, and GYKI53655, suppress light responses (Cohen and Miller, 1994; Lukasiewicz et al., 1995, 1997).

An interesting paradox concerns the localization of NMDA and non-NMDA receptors on the RGCs. Light-evoked responses have dual NMDA and non-NMDA components at all light intensities (Diamond and Copenhagen, 1993). It would be presumed that, similar to other glutamatergic synapses in the CNS, the receptors would therefore be colocalized adjacent to the site of glutamate release from bipolar cells. Interestingly, spontaneous quantal release activates an AMPA-mediated response only. Even though the NMDA receptors have a higher sensitivity to glutamate, no NMDA component has been detected in the quantal events (Matsui et al., 1998; Taschenberger and Grantyn, 1995; Taylor et al., 1995). One possible explanation for the paradox is that NMDA receptors are localized in perisynaptic regions of the synapse and are only stimulated by evoked release of several vesicles (Taylor et al., 1995). Recent findings in rat retina demonstrated that blockade of glutamate uptake caused spontaneous EPSCs to acquire an NMDA component. This argues that glutamate uptake limits the activation of NMDA receptors during release of single quanta (Chen and Diamond, 2002).

Summary

Extensive work by scores of investigators has given us a reasonably good idea of the major features of glutamatergic synaptic transmission in retina. Many of the properties of synaptic transmission, such as the type of glutamate receptors, calcium control of exocytosis, and glutamate uptake, are closely analogous to those utilized by glutamatergic neurons in the CNS. Other features, such as the slower signal transfer and tonic release of neurotransmitter, are unique to the retina. Future studies will reveal much more about how the cellular signaling of visual information is modulated by light and dark and paracrine/hormonal influences.

22 Peptide and Peptide Receptor Expression and Function in the Vertebrate Retina

NICHOLAS C. BRECHA

Introduction

The retina contains a rich variety of transmitters and related signaling molecules, including neuroactive peptides and growth factors. Peptides and growth factors have multiple roles in the retina, including participation in cellular signaling and slow synaptic transmission that contribute to visual function (Akopian et al., 2000; Savchenko et al., 2001; Veruki and Yeh, 1992; Zalutsky and Miller, 1990b). Evidence for abundant peptide expression in the vertebrate retina began with descriptions in the late 1970s of peptide activity and peptide receptor binding sites in retinal extracts and peptide immunoreactivity in amacrine cells (Brecha, 1983). Peptides are generally localized to wide-field amacrine cells, which form low-density cell populations that likely have a wide influence on other retinal neurons. A few peptides (e.g., pituitary adenylate cyclase activating polypeptide [PACAP] and substance P [SP]) are also localized to ganglion cells in some species (Brecha et al., 1987; Cuenca et al., 1995; Hannibal et al., 1997). More recently, peptide receptor mRNAs and immunoreactivity have been identified in retinal extracts and localized to multiple retinal cell types (Casini et al., 1997; Johnson et al., 2000; Tsuchida et al., 1990). Interestingly, there is often a difference between the localization of peptide-containing cells and processes, and the cellular distribution of their receptors, suggesting that peptides act in a paracrine manner and therefore have a broad influence on retinal circuits in both the outer and inner retina. Peptides can influence transmitter release from the retina (Bruun and Ehinger, 1993), and they modulate the cellular activity of multiple retinal neurons (Akopian et al., 2000; Feigenspan and Bormann, 1994; Zalutsky and Miller, 1990a). In general, peptide actions are characterized as being slow in onset, long lasting, and potent at low concentrations. Recent cellular studies have shown that peptides influence multiple intracellular effectors, including cAMP and Ca^{2+} , and that they modulate K^+ and Ca^{2+} currents and GABA_A receptor currents in retinal neurons (Akopian et al., 2000; Bruun et al., 1994; Feigenspan and Bormann, 1994; Johnson et al., 2001). Peptides, therefore, influence the efficacy of synaptic transmission in the retina by regulating cellular excitability as well as by modulating the release of GABA and glutamate from

presynaptic axonal terminals. Peptide actions are too slow to participate in light-activated responses, and since their actions are long lasting, peptides are likely to have an important role in adaptive mechanisms, such as light and dark adaptation. Together, these findings provide strong support for a functional role of peptides in the retina.

This chapter is mainly focused on neuropeptide Y (NPY), PACAP, SP, somatostatin (SRIF), and vasoactive intestinal polypeptide (VIP) as examples of peptides that are expressed in and affect the mammalian retina via the activation of selective receptors (Table 22.1). These peptides are characterized by a widespread distribution and abundant expression in the peripheral and central nervous system, where they provoke a broad spectrum of biological actions (Arimura, 1998; Gozes and Brenneman, 1989; McDonald, 1988; Otsuka and Yoshioka, 1993; Patel, 1999).

Peptide and Peptide Receptor Expression and Function

Peptide content. Early evidence for the presence of neuroactive peptides in the retina comes from experiments in the 1950s by Euler and his colleagues showing SP bioactivity in dog and bovine retinal extracts (Dunér et al., 1954). However, it was not until the late 1970s with the development of additional bioassay systems and radioimmunoassays (RIAs) that the rich variety of peptides, including cholecystokinin (CCK), the enkephalins, glucagon, SRIF, SP, thyrotropin-releasing hormone (TRH), and VIP, was shown to be present in the vertebrate retina (Brecha, 1983). At the present time over 20 peptides have been shown to be expressed in the vertebrate retina (Table 22.2).

In general, bioassay and RIA studies reported low to moderate levels of peptides in retinal extracts (Brecha, 1983; Ekman and Tornqvist, 1985; Rorstad et al., 1979). In most cases, findings from these investigations are congruent with those of immunohistochemical studies, which demonstrate that these peptides are found in subsets of amacrine and ganglion cells. For instance, SRIF immunoreactive content in the rat retina is relatively low, and this peptide is mainly localized to sparsely occurring amacrine and displaced amacrine cells (Eskay et al., 1980; Larsen et al., 1990; Sagar

TABLE 22.1
Peptides and peptide receptors in the retina.

Peptides	Preferred Receptors
Neuropeptide Y	Y _{1,2,4,5}
Pituitary adenylate cyclase activating polypeptide	PAC1, VAC1, VAC2
Somatostatin	sst ₁₋₅
Tachykinin peptides	
• Substance P	NK-1
• Neurokinin A	NK-2
• Neurokinin B	NK-3
Vasoactive intestinal polypeptide	VAC1, VAC2

TABLE 22.2
Peptide expression in the vertebrate retina.

Angiotensin II
Cholecystokinin
Corticotropin-releasing hormone
Enkephalins
• Leu ₅ -enkephalin
• Met ₅ -enkephalin
β-endorphin
FMRFamide
Glucagon
Luteinizing hormone releasing hormone
Natriuretic peptides
Atrial natriuretic peptide (α-ANP and γ-ANP)
Brain natriuretic peptide
C-type natriuretic peptide
Neurotensin
Neuropeptide Y
Nociceptin
Pituitary adenylate cyclase activating polypeptide
Peptide histidine isoleucine
Somatostatin
Tachykinin peptides
• Substance P
• Neurokinin A
• Neurokinin B
Thyrotropin-releasing hormone
Vasoactive intestinal polypeptide

et al., 1985). Many earlier studies also showed that peptides detected in the vertebrate retina corresponded in molecular structure to the same peptide in other tissues or the authentic peptide. For instance, glucagon, NPY, SRIF, and VIP immunoreactivity in retinal extracts were shown to correspond in molecular size to authentic peptides using gel or high-pressure liquid chromatography (Bruun et al., 1991; Ekman and Tornqvist, 1985; Sagar et al., 1985).

Peptide mRNAs. Peptide mRNAs have been detected in rat and human retinal extracts using Northern blots and RT-PCR, and in tissue sections using *in situ* hybridization histochemistry. For instance, preprotachykinin (PPT) I and PPT II mRNAs are in rat retinal extracts, indicating that all three TK peptides are expressed in the rat retina (Brecha et al., 1989). PACAP, SRIF, and VIP mRNAs have also been reported in rat retina (Casini et al., 1994; Larsen et al., 1990; Olianias et al., 1997). These findings indicate that the mammalian retina synthesizes various peptides, and it is reasonable to assume, based on these findings, that other peptides located in the retina by RIA or immunohistochemistry are also synthesized by retinal neurons.

Peptide localization. Immunohistochemical studies beginning in the late 1970s and early 1980s reported numerous peptides in the vertebrate retina (Brecha, 1983; Tornqvist et al., 1982). Peptides are most commonly localized to amacrine and ganglion cells, and usually to a single-cell population as defined by their morphology and neurochemistry (Brecha, 1983; Casini and Brecha, 1991; Hannibal et al., 2002; Vaney et al., 1989). Peptide immunoreactivity is commonly reported in very low to medium density wide-field amacrine cell populations. These cells are characterized by processes that are localized to distinct laminae of the inner plexiform layer (IPL) (Cajal, 1893). In addition, these processes ramify widely and overlap to form a network across the retinal surface. Some wide-field amacrine cell types that contain peptide immunoreactivity also have axon-like processes (Cuenca et al., 1995; Rickman et al., 1996; Sagar and Marshall, 1988). These amacrine cell types are likely to be polyaxonal amacrine cells, which are characterized by a distinct dendritic field and multiple axons that extend beyond their major field of dendrites (Volgyi et al., 2001). Finally, interplexiform cells, which are characterized by processes that ramify in both the IPL and outer plexiform layer (OPL) may also be considered an amacrine cell variant (Wässle and Boycott, 1991). There are several examples of a few peptide immunoreactive processes crossing the inner nuclear layer (INL) and ramifying in the OPL (Brecha, 1983; Spira et al., 1984). Wide-field amacrine cell populations, because of their low density and the widespread distribution of their processes, are thought to have broad influence on multiple retinal neurons and to participate in regulatory events such as dark adaptation rather than in more rapid events involving through-conducting pathways mediated by narrow-field and high-density cell populations (Masland, 1988; Wässle and Boycott, 1991). Peptide-containing ganglion cells are characterized by multistratified dendrites and wide dendritic fields. Peptide-containing ganglion cells usually innervate multiple retinorecipient targets, including those in the hypothalamus and midbrain (Brecha et al., 1987; Hannibal et al., 1997). There are only a few reports of peptide immunore-

activity in bipolar or horizontal cells (Marshak et al., 1990; Thier and Bolz, 1985).

There have been a modest number of ultrastructural investigations concerning the connectivity of peptide immunoreactive cells in rat, guinea pig, and primate retina (Cuenca and Kolb, 1998; Kang et al., 2001; Lee et al., 1995; Marshak, 1989; Oh et al., 2002). Several peptide-containing amacrine cell types have been studied in the macaque monkey retina (Marshak, 1989). In general, the main input to peptide immunoreactive processes is from amacrine cells, whereas the major output formed by conventional synapses is onto amacrine and ganglion cells. There is a smaller percentage of input and output connections with bipolar cell axonal terminals. The large degree of synaptic connections with amacrine cells indicates that peptide-containing cells are influenced principally by other amacrine cells and to a lesser degree by bipolar cells. There is more limited information about the connectivity of peptide-containing cells in other species, although overall the pattern of connectivity of these cells appears to be quite similar to that observed in monkey retina.

A feature of many wide-field amacrine cells is the coexpression of GABA and a peptide (Casini and Brecha, 1992; Vaney and Young, 1988). For example, in rat, cat, and monkey retina, GABA is colocalized with NPY, SP, and VIP in different amacrine cell types (Casini and Brecha, 1992; Cuenca and Kolb, 1998; Oh et al., 2002; Pourcho and Goebel, 1988a; Vaney et al., 1989). In addition, glutamate, the predominant ganglion cell transmitter, is coexpressed with PACAP in ganglion cells that innervate the suprachiasmatic nucleus (SCN) of the hypothalamus (Hannibal et al., 2000). These observations are consistent with findings elsewhere in the nervous system reporting the coexpression and corelease of classical transmitters and peptides from the same cell (Hökfelt et al., 2000). Interestingly, a differential release of classic transmitters and peptides depending on the frequency and pattern of cell firing has been shown in several systems (Lundberg, 1996). GABA or glutamate and peptides can act together at the same site, or the peptides can diffuse through the tissue and act at more distant cellular sites. There is evidence for both modes of action in the retina. GABA and peptides released from wide-field amacrine cells may act locally at GABA_A receptors; for instance, both VIP and GABA act on GABA_A receptors expressed by bipolar cell axons and ganglion cells (Veruki and Yeh, 1992). Peptides can also diffuse from their release site and act in a paracrine manner as suggested, for example, by the different distributions of SRIF immunoreactive processes and SRIF receptors, which are expressed by multiple retinal cell types (Johnson et al., 2000).

Peptide binding sites and localization. High-affinity peptide binding sites have been reported in many mammalian species using binding assay protocols and radiolabeled pep-

tides (Kossut et al., 1989; Nilsson et al., 1994; Orianas and Onali, 1995; Osborne, 1984). Autoradiographic techniques have also been used to define the regional distribution of peptide binding sites. For example, SRIF binding sites, identified with SRIF and the SRIF analog octreotide, are on photoreceptors and over both plexiform layers of the mouse and rat retina (Ferriero, 1992; Kossut et al., 1989). SP and VIP binding sites are homogeneously distributed across the inner retina (Denis et al., 1991a; Denis et al., 1991b; Mantyh et al., 1989). However, there are major difficulties in defining the cell types associated with these binding sites because of the low resolution of the autoradiographic technique. Furthermore, there are very few selective peptide agonists or antagonists available to distinguish between the different receptor isoforms. For example, octreotide binds to several somatostatin receptor types (Hoyer et al., 1995), and therefore there is a high likelihood that multiple receptors were detected in the autoradiographic studies of mouse and rat retina (Ferriero, 1992; Kossut et al., 1989).

Functional peptide receptors. Peptide receptors act through G-protein-coupled receptors to regulate intracellular signaling pathways. NPY and SRIF potently inhibit forskolin-induced cAMP accumulation (Bruun et al., 1994; Colas et al., 1992). The potent stimulation of adenylate cyclase activity by VIP is well established (Brecha, 1983; D'Agata and Cavallaro, 1998; Osborne, 1991). In addition, PACAP-27 and PACAP-38 are positively coupled to adenylate cyclase activity (D'Agata and Cavallaro, 1998; Nilsson et al., 1994; Orianas et al., 1997). Finally, the TK peptides stimulate inositol phosphate accumulation and Ca²⁺ mobilization (Osborne and Ghazi, 1989). These investigations, along with peptide binding and autoradiographic studies, have been valuable in establishing the presence of functional peptide receptors in the retina.

Peptide receptor mRNAs. Multiple peptide receptor mRNAs, including SRIF subtype (sst), TK or neurokinin (NK), and VIP/PACAP, are in rat retinal extracts. Multiple isoforms of these peptide receptor mRNAs are found in the retina; for instance, all five sst receptor mRNAs with different relative levels of abundance are expressed in rat and rabbit retinal extracts (Cristiani et al., 2000; Johnson et al., 1999; Mori et al., 1997). In addition, all of the known NK receptor mRNAs are present in rat eye extracts (Tsuchida et al., 1990). Finally, mRNAs of both the selective PACAP receptor, PAC1, and the VIP/PACAP-preferring receptors, VPAC1 and VPAC2, are found in retinal extracts (D'Agata and Cavallaro, 1998; Orianas et al., 1997). These findings indicate that multiple peptide receptors are synthesized by the mammalian retina, in agreement with binding, autoradiographic, and immunohistochemical studies, which corroborate the expression of multiple peptide receptors in the retina.

Peptide receptor localization. Numerous peptide receptors, including Y receptors, three different sst receptors, and the NK receptors have been localized to the retina (Casini et al., 1997; Cristiani et al., 2000; D'Angelo et al., 2000; Helboe and Moller, 1999; Johnson et al., 2000; Oyamada et al., 1999). These receptors are expressed by one or more retinal cell types. The cellular distributions of peptides and their receptors usually differ; peptides are often localized to a single or at most a few cell types, and their receptors are typically expressed by multiple cell types. For example, in rat retina, TK immunoreactive cells are sparsely distributed and ramify primarily in laminae 1, 3, and 5 of the IPL (Brecha et al., 1989; Zhang and Yeh, 1992). In contrast, NK-1 and NK-3 receptor immunoreactivity is predominantly expressed by numerous GABA-containing amacrine cells with processes over the entire IPL and OFF-type bipolar cells with dendritic processes in the OPL and axonal processes in laminae 1 and 2 of the IPL (Blumauer and Brecha, 1998; Casini et al., 1997; Oyamada et al., 1999). These studies are beginning to define the peptide expression pattern in the retina, which in turn is providing important insights into the mode of action of peptides in the retina.

Cellular physiology studies—ion channels and Ca^{2+} imaging. Experimental approaches using patch clamp and Ca^{2+} imaging techniques have been used to investigate peptide modulation of ion channels expressed by retinal neurons. In goldfish retina, several peptides, including SP, SRIF, and met-enkephalin, inhibit a voltage-dependent Ca^{2+} current in rod bipolar cell axon terminals (Ayoub and Matthews, 1992). In the mammalian retina, SRIF and VIP modulate ion channels in several cell types. For instance, a low concentration of SRIF reduces a K^{+} -stimulated increase of intracellular Ca^{2+} ($[Ca^{2+}]_i$) via voltage-activated L-type Ca^{2+} channels in rod bipolar cell terminals (Akopian et al., 2000; Johnson et al., 2000; Petrucci et al., 2001). SRIF also modulates both K^{+} and Ca^{2+} currents in salamander photoreceptors and rabbit rod bipolar cells (Akopian et al., 2000; Petrucci et al., 2001). In addition, VIP is reported to modulate Cl^{-} currents evoked by GABA at $GABA_A$ receptors in bipolar, amacrine, and ganglion cells of the rat retina (Feigenspan and Bormann, 1994; Veruki and Yeh, 1992). These findings show that peptides modulate ion channels, which in turn would influence cellular activity and transmitter release. For example, the modulation of voltage-activated Ca^{2+} currents in photoreceptor and bipolar cell terminals would influence transmitter release from these terminals.

Peptide modulation of transmitter release. Several investigations have been concerned with the influence of peptides on transmitter release from the retina. The general experimental paradigm is to preload the retina with a radiolabeled

transmitter, such as GABA, glycine, or dopamine, and, following a washout period, to add the peptide and measure changes of radiolabeled transmitter levels induced by the peptide. Low concentrations of exogenously applied NPY stimulate the release of glycine, dopamine, acetylcholine, and 5-hydroxytryptamine from the rabbit retina (Bruun and Ehinger, 1993). A variant of this approach involves the use of flashing light to stimulate transmitter release to determine if peptides influence this light-evoked transmitter release. For example, SRIF and SP do not change the level of light-evoked release of acetylcholine from rabbit retina (Cunningham and Neal, 1983). By contrast, the mu opioid receptor agonist, [D-Ala2, MePhe4, Gly-ol5]-enkephalin (DAMGO), increases light-evoked release of acetylcholine from rabbit retina (Neal et al., 1994).

Functional studies—electroretinogram (ERG), intracellular and extracellular recordings. The action of peptides on the retina has also been evaluated using ERG, as well as extracellular and intracellular recordings. The experimental approach that has been used most often is an in vitro retinal eyecup preparation and the bath application of a given peptide. In rabbit retina eyecups, application of low concentrations of SRIF increases the amplitude of the ERG a-, b- and c-waves, but several other peptides, including CCK and SP (Cunningham and Neal, 1983; Zalutsky and Miller, 1990b), do not affect the ERG. Studies using extracellular recordings of retinal neurons report that peptides increase the general excitability of cells (Downing and Djamgoz, 1993; Jensen, 1993; Zalutsky and Miller, 1990a, 1990b). Peptide actions are characterized as slow in onset, long lasting, and potent at low concentrations. Intracellular recordings indicate direct peptide actions on amacrine and ganglion cells. There is also some specificity in peptide action. For example, in rabbit retina, where the actions of SRIF, TK peptides, and VIP on ganglion cells have been studied, SRIF acts on all ganglion cell types; by contrast, SP acts on most brisk ganglion cells and VIP acts on ON- and OFF-center brisk ganglion cell types, respectively (Jensen, 1993; Zalutsky and Miller, 1990a, 1990b). Overall, peptide actions are characterized as being modulatory and too slow to participate in fast, light-evoked responses.

NPY, SRIF, SP, and VIP / PACAP expression and function

NPY, SRIF, SP, and VIP / PACAP expression in the mammalian retina. NPY, SRIF, SP, and VIP have been extensively studied in numerous mammalian species, including mouse, rat, guinea pig, rabbit, cat, monkey, and human retina.

NPY in amacrine and ganglion cells. NPY immunoreactivity is reported in the retina of numerous mammalian species

FIGURE 22.1. NPY immunoreactive cells in the rat retina. *A*, NPY immunostaining was localized to cell bodies in the proximal INL and varicose fibers distributed in laminae 1, 3, and 5 of the IPL. *B*, NPY immunoreactivity was absent from a retinal section incubated with the NPY antibody that was preincubated with 10^{-6} M NPY. Scale bar = 30 μ m. (From Oh et al., 2002.)

(Bruun et al., 1991; Ferriero and Sagar, 1989). Chromatographic studies show that NPY immunoreactivity isolated from mammalian retinal extracts corresponds to authentic NPY (Bruun et al., 1991). In addition, the NPY gene is expressed by cells located in the INL and GCL of the mouse retina (Ammar et al., 1998; Sinclair and Nirenberg, 2001).

NPY immunoreactivity is mainly localized to wide-field amacrine and displaced amacrine cells. Overall, these cells are similar in their appearance and distribution across species (Bruun et al., 1984; Bruun et al., 1986; Hutsler and Chalupa, 1994; Kang et al., 2001; Marshak, 1989; Oh et al., 2002; Sinclair and Nirenberg, 2001; Tornqvist and Ehinger, 1988) (Fig. 22.1). Immunoreactive amacrine cells have thin, varicose processes that ramify narrowly in lamina 1 of the IPL and, in some species, processes in laminae 3 and 5 of the IPL. In addition, in other species there are a few NPY immunoreactive displaced amacrine cells. In cat retina, immunoreactive cells only ramify in lamina 1 of the IPL (Hutsler and Chalupa, 1994). Furthermore, the mouse and rat retina have a well-defined displaced amacrine cell population (Oh et al., 2002; Sinclair and Nirenberg, 2001) with cells ramifying in lamina 5 of the IPL. NPY immunoreactivity is also reported in ganglion cells of the cat and human retina (Hutsler et al., 1993; Jen et al., 1994; Straznicky and Hiscock, 1989). In rat, guinea pig, and macaque monkey retina, the synaptic inputs to immunoreactive processes are predominantly from amacrine cell processes and from a small percentage of bipolar cell axon terminals (Kang et al., 2001; Marshak, 1989; Oh et al., 2002). Immunoreactive processes form conventional synaptic output mainly with amacrine cell processes and ganglion cell dendrites.

NPY immunoreactive cells are distributed to all retinal regions. These cells form different density cell populations in the mouse, rat, and cat retina. Cell density in rat retina is about 260 cells/mm² in the INL and 86 cells/mm² in the GCL (Oh et al., 2002), in the mouse retina is about 1452

cells/mm² in the INL and 644 cells/mm² in the GCL (Sinclair and Nirenberg, 2001), and in the cat retina, is about 1000 cells/mm² in central retinal regions and 390 cells/mm² in peripheral retina (Hutsler and Chalupa, 1994).

NPY immunoreactivity occurs also in ganglion cells of the cat retina and perhaps in the human retina (Hutsler et al., 1993; Jen et al., 1994; Straznicky and Hiscock, 1989). In cat retina, NPY immunoreactivity is in a subpopulation of gamma-type ganglion cells that have a small to medium cell body and sparsely branching dendrites that ramify in the ON sublamina of the IPL (Hutsler et al., 1993). These ganglion cells are sparsely distributed across the retina, are highest in density in area centralis, and number about 2000 per retina. NPY immunoreactive ganglion cells terminate in the C layers of the lateral geniculate nucleus and the superior colliculus. In adult human retina, NPY immunoreactivity is mainly in large ganglion cells that are distributed to all retinal regions (Straznicky and Hiscock, 1989) and that make up about 6% of the total ganglion cell population. Only a few, possibly wide-field NPY immunoreactive amacrine cells are reported in this study. In contrast, in the fetal human retina, NPY immunoreactive ganglion cell bodies are small and are identified solely on the basis of their localization to the GCL (Jen et al., 1994). These putative NPY immunoreactive ganglion cells appear to be the same size as the immunoreactive amacrine cells, suggesting that they may be displaced amacrine cells. The reports of NPY-containing ganglion cells are in contrast to the findings from other studies that describe NPY immunoreactive amacrine and displaced amacrine cells in adult and fetal human retina (Jotwani et al., 1994; Tornqvist and Ehinger, 1988).

Y receptor expression. The cellular actions of NPY are mediated via multiple Y receptors. The presence of NPY receptors is indicated by the potent inhibition of forskolin-induced cAMP accumulation by NPY (Bruun et al., 1994). Pharmacological studies have indicated the presence of several functionally coupled Y receptors, including the Y₂ receptor in the pigmented epithelium (Ammar et al., 1998). Therefore, NPY released by amacrine cells in the inner retina must have a paracrine mode of action to affect Y receptors expressed by the pigmented epithelium. Y₁ receptor immunoreactivity is in horizontal cell bodies in the distal INL and their processes in the OPL (D'Angelo et al., 2002). Immunoreactive amacrine cell processes ramify in lamina 2/3 and 4, and immunoreactive puncta are distributed to laminae 4 and 5 of the IPL. Immunoreactivity in lamina 2/3 and 4 of the IPL is localized to cholinergic amacrine cell processes (Voigt, 1986). The presence of NPY-containing amacrine and displaced amacrine cells and Y₁ receptor immunoreactive amacrine and horizontal cells (D'Angelo et al., 2002; Oh et al., 2002) suggests that this peptide acts on multiple cells in the inner and outer retina.

FIGURE 22.2. SRIF immunoreactive cells in a whole mount preparation of the rabbit retina. *A, C*, SRIF immunoreactive cell body located in the GCL. Primary processes ramify in lamina 5 of the IPL. *B, D*, Same fields as in *A* and *C*, respectively, with the plane of focus at lamina 1 of the IPL. A network of fine varicose processes is present in this lamina. Scale bar = 50 μ m. (From Rickman et al., 1996.)

SRIF in amacrine and ganglion cells. SRIF immunoreactivity and bioactivity are described in many mammalian species (Brecha, 1983; Eskay et al., 1980; Marshak and Yamada, 1984). Bioassay and chromatographic studies indicate that SRIF-14 is the predominant form in the rat and human retina and the larger SRIF-28, in addition to SRIF-14, is in guinea pig and rabbit retina (Larsen et al., 1990; Rorstad et al., 1980; Sagar et al., 1985; Sagar et al., 1982; Spira et al., 1984). In rat retina, SRIF mRNA-containing cells are in the INL and GCL (Larsen et al., 1990; Xiang et al., 2001). The coexpression of SRIF mRNA and SRIF immunoreactivity (Gaur et al., 1990) further confirms that amacrine and displaced amacrine cells in the rat retina synthesize this peptide.

SRIF immunoreactivity is localized to sparsely distributed, wide-field amacrine and displaced amacrine cells in the mouse (unpublished observations), rat (Larsen et al., 1990; Sagar et al., 1985), guinea pig (Spira et al., 1984; Tornqvist et al., 1982), and human retina (Tornqvist and Ehinger, 1988). In the rabbit, cat, macaque monkey, the New World monkey *Tupaia belangeri*, and human retina, most SRIF immunoreactive cells are displaced amacrine cells (Engelmann and Peichl, 1996; Marshak, 1989; Mitrofanis et al., 1989; Rickman et al., 1996; Sagar, 1987a; Sagar and Marshall, 1988; White et al., 1990) (Fig. 22.2). SRIF immunoreactive cells in rabbit and human retina have also been classified as “associational ganglion cells” on the basis of an intraretinal axon (Sagar, 1987a; Sagar and Marshall, 1988). These cells are also considered to be an amacrine cell variant, called a polyaxonal amacrine cell (Volgyi et al., 2001). Immunoreactive somata have thin varicose fibers that

form a narrow and continuous plexus in lamina 1 of the IPL. In many species, there is also a narrow plexus of varicose fibers in laminae 3 and 5 of the IPL. Frequently, a smooth, thin-caliber, axon-like process is observed to arise from a cell body or a primary process cross the retinal surface (Marshak, 1989; Rickman et al., 1996; Sagar and Marshall, 1988). A few immunoreactive fibers also cross the INL to ramify in the OPL in both ventral and dorsal retina. These fibers can be traced to the plexus in lamina 1 of the IPL. Finally, in rabbit retina, there is a dense accumulation of SRIF immunoreactive fibers along the retinal margin, which form a circumferential band in all retinal regions (Rickman et al., 1996). In macaque monkey retina, the predominant synaptic input is from amacrine cell processes and bipolar cell axon terminals. Synaptic output, formed by conventional synapses, is onto amacrine cell processes and ganglion cell dendrites (Marshak, 1989). In cat retina, synaptic connections differ from those in macaque retina, with input from amacrine cell processes, and output of immunostained profiles having both ribbon and conventional synaptic specializations to amacrine and ganglion cell processes (see Chun et al., 1992, for a discussion of the immunolabeled ribbon-containing profiles).

The larger proportion of displaced amacrine cells and their predominant distribution to the ventral retina are major features of the SRIF expression in the rabbit, cat, and human retina (Rickman et al., 1996; Sagar, 1987a; Sagar and Marshall, 1988; White et al., 1990). Furthermore, in rabbit and cat retina, there is a band of immunoreactive cells along the retinal margin. SRIF immunoreactive displaced amacrine cells form a low-density cell population in rabbit, cat, and human retina (Mitrofanis et al., 1989; Rickman et al., 1996; Sagar, 1987a; White et al., 1990). Immunoreactive cells are distributed predominantly in the ventral retina with few cells in the dorsal retina. Many immunoreactive cells are located along the retinal margin adjacent to the ora serrata. Cell density is very low; for example, in rabbit retina, cell density ranges from 6 cells/mm² in ventral retina to 11 cells/mm² at the retinal margins (Rickman et al., 1996). The total number of SRIF immunoreactive cells is correspondingly very low and in rabbit number about 1100 cells per retina (Rickman et al., 1996; Sagar et al., 1986). A very low-density SRIF-containing cell population is also present in cat and human retina (Mitrofanis et al., 1989; White et al., 1990). The distribution of SRIF immunoreactive cells in the guinea pig retina also differs from the general patterns of SRIF expression (Spira et al., 1984). SRIF immunoreactive cells are sparsely distributed along the margin of the retina in all retinal regions, and cells are located in the INL, IPL, and GCL. In the guinea pig, there is a density of about 35 cells/mm² in the area along the retinal margin (Spira et al., 1984). In contrast, SRIF immunoreactive cells in *Tupaia belangeri* are distributed in all retinal regions (Engelmann and

Peichl, 1996). The SRIF immunoreactive cell density is many times higher than in other vertebrate retinas (Engelmann and Peichl, 1996) with about 5000 cells/mm² in central retinal regions and 100 cells/mm² in peripheral retina.

SRIF immunoreactivity is also in a small percentage of ganglion cells (Engelmann and Peichl, 1996; White and Chalupa, 1991). In *Tupaia belangeri* retina, about 5% of the total number of SRIF immunoreactive cells are ganglion cells (Engelmann and Peichl, 1996). In cat retina, SRIF immunoreactivity is predominantly localized to a very small number of OFF-center alpha ganglion cells that are predominantly distributed to the inferior retina (White and Chalupa, 1991).

SRIF binding sites, localization, and coupling to adenylate cyclase. High-affinity binding sites for SRIF have been found in the retina of several species (Colas et al., 1992; Ferriero, 1992; Kossut et al., 1989; Liapakis and Thermos, 1992). Furthermore, SRIF binding sites, identified with SRIF and the SRIF analog SMS 204-090, have been localized to photoreceptors and both plexiform layers (Ferriero, 1992; Kossut et al., 1989). Functionally coupled SRIF receptors are indicated by the potent inhibition of VIP-induced cAMP accumulation by SRIF (Colas et al., 1992).

SRIF subtype (sst) receptor expression. SRIF actions are mediated through five sst receptors, sst₁–sst₅, and two sst₂ receptor isoforms, sst_{2A} and sst_{2B}, derived from alternative mRNA splicing (Hoyer et al., 1995). All five sst receptor mRNAs are in rat and rabbit retinal extracts (Cristiani et al., 2000; Johnson et al., 1999; Mori et al., 1997). In rat retina, sst₂ and sst₄ receptor mRNAs are the most abundant, whereas sst₁, sst₃, and sst₅ receptor mRNAs are at low abundance (Mori et al., 1997). In contrast, in rabbit retina, sst₁ receptor mRNA is the most abundant, sst₂ receptor mRNA is moderate, and sst₃, sst₄, and sst₅ receptor mRNAs are low in abundance (Cristiani et al., 2000).

Sst₁ receptor immunoreactivity is reported in amacrine and very sparsely occurring ganglion cells in the rat and rabbit retina (Cristiani et al., 2000; Helboe and Moller, 1999). In rat retina, sst₁ receptor immunoreactivity is in SRIF-containing amacrine and displaced amacrine cells (Helboe and Moller, 1999). A few ganglion cells, identified on the basis of their position, are also reported to contain sst₁ receptor immunoreactivity. In addition, Müller cell endfeet are strongly immunoreactive. The sst₁ receptor immunoreactivity pattern in the rabbit retina is different and more complex (Cristiani et al., 2000). Numerous amacrine cell types, including all tyrosine hydroxylase-containing and SRIF-containing cells, are sst₁ receptor immunoreactive. In addition, there are numerous amacrine cells that only have strong somatic immunostaining. These cells have a moder-

FIGURE 22.3. Sst_{2A} receptor immunoreactive rod bipolar cells in the rabbit retina. Coexpression of sst_{2A} receptor immunoreactivity (A) and protein kinase C (PKC) immunoreactivity (B) in rod bipolar cells. PKC is a cell-specific marker for rod bipolar cells in the rabbit retina. Sst_{2A} receptor immunoreactive amacrine cell processes (arrows) are also found in the rabbit retina. Scale bar = 15 μ m. (From Johnson et al., 1998.)

ate overall density of 112 cells/mm². In addition, there are a very small number of sst₁ receptor-containing ganglion cells, identified on the basis of cell body size, morphology, and disappearance following optic nerve transection.

Sst_{2A} receptor immunoreactivity is localized to multiple cell types in all regions of the mouse, rat, and rabbit retina (Fontanesi et al., 2000; Helboe and Moller, 1999; Johnson et al., 1998; Johnson et al., 1999; Petrucci et al., 2001; Vasilaki et al., 2001). In mouse, rat, and rabbit retina, three different sst_{2A} receptor immunoreactive patterns have been reported. In the mouse and rat retina, sst_{2A} receptor immunoreactivity is in cone photoreceptor terminals, many bipolar cells including rod bipolar cells, horizontal cells, and TH-containing amacrine cells (Johnson et al., 1999). A second study (Helboe and Moller, 1999) reports a less extensive distribution of this receptor with immunoreactivity localized to the inner segments of cone photoreceptors, many amacrine cells including the TH-containing amacrine cells, and Müller cell processes in the inner retina. In contrast to these studies, a third report (Vasilaki et al., 2001) describes sst_{2A} receptor immunoreactivity solely localized to rod bipolar cells. In rabbit retina, sst_{2A} receptor immunoreactivity is localized to all rod bipolar cells and to sparsely occurring amacrine cells (Johnson et al., 1998) (Fig. 22.3). Immunoreactive amacrine cells give rise to widely ramifying and overlapping processes in laminae 2 and 4 of the IPL. Two other studies report a similar pattern of expression in the rabbit retina, with sst_{2A} receptor immunoreactivity in many rod bipolar cells, amacrine cells including some TH-containing amacrine cells, and rare putative horizontal cells

(Fontanesi et al., 2000; Petrucci et al., 2001). Not all rod bipolar (68%) and TH-containing (34%) cells express sst_{2A} receptor immunoreactivity. Finally, an investigation (Vasilaki et al., 2001) describes sst_{2A} receptor immunoreactivity in rabbit rod bipolar cells. There is no obvious explanation for these discrepant observations, which might be due to differences in antibody specificity and sensitivity. One antibody is made to a fusion protein of the C-terminal part of the human sst_{2A} receptor (Helboe and Moller, 1999), and the other three antibodies are made to different synthetic peptides corresponding to the C-terminus of the sst_{2A} receptor (Fontanesi et al., 2000; Johnson et al., 1998; Vasilaki et al., 2001).

Sst_{2B} receptor immunoreactivity has been reported on photoreceptor outer segments of the rat retina (Vasilaki et al., 2001).

In situ hybridization experiments describe sst_4 receptor mRNA expressing cells in the GCL and INL (Mori et al., 1997). Sst_4 receptor immunoreactivity is in medium and large cell bodies in the GCL and numerous multistratified processes in the IPL (Brecha et al., 2002). Immunoreactivity is also in the optic nerve fiber layer and the optic nerve. Together, these findings indicate the presence of SRIF receptors on ganglion cells.

Additional investigations are needed to establish the exact cell types expressing the sst_{2A} receptor; in view of the very different immunostaining patterns reported to date. There is better agreement regarding sst_1 receptor expression on SRIF immunoreactive amacrine and displaced amacrine cells. The presence of sst_1 receptor would provide a mechanism for inhibitory feedback to modulate SRIF release. Finally, the sst_4 receptor appears to be only localized to ganglion cells (Brecha et al., 2002). The presence of sparsely distributed SRIF mRNA-containing and immunoreactive amacrine and displaced amacrine cells (Gaur et al., 1990; Larsen et al., 1990; Rickman et al., 1996; Sagar, 1987a; Sagar et al., 1985) and the widespread cellular expression of sst receptors suggest that SRIF acts on multiple cells in the retina via a paracrine mode of action and has a broad modulatory influence in the retina.

Cellular physiology—ion channels and Ca^{2+} imaging. SRIF modulates both voltage-activated K^+ and L-type Ca^{2+} currents in photoreceptor terminals in a salamander retina slice preparation (Akopian et al., 2000) (Fig. 22.4). SRIF enhances a delayed outwardly rectifying K^+ current in both rod and cone photoreceptors. SRIF differentially modulates L-type Ca^{2+} channel currents; SRIF reduces the Ca^{2+} current in rods and increases the Ca^{2+} current in cones. Ca^{2+} imaging experiments are consistent with these findings. These findings suggest that SRIF has a role in the regulation of transmitter release from photoreceptors through modulation of voltage-gated K^+ and Ca^{2+} currents.

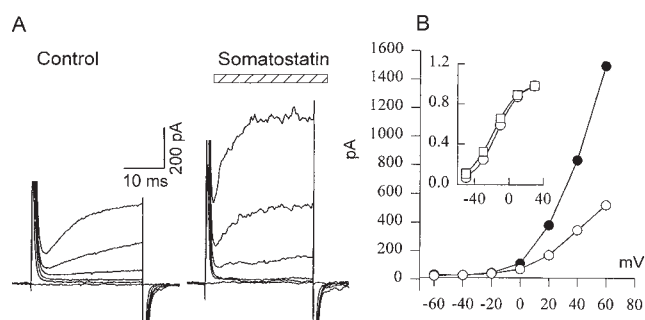

FIGURE 22.4. SRIF enhances a delayed outward K^+ current in rods. *A*, SRIF increased voltage-activated K^+ current. *B*, I-V relationship of the K^+ current obtained by holding cells at -70 mV and stepping from -60 to $+40$ mV in 20 mV increments. (From Akopian et al., 2000.)

In rat rod bipolar cells, there is no detectable change in $[\text{Ca}^{2+}]_i$ levels following direct application of SRIF (Johnson et al., 2001). However, SRIF strongly inhibits a K^+ -stimulated increase of $[\text{Ca}^{2+}]_i$ via L-type Ca^{2+} channels in a dose-dependent manner in rod bipolar axon cell terminals (Fig. 22.5). SRIF also enhances GABA-evoked whole-cell currents in amacrine cells likely due to GABA_A receptor phosphorylation following activation of adenylate cyclase (Feigenspan and Bormann, 1994). In rabbit retina, SRIF and octreotide, an SRIF agonist, reduce a K^+ -stimulated increase in $[\text{Ca}^{2+}]_i$ (Petrucci et al., 2001). In addition, SRIF inhibits Ca^{2+} -activated K^+ channels in these cells. The octreotide effect is prevented by L-Tyr8-Cyanamid 154806, an sst_2 receptor antagonist, indicating that SRIF effects are likely to be mediated by sst_2 receptor activation (Petrucci et al., 2001). Together, these investigations indicate that SRIF modulates both voltage-gated channels and ligand-gated receptors in mammalian retinal neurons.

Functional studies. In rabbit retina, low concentrations of SRIF excite all ganglion cell types, change their “signal-to-

FIGURE 22.5. SRIF strongly inhibits a K^+ -stimulated increase of $[\text{Ca}^{2+}]_i$ via L-type Ca^{2+} channels in a rod bipolar axon cell terminal. *A*, K^+ -stimulated increase of $[\text{Ca}^{2+}]_i$ in an axonal terminal. *B*, Inhibition of K^+ -stimulated increase of $[\text{Ca}^{2+}]_i$ in an axonal terminal by SRIF treatment (striped bar). (From Johnson et al., 2001.)

noise ratio” discharge activity, and shift their center-surround balance toward a more dominant center (Zalutsky and Miller, 1990a) (Fig. 22.6). SRIF actions are characterized as being slow in onset and having a long latency. SRIF is also reported to act on multiple cells in the inner and outer retina; it directly affects bipolar, amacrine, and ganglion cells and influences the horizontal cell network. SRIF is also reported to increase input resistance of amacrine and bipolar cells, suggesting an action on ion channels. This would be consistent with other studies showing that SRIF affects K^+ and Ca^{2+} currents in retinal neurons (Akopian et al., 2000; Johnson et al., 2001; Petrucci et al., 2001). Together these observations indicate that SRIF acts on multiple retinal circuits to produce long-lasting changes in ganglion cell activity and receptive field organization, which is consistent with the hypothesis that this peptide acts as a modulator to affect adaptation in the retina.

TK peptides in amacrine and ganglion cells. SP and the related peptides, neurokinin A and neurokinin B, have a common C-terminus and are collectively referred to as the tachykinins (TKs), or TK peptides (Otsuka and Yoshioka, 1993). The TK peptides are products of two genes; SP and neurokinin A are derived from preprotachykinin (PPT) I by alternative processing, and neurokinin B is derived from a second gene, PPT II.

SP immunoreactivity is reported in the retina of numerous mammalian species, and chromatographic studies indicate the presence of authentic SP in retinal extracts (Brecha, 1983; Eskay et al., 1981; Osborne, 1984). PPT I and PPT II mRNAs are in rat retinal extracts, and *in situ* hybridization histochemistry studies show a differential expression of PPT mRNAs, with PPT I mRNA in cells distributed to the INL, IPL, and GCL and PPT II mRNA in cells distributed to the GCL (Brecha et al., 1989).

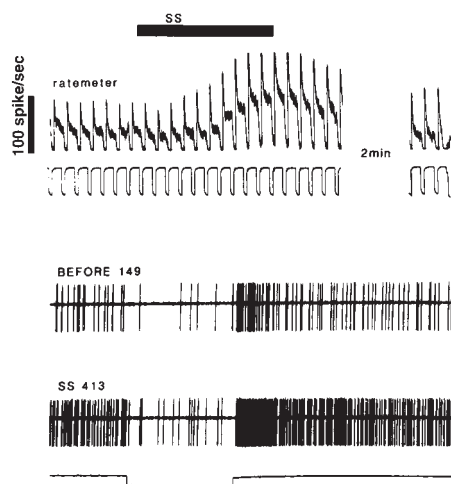

FIGURE 22.6. SRIF excitation of ganglion cells. A, Rate meter record. B, C, An OFF ganglion cell response before and after SRIF application. (From Zalutsky and Miller, 1990a.)

FIGURE 22.7. SP immunoreactivity in the rat retina. Immunoreactive cell bodies are localized to the INL and GCL, and processes are mainly distributed to laminae 1, 3, and 5 of the IPL. Scale bar = 25 μ m. (From Brecha et al., 1989.)

SP immunoreactivity is mainly localized to sparsely distributed wide-field amacrine and displaced amacrine cells in all retinal regions (Brecha, 1983; Kolb et al., 1995). Similar to other peptide-containing cells, SP immunoreactive somata have varicose processes that ramify extensively in the retina. In mouse, rat, rabbit, and primate (monkey and human) retina, immunoreactive processes are distributed to laminae 1, 3, and 5 of the IPL (Brecha, 1983; Brecha et al., 1989; Cuenca et al., 1995; Fukuda et al., 1981; Haverkamp and Wässle, 2000; JenLi and Lam, 1990; Li et al., 1999; Marshak, 1989; Oyamada et al., 1999; Tornqvist and Ehinger, 1988; Zhang and Yeh, 1992) (Fig. 22.7). There are differences in the laminar distribution of processes in the IPL; for example, in rat, hamster, and rabbit retina, processes are mainly in lamina 5, and in primate retina they are mainly in lamina 3 of the IPL. Primate retina is also characterized by numerous immunoreactive cell bodies in lamina 3 of the IPL, and most of the immunoreactive processes are in this lamina. In contrast, SP immunoreactive processes in the guinea pig retina ramify in laminae 4 and 5 of the IPL (Lee et al., 1995). Furthermore, in cat retina, processes mainly ramify in lamina 3/4 and more sparsely in

lamina 1 of the IPL (Pourcho and Goebel, 1988b; Vaney et al., 1989). In several species a few SP immunoreactive processes cross the INL and ramify in the OPL. Axon-like processes are also described in the human retina (Cuenca et al., 1995). They are present in several IPL laminae and they cross the INL and run in the OPL. In some cases, these axon-like processes are associated with retinal vessels. SP immunoreactivity is also in ganglion cells of the rat, hamster, rabbit, and monkey (Brecha et al., 1987; Kolb et al., 1995; Miguel-Hidalgo et al., 1994). Immunoreactive ganglion cells terminate in several CNS structures located in the hypothalamus, thalamus, and midbrain. In primate and guinea pig retina, the synaptic inputs to immunoreactive processes are mainly from amacrine cell processes and about 30% of the input is from bipolar cells (Cuenca and Kolb, 1998; Lee et al., 1995; Li et al., 1999; Marshak, 1989). There are differences in the output of the immunoreactive processes: most of the output in guinea pig is to ganglion cells; in monkey it is to amacrine and ganglion cells; in human retina it is to bipolar, amacrine, and ganglion cells. Interestingly, SP immunoreactive fibers also terminate on blood vessels, suggesting an influence of TK peptides on retinal blood flow (Cuenca and Kolb, 1998).

SP immunoreactive cells are distributed to all retinal regions and form low- to medium-density cell populations. For example, in rat retina, SP-containing cells in the INL are reported in all retinal regions, whereas immunoreactive cells in the GCL are restricted to the superior temporal retina (Zhang and Yeh, 1992). Cell density is 300 to 900 cells/mm² in the INL and 100 to 400 cells/mm² in the GCL. In rabbit retina, there are 1000 to 1400 cells/mm² in the visual streak and 125 to 200 cells/mm² in peripheral retina (Brecha et al., 1987). Finally, in human retina, cell density of SP immunoreactive cells is lower: 35 cells/mm² in temporal superior retina (5 to 9 mm from the fovea) and 5 to 9 cells/mm² in a more peripheral area of the inferior temporal retina (12 to 15 mm from the fovea) (Cuenca et al., 1995).

SP-containing ganglion cells are present in the rat, hamster, rabbit, monkey, and human retina. These cells have been identified by either retrograde transport of fluorescent tracers injected into retinorecipient nuclei or by the loss of immunostaining following optic nerve section. SP-containing ganglion cells terminate in several CNS structures. For instance, in the rat, SP immunoreactive ganglion cells project to the suprachiasmatic nucleus (SCN) and olivary pretectal nucleus (OPN) and perhaps the superior colliculus (Caruso et al., 1990; Klooster et al., 2000; Miguel-Hidalgo et al., 1994; Takatsuji et al., 1991). In hamster, about 3% of all retinal ganglion cells contain SP immunoreactivity, and immunoreactivity is eliminated in the lateral geniculate nucleus (LGN) following optic nerve section (Li et al., 1999). Similarly, in rabbit, 25% to 35% of all retinal ganglion cells contain SP immunoreactivity (Brecha et al., 1987). These cells have

medium to large somata and dendrites that ramify extensively in lamina 5 of the IPL. Their axons terminate in several retinorecipient nuclei, including the LGN, superior colliculus, and accessory optic nuclei. In human retina, weakly staining SP-containing ganglion cells have also been identified on the basis of their morphology (Cuenca et al., 1995). These cells have a large cell body and ramify in lamina 3 of the IPL. Furthermore, in the monkey (*Macaca fuscata yakui*), the presence of SP immunoreactive ganglion cells is suggested by the partial loss of SP immunoreactive processes in the pregeniculate nucleus and the OPN following bilateral eye enucleation (Nakagawa et al., 1988).

TK binding sites, localization, and coupling to phospholipase C. The cellular actions of the TK peptides are mediated through three receptors, known as NK-1, NK-2, and NK-3 (Otsuka and Yoshioka, 1993). The preferred ligands for the NK-1, NK-2, and NK-3 receptors are SP, neurokinin A (also called substance K), and neurokinin B (also called neuromedin K), respectively (Otsuka and Yoshioka, 1993).

High-affinity SP binding sites have been reported in retinal extracts and are homogeneously distributed over the IPL and GCL in tissue sections (Denis et al., 1991b; Mantyh et al., 1989; Osborne, 1984). In addition, substance K and neuromedin K binding sites are evenly distributed over the IPL of the guinea pig retina (Mantyh et al., 1989). Finally, the presence of functional NK receptors in the rabbit retina has been shown by the dose-dependent stimulation of inositol phosphate accumulation and [Ca²⁺]_i mobilization by SP, neurokinin A, and neurokinin B (Osborne and Ghazi, 1989).

NK receptor expression. All NK receptor mRNAs are detected in rat eye extracts (Tsushima et al., 1990). *In situ* hybridization experiments in the rat retina report the localization of NK-1 and NK-3 receptor mRNAs to cells in the inner retina (Kondoh et al., 1996; Shughrue et al., 1996). NK-3 mRNA is mainly distributed to the middle and outer regions of the INL, corresponding to the location of bipolar cell bodies.

NK-1 receptor immunoreactivity is in numerous amacrine cell bodies in the INL and in some small and large cell bodies in the GCL in the rat (Casini et al., 2000; Casini et al., 1997; Oyamada et al., 1999) (Fig. 22.8). Immunoreactivity is prominent in all IPL laminae, and there are fine caliber and varicose processes in the OPL and a few processes in the ganglion cell axon layer. Most NK-1 receptor immunoreactive amacrine cells contain GABA immunoreactivity, suggesting that they comprise multiple amacrine cell subpopulations. NK-1 receptor immunoreactivity is also in tyrosine hydroxylase-containing cell bodies and their processes in the OPL. Some ganglion cells, based on cell body size, appearance, and position, are also likely to express NK-1 receptor immunoreactivity.

FIGURE 22.8. NK-1 receptor immunoreactivity in the rat retina. Immunoreactive amacrine cell bodies are localized to the INL and GCL and processes are dense in all IPL laminae. Scale bar = 50 μ m. (From Casini et al., 1997.)

There are differences in the NK-1 immunoreactivity and mRNA hybridization patterns in the INL and GCL (Casini et al., 2000; Casini et al., 1997; Kondoh et al., 1996; Oyamada et al., 1999). NK-1 receptor immunoreactivity is in numerous amacrine cell bodies and some putative ganglion cells. In contrast, there are few NK-1 mRNA-containing amacrine cells in the INL, and many ganglion cells are reported to contain NK-1 mRNAs (Kondoh et al., 1996). There is no simple explanation for these differences, which may be due to the NK-1 antibodies cross-reacting with other proteins, NK-1 mRNA not being translated to protein, or nonspecific hybridization to cells in the GCL.

NK-3 receptor immunoreactivity is in OFF-type cone bipolar cells and tyrosine hydroxylase-containing amacrine cells (Blumauer and Brecha, 1998; Casini et al., 2000; Chen et al., 2000; Oyamada et al., 1999). NK-3 immunoreactivity is primarily in cell bodies in the middle of the INL, and processes in the OPL and IPL. NK-3 immunoreactive bipolar cells ramify in laminae 1 and 2 of the IPL, suggesting they are cone bipolar (Cb)1 or Cb2 cells that were previously classified using intracellular labeling (Euler and Wässle, 1995; Hartveit, 1997). Many NK-3 receptor immunoreactive bipolar cells also contain recoverin immunoreactivity, a marker for Cb2 bipolar cells (Euler and Wässle, 1995). Together, these findings show that NK-3 receptor immunoreactivity is localized to at least two types of cone bipolar cells, Cb1 and Cb2 (Blumauer and Brecha, 1998). In addition, NK-3 immunoreactivity is also in tyrosine hydroxylase-containing amacrine cells (Chen et al., 2000).

The presence of amacrine and displaced amacrine cells containing both TK immunoreactivity and PPT mRNAs indicates that all three TK peptides are present in the retina.

These findings, regarding the presence of high-affinity TK binding sites and the distribution of NK-1 and NK-3 receptor mRNAs and immunoreactivity in the inner retina, suggest that a major site of action for SP is GABA-containing amacrine cells and the site of action for neurokinin B is OFF-type cone bipolar cells. In addition, these two peptides likely act on dopaminergic amacrine cells, since they express both NK-1 and NK-3 receptor immunoreactivity.

Cellular physiology studies—ion channels. In goldfish retina, SP reduces a voltage-dependent inhibition of Ca^{2+} currents in rod bipolar cell axonal terminals (Ayoub and Matthews, 1992) with a maximum reduction of the Ca^{2+} current of about 27%.

Functional studies. SP at low to moderate concentrations excites most brisk ganglion cells, including ON- and OFF-center and ON-OFF directionally selective ganglion cells in the rabbit retina (Zalutsky and Miller, 1990b). SP exerts these excitatory effects without affecting ganglion cell receptive field properties. The latency of the SP response was faster than that of SRIF (Zalutsky and Miller, 1990a). Intracellular recordings show that SP depolarized amacrine cells, including GABA-containing amacrine cells. These experiments are consistent with the expression of NK-1 receptor immunoreactivity by GABA-containing amacrine cells in the rat retina (Casini et al., 1997). SP did not affect horizontal cell activity, consistent with the lack of TK binding sites and of NK-1 or NK-3 immunostaining in the outer retina. Investigations in mudpuppy and fish retina also report that SP excites most ganglion cells (Dick and Miller, 1981; Downing and Djamgoz, 1993; Glickman and Adolph, 1982). Together, these findings indicate that TK peptides act in the inner retina and affect the general excitability of ganglion cells and their level of spontaneous activity, rather than altering the characteristics of ganglion cell receptive field properties, like SRIF and VIP.

VIP in amacrine cells. VIP immunoreactivity is present in mammalian retinas, and chromatographic studies show that it corresponds to authentic VIP (Brecha, 1983; Ekman and Tornqvist, 1985; Stone et al., 1990). In rat retina, VIP mRNA is in sparsely distributed cells in the inner retina (Casini et al., 1994; Okamoto et al., 1992). Double label studies show that VIP mRNA and VIP immunoreactivity occur in the same amacrine cells (Casini et al., 1994), confirming that this peptide is synthesized by these cells.

VIP immunoreactivity is localized to sparsely distributed wide-field amacrine cells in the mammalian retina (Tornqvist et al., 1982) (Fig. 22.9). VIP immunoreactive cells in the rabbit retina also coexpress peptide histidine isoleucine (PHI) immunoreactivity (Pachter et al., 1989), and

FIGURE 22.9. VIP immunoreactivity in the rabbit retina. Immunoreactive amacrine cell bodies are localized to the INL and processes ramify in laminae 1, 3, and 5 of the IPL. Whole-mount preparation. Scale bar = 50 μm . (From Casini and Brecha, 1991.)

in rat and monkey retina, the PHI immunoreactivity matches the pattern of VIP immunoreactivity (Marshak, 1989; Mikkelsen et al., 1987; Tornqvist and Ehinger, 1988) consistent with VIP and PHI translation from the same VIP/PHI gene (Itoh et al., 1983). Overall, VIP immunoreactive amacrine cells are similar in their appearance and distribution in different mammalian retina (Casini and Brecha, 1991; Casini et al., 1994; JenLi and Lam, 1990; Lammerding-Koppel et al., 1991; Marshak, 1989; Sagar, 1987b; Tornqvist and Ehinger, 1988; Tornqvist et al., 1982). Immunoreactive cells are most often located in the proximal INL. They are characterized by multiple varicose processes and collaterals that ramify in laminae 1, 3, and 5 of the IPL. The immunostaining pattern in the baboon and cynomolgus monkey retinas are exceptions, with their cell bodies and processes in laminae 3 of the IPL (Tornqvist et al., 1982). In macaque monkey and rabbit retina, the synaptic inputs to immunoreactive processes are predominantly from amacrine cell processes (Marshak, 1989; Pachter et al., 1989). VIP immunoreactive processes form conventional

synaptic outputs mainly to unlabeled amacrine cell processes and to ganglion cell dendrites.

VIP mRNA-containing and immunoreactive cells are in all retinal regions and they form low-density cell populations (Casini and Brecha, 1991; Casini et al., 1994; Lammerding-Koppel et al., 1991; Sagar, 1987b). For example, in rat retina, neurons expressing VIP/PHI mRNA have an overall density of about 190 cells/ mm^2 (Casini et al., 1994). There is a lower density of VIP immunoreactive cells in rabbit and monkey retina: in rabbit, immunoreactive cells have an overall cell density of 25 cells/ mm^2 in the retina; in monkey, there is an overall cell density of 50 cells/ mm^2 in the INL and 12 cells/ mm^2 in the GCL (Casini and Brecha, 1991; Lammerding-Koppel et al., 1991; Sagar, 1987b).

PACAP in ganglion cells. PACAP is structurally homologous to VIP. There are two molecular forms of PACAP, PACAP-27 and -38 (Arimura, 1998). PACAP mRNA has been reported in human retinal extracts (Olianas et al., 1997). PACAP-27 and -38 immunoreactivities are in the retina of many mammalian species (Onali and Olianas, 1994), and PACAP immunoreactivity is reported in many cell types, processes in the IPL, and ganglion cell axon layer of the rat retina (Seki et al., 2000). However, no detailed information is given about the individual cell types and the distribution of processes of the immunoreactive cells. In contrast, another group reports a sparse population of PACAP immunoreactive ganglion cells in the rat retina; these cells are characterized by 2 to 4 thin dendrites that ramify in multiple laminae of the IPL and axons that innervate the SCN of the hypothalamus and the intergeniculate leaflet of the thalamus (Hannibal et al., 1997). PACAP mRNA-containing and immunoreactive ganglion cells form a low-density cell population; there is a differential distribution of cells with a density of 31 to 37 cells/ mm^2 in the superior retina and 5 to 8 cells/ mm^2 in the inferior retina (Hannibal et al., 2002). PACAP immunoreactive ganglion cells also contain glutamate immunoreactivity (Hannibal et al., 2000) and melanopsin immunoreactivity (Hannibal et al., 2002). The presence of the photopigment melanopsin in PACAP immunoreactive ganglion cells, the activation of these cells by light during subjective day (Hannibal et al., 2001), and the demonstration that both glutamate and PACAP have a role in light entrainment generated in the SCN (Mintz et al., 1999; Nielsen et al., 2001) provide compelling evidence that this ganglion cell population participates in the circadian light response.

VIP and PACAP binding sites, localization, and coupling to adenylate cyclase. Several different experimental approaches have indicated the presence of PACAP and VIP receptors in the mammalian retina. High-affinity VIP binding sites are in rat

and rabbit retinal extracts, and VIP binding sites are homogeneously distributed over all layers of the retina (Denis et al., 1991a). The potent stimulation of adenylate cyclase activity by VIP is well established in several retinas (Brecha, 1983; D'Agata and Cavallaro, 1998; Schorderet et al., 1984). PHI also can stimulate adenylate cyclase activity (Pachter et al., 1989). PACAP-27 and -38 positively couple to adenylate cyclase in retinal homogenates, and their actions are more potent than VIP, indicating the presence of the PACAP-preferring receptors known as PAC1 receptors (D'Agata and Cavallaro, 1998; Nilsson et al., 1994; Orianas et al., 1997; Onali and Orianas, 1994). Furthermore, in rat retinal homogenates, PACAP-27 and -38, but not VIP, show a dose-dependent stimulation of inositol phosphate levels, suggesting multiple signal transduction pathways for the PACAP peptides (D'Agata and Cavallaro, 1998).

PACAP/VIP receptor expression. The cellular actions of VIP and PACAP are mediated through three PACAP/VIP receptors: PACAP-preferring type 1 (PAC1) and the VIP/PACAP-preferring types (VPAC1 and VPAC2) receptor (Harmar et al., 1998). PAC1 receptors have a higher affinity for PACAP than VIP; VPAC1 and VPAC2 have a similar affinity for both PACAP and VIP.

PAC1, VPAC1, and VPAC2 receptor mRNAs are in rat and human fetal retinal extracts (D'Agata and Cavallaro, 1998; Orianas et al., 1997). A brief report describes a high level of PACAP receptor mRNA hybridization signal, distributed homogeneously over the entire INL and GCL with lower levels of hybridization signal distributed over the IPL, ONL, and OPL (Seki et al., 1997). Furthermore, using an antibody that cross-reacts with different PACAP receptor splice variants, immunoreactivity is reported in scattered and faintly stained cell bodies in the INL and GCL (Seki et al., 1997). No immunostained processes are observed in the IPL or OPL. The presence of VPAC1 and VPAC2 receptor mRNA and immunoreactivity have not yet been reported.

Cellular physiology studies—ion channels. There is no detectable change in membrane currents following direct application of VIP to isolated rod bipolar and ganglion cells (Gillette and Dacheux, 1995; Veruki and Yeh, 1992). However, VIP influences GABA's action at GABA_A receptors. VIP potentiates GABA-evoked whole-cell currents in bipolar cells by 65% and ganglion cells by 54% (Fig. 22.10). The onset of VIP action was slow and there was a long recovery period. VIP-induced potentiation of whole-cell GABA currents is mediated via phosphorylation of GABA_A receptors following adenylate cyclase activation (Feigenspan and Bormann, 1994; Veruki and Yeh, 1994). The activation of a cAMP-dependent pathway is consistent with numerous other

FIGURE 22.10. VIP potentiation of GABA-evoked Cl^- current in a bipolar cell (A) and a ganglion cell (B). A, The whole cell GABA-evoked current in both the bipolar and ganglion cells were potentiated after a 11 second application of VIP.

studies showing that VIP increases cAMP levels in the mammalian retina (Brecha, 1983; Longshore and Makman, 1981; Osborne, 1991). In contrast to these observations in rat, VIP reduces GABA-evoked whole-cell currents of rabbit bipolar cells by 37% (Gillette and Dacheux, 1995). Finally, in rat amacrine cells, VIP also enhances GABA-evoked whole-cell currents, likely due to GABA_A receptor phosphorylation by the activation of adenylate cyclase (Feigenspan and Bormann, 1994).

Functional studies. VIP excites ON- and OFF-center brisk ganglion cells in the rabbit retina (Jensen, 1993). Similar to observations using SRIF and SP, VIP is potent at low concentrations and there is a delay in the onset of its action on ganglion cells. The maintained activity of ON- and OFF-center ganglion cells is increased by VIP and their excitatory responses to flashes of light are unaffected or slightly reduced in the presence of VIP. In contrast, VIP has little effect on the maintained activity of ON/OFF directionally selective ganglion cells and the response of these cells to a moving stimulus. Finally, the action of VIP on ganglion cells in rabbit retina is consistent with other reports of the action of VIP on GABA currents on isolated ganglion cells in the rat retina (Veruki and Yeh, 1992).

Expression and function of other peptides in retinal neurons

Expression of other peptides in the mammalian retina. Several other peptides are also found in the mammalian retina. These include atrial natriuretic peptide (ANP), angiotensin II of the renin-angiotensin system, CCK, corticotropin releasing hormone (CRH), and opioids.

ANP expression. ANP mRNA could not be detected in rat retina using RT-PCR, but ANP immunoreactivity was shown to be in the retina based on RIA and chromatography studies (Gaspar et al., 1991; Stone and Glembotski, 1986). Another study reports the presence of brain natriuretic peptide (BNP) and C-type natriuretic peptide (CNP) mRNAs in the mammalian retina (Fernandez-Durango et al., 1995). Alpha-ANP₁₋₂₈ immunoreactivity has been described in both the OPL and IPL (Palm et al., 1989), and the immunoreactivity of the related peptide, gamma-ANP₁₋₂₅, has been found in rat rod bipolar cells (Haverkamp et al., 1999). High-affinity ANP binding sites are reported in retinal extracts (Fernandez-Durango et al., 1989), although they have not been detected by autoradiography (Mantyh et al., 1986). Finally, ANP, BNP, and CNP receptor mRNAs are reported in the retina (Fernandez-Durango et al., 1995). Consistent with these latter findings is the presence of particulate guanylate cyclase, which is coupled to natriuretic peptide receptors (Ahmad and Barnstable, 1993; Kutty et al., 1992).

Renin and angiotensin expression. The renin-angiotensin system (Phillips, 1987) has been found in mammalian retina. The angiotensin II precursors, angiotensinogen and renin, and angiotensin converting enzyme (ACE) are present in the mammalian retina (Deinum et al., 1990; Kohler et al., 1997; Wagner et al., 1996). Renin immunoreactivity is localized to Müller cells (Berka et al., 1995). Angiotensin II immunoreactivity is reported in rabbit, cat, and bovine retina with weak immunoreactivity in amacrine cells of the rabbit retina. However, pretreatment of the rabbit and cat retina with protease inhibitors and incubation in angiotensin II before immunostaining result in enhanced immunoreactivity, revealing processes in the INL and ONL and possibly ganglion cells (Kohler et al., 1997). This treatment also results in immunoreactivity in Müller cells.

Angiotensin II binding sites are present in the rabbit retina (Mallorga et al., 1989). Furthermore, angiotensin II (AT_{1A} and AT₂) receptor mRNAs are in rat retinal extracts (Murata et al., 1997; Wheeler-Schilling et al., 1999). A role for angiotensin II in regulating vascular tone is indicated by the presence of angiotensin II binding sites on arterioles, but not veins or capillaries, in the cat retina (Ferrari-Dileo et al., 1991). Consistent with this suggestion is a decrease of sys-

temic blood pressure following the intravenous injection of an ACE inhibitor, which depletes angiotensin II levels in the retina (Jacobi et al., 1994).

Weak AT₂ receptor mRNA hybridization signal is localized to neurons sparsely distributed in the INL and GCL (Murata et al., 1997; Wheeler-Schilling et al., 1999). In addition, weak AT₁ immunoreactivity is localized to cell bodies in the INL and most cell bodies in the GCL. Very few weakly staining processes are observed in the IPL or OPL. These latter findings indicate an action by angiotensin II on retinal neurons. Consistent with this suggestion are findings that angiotensin II influences both N- and L-type Ca²⁺ currents in rat ganglion cells (Guenther et al., 1997). Finally, application of angiotensin does not change the level of light-evoked release of acetylcholine from rabbit retina (Cunningham and Neal, 1983), although inhibition of ACE in the cat retina, which depletes angiotensin II levels, results in increased sensitivity and gain of the rod b-wave amplitude of the ERG (Jacobi et al., 1994).

CCK expression. CCK prepropeptide precursor immunoreactivity is in two types of amacrine cells and cone bipolar cells of the monkey retina (Marshak et al., 1990), and CCK immunoreactivity is in amacrine and horizontal cells of the cat retina (Thier and Bolz, 1985). In macaque monkey retina, CCK immunoreactivity is in all blue cone bipolar cells, which terminate in lamina 5 of the IPL (Marshak et al., 1990). These cells form synaptic contacts with amacrine and ganglion cell dendrites. Immunoreactivity is also in two types of wide-field amacrine cells: bistratified amacrine cells with their somata in the INL and GCL and processes that ramify extensively in laminae 2 and 4 of the IPL, and unistratified amacrine cells with processes in the same laminae. The majority of synaptic contacts are with other amacrine cells. Functionally, iontophoresis of CCK onto ganglion cells in the intact retina suppresses maintained and light evoked ganglion cell activity (Thier and Bolz, 1985).

CRH expression. CRH immunoreactivity is in wide-field amacrine and displaced amacrine cells of the rat and monkey retina (Marshak, 1989; Yeh and Olschowka, 1989). In rat retina, CRH-containing amacrine and displaced amacrine cells are distributed in all retinal regions with a slightly higher density in superior temporal retina (Yeh and Olschowka, 1989). There appear to be two cell types, based on the distribution of their processes in the IPL. Cell bodies in both the INL and GCL give rise to two cell types: an unistratified cell type that ramifies in lamina 5 of the IPL, and a second bistratified type that primarily ramifies in lamina 5 and with a fine process in lamina 1. There is a greater density of displaced amacrine cell bodies; in the GCL, cell density is about 120 cells/mm² and in the INL, cell density is about 35 cells/mm². In macaque monkey retina, immunoreactivity

is in sparsely occurring displaced amacrine cells with processes in laminae 1, 3, and 5 of the IPL (Marshak, 1989). These cells receive most of their synaptic input from amacrine cells and form conventional synapses onto amacrine and ganglion cells. These cells have a similar appearance and morphology to SRIF immunoreactive displaced amacrine cells. High-affinity CRH binding sites are present in several mammalian retinas, and CRH stimulates adenylate cyclase activity in these retinas, suggesting functional CRH receptors (Olianas and Onali, 1995; Olianas et al., 1993).

Opioid expression. The endogenous opioid enkephalin is expressed by amacrine cells in nonmammalian retinas (Brecha, 1983). However, there is little evidence for the expression of opioid peptides in the adult mammalian retina, except for reports of enkephalin immunoreactive amacrine cells in the guinea pig retina (Altschuler et al., 1982). Consistent with these observations are chromatographic studies indicating the presence of enkephalins in guinea pig retina (Hoffman, 1983). Interestingly, enkephalin immunoreactivity was not detected in the rat retina using the same antibody to detect enkephalin in the guinea pig retina (Altschuler et al., 1982).

There are three endogenous opioid receptors, known as mu, delta, and kappa. Opiate binding sites were first reported in rat retinal homogenates in the mid-1970s (Brecha, 1983), and mu opioid binding sites are distributed homogeneously over the IPL and GCL of the rat and monkey retina (Wamsley et al., 1981). The presence of functional mu opioid receptor (MOR) in rabbit retina is suggested by the increased levels of acetylcholine release evoked by flickering light in the presence of the MOR agonist, DAMGO (Neal et al., 1994). Consistent with autoradiographic localization studies, MOR immunoreactivity is localized to bistratified ganglion cells of the rat retina (Brecha et al., 1995). These ganglion cells are distributed to all retinal regions and ramify extensively in laminae 2/3 and 4 of the IPL. Furthermore, MOR immunoreactive axons and axonal terminals are detected in retinorecipient nuclei, with the highest levels of immunostaining in the accessory optic nuclei and the OPN, and with moderate levels in the LGN and superior colliculus. Immunoreactivity in these nuclei is reduced or eliminated in the case of the accessory optic nuclei following retinal enucleation (Brecha et al., 1995). Furthermore, ultrastructural studies report MOR immunoreactivity on retinal terminals in the accessory optic nuclei (Ding et al., 1995). Together, these findings show that in the rat, bistratified ganglion cells give rise to MOR immunoreactivity in several retinorecipient structures. The failure to detect enkephalin immunoreactivity in the adult rat retina and the prominent MOR immunostaining in the terminals of ganglion cells suggests that endoge-

nous opioids have a presynaptic action on ganglion cell axonal terminals.

Orphan receptor-like 1 is related to opioid receptors and its endogenous ligand orphanin FQ or nociceptin (Mollereau et al., 1994; Nothacker et al., 1996) may also be expressed in the retina (Neal et al., 1997). High-affinity nociceptin binding sites are in the rabbit retina, and nociceptin inhibits acetylcholine release evoked by flickering light.

Peptide function in the retina

Peptides act as slow transmitters whose actions are mediated by multiple intracellular effectors, including cAMP, Ca^{2+} , protein kinases, and phosphatases, to modulate ion channels, ligand-gated channels, transporters, and receptors, as well as to affect nuclear transcription factors (Greengard, 2001). These peptide actions are characterized by long-lasting changes in cellular properties that modulate both transmitter release from axon terminals and neuronal activity. Peptide actions are often characterized as being modulatory, compared to the rapid action of excitatory and inhibitory transmitters at ligand-gated ion channels.

There are experimental findings consistent with peptides acting as slow transmitters in the retina. Several peptides, including NPY, PACAP, SRIF, SP, and VIP, acting via G-protein-coupled receptors, influence adenylate cyclase or phospholipase C activity in retinal homogenates and whole retina. Peptides also have potent modulatory effects on both Ca^{2+} and K^{+} currents in retinal neurons. For example, (1) low concentrations of SRIF partially inhibit Ca^{2+} currents of isolated ON-type bipolar cells from rat and rabbit rod bipolar cells, (2) SRIF enhances a delayed outwardly rectifying K^{+} current in salamander rod and cone photoreceptors, (3) SRIF inhibits the large conductance and Ca^{2+} - and voltage-dependent K^{+} current in rabbit rod bipolar cells, and (4) SRIF partially inhibits a K^{+} -stimulated $[\text{Ca}^{2+}]_i$ increase via an L-type Ca^{2+} channel in axon terminals of rat rod bipolar cells and salamander photoreceptors (Akopian et al., 2000; Johnson et al., 2001; Petrucci et al., 2001). In addition, the action of GABA at GABA_A receptors is modulated by VIP via phosphorylation of GABA_A receptors by protein kinase A in rat rod bipolar, amacrine, and ganglion cells (Feigenspan and Bormann, 1994; Veruki and Yeh, 1992, 1994). Presumably these peptide actions result in the regulation of transmitter release and the excitability of retinal neurons, leading to the modulation of the efficacy of synaptic transmission in the retina.

The concept that peptides act as modulators of retinal circuitry or networks is based on both anatomical and physiological studies. Peptide-containing cells in most cases are wide-field amacrine cells that are characterized by a very low to medium cell density. These cells ramify widely and have overlapping processes that cover the entire retinal surface.

Therefore, they would have a broad influence on a large number of cells and are unlikely to mediate discrete point-to-point information processing. Connectivity studies show that most synaptic input onto peptide-containing amacrine cell processes is from amacrine cells, and these cells in turn terminate mainly on amacrine and ganglion cells. Peptides released from these cells could therefore influence synaptically multiple cells in a local fashion. In addition, a consistent finding for several peptides is a differential distribution of peptide-containing and peptide receptor-bearing processes and cells. These findings suggest that peptides are likely to diffuse from their release sites and act at a distance in a paracrine fashion. Together, these findings suggest that peptides can have a widespread effect on multiple types of retinal neurons.

Functional studies also support the concept that peptides act as modulators of retinal circuitry. In general, the cellular effects of peptides have a slow onset, are long lasting, and occur at multiple locations in the retina. For instance, both SRIF and VIP produce excitatory changes in the range of seconds to minutes in the spontaneous activity and neuronal discharge patterns of ganglion cells (Jensen, 1993; Zalutsky and Miller, 1990a). Moreover, SRIF affects the center-surround balance of all types of ganglion cells. Thus SRIF appears to play a role in light/dark adaptation (Zalutsky and Miller, 1990a). The role of other peptides in visual function is less well understood. However, as their wide-ranging actions are also likely to be too slow to mediate fast, throughput signaling, these peptides will probably act in modulatory processes that occur on longer timescales (Dowling and Ripps, 1977) and participate in adaptive mechanisms that globally affect the state of retinal circuits and networks.

Acknowledgments

I thank Drs. Arlene Hirano and Catia Sternini for their comments and invaluable assistance in preparing this chapter. I also thank Alex Vila for his assistance, including preparing the figures.

Support has been provided by NEI EY 04067 and a VA Career Scientist Award.

23 Inhibition in the Retina

MALCOLM M. SLAUGHTER

AMACRINE CELLS PRODUCE a complex array of inhibition to bipolar cells, ganglion cells, and other amacrine cells. Gamma-aminobutyric acid (GABA) and glycine are the primary inhibitory neurotransmitters, each contained in about 35% of all amacrine cells, with little coexpression. Both provide feedback inhibition to bipolar cells, although GABAergic feedback is more prominent. It is most evident in ON bipolar cells, where the GABA_C receptor is particularly important. This feedback improves spatial and temporal contrast and increases the dynamic range at the synapse. There is lateral inhibition between amacrine cells, notably long-range glycinergic inhibition. Both GABAergic and glycinergic amacrine cells feed forward to inhibit ganglion cells. They produce sustained and transient surround inhibition that shortens the response time and improves the resolution of ganglion cells. Glycinergic synapses are often responsible for transient inhibition. There are also inhibitory GABAergic bipolar cells and both glycinergic and GABAergic interplexiform cells. This chapter reviews the history of inhibitory amino acid neurotransmitters in retina, the properties of the receptors, the synaptic mechanisms, and the retinal circuits.

Background history

Kishida and Naka (1967) were the first to show that GABA and glycine inhibit spike activity of retinal ganglion cells. This was at a time when neuroscientists were just discovering inhibitory amino acid transmitters. Retinal experiments were a spearhead of this research, satisfying the criteria for neurotransmitters, including autoradiographic localization of GABA and glycine within the retina (Ehinger and Falck, 1971), measurements of endogenous amino acid levels, and demonstrating that light caused transmitter release (Ehinger and Lindberg, 1974; Voaden and Starr, 1972).

EFFECTS OF GABA AND GLYCINE INHIBITION It rapidly became apparent that the retina was unusual in the juxtaposition of GABA and glycine inhibition. A central question arose that is still not fully answered: why are two very similar transmitters in the same circuit? Clearly there must be a division of labor. The earliest study suggested that some ganglion cells received GABAergic IPSPs exclusively, and others, glycinergic IPSPs (Miller et al., 1977). The two transmitters regulate different visual processes. GABAergic inhibition is

essential for the formation of directional selectivity in ganglion cells; glycine has key effects on other receptive field properties (Caldwell et al., 1978). Glycine is linked to inhibitory surrounds in X cells, GABA in Y cells (Kirby, 1979). Both control the activity of the only known excitatory amacrine cell, the cholinergic starburst amacrine cell (Massey and Neal, 1979b; Neal and Cunningham, 1995). In an intriguing forerunner of recent research, early field potential studies suggested that GABAergic inhibition produced the sustained to transient transition that is a hallmark of retinal ganglion cells (Mooney, 1978). Hence, there was a phenomenological separation of function, but there was no evidence of principle that guided this division.

Thus, within the first decade of discovery the key elements and enduring puzzles were in place. After that stunning progress, there was a change in focus over the next two decades. This led to discovery of new receptors and inhibitory mechanisms. It also helped resolve some of the apparently contradictory observations that had emerged.

DISTINCT INHIBITORY FUNCTIONS The earliest studies in vertebrate retinal physiology revealed that ganglion cell signals are divided into ON and OFF pathways, or alternatively divided into sustained and transient pathways. The physiological characterization was reinforced by anatomical differences, and the distinctions existed not only in the retina, but also in the lateral geniculate and cortex. Naturally, attention turned to the roles that GABA and glycine play in formation or modulation of these essential pathways.

At one end of the spectrum arose the concept that there is a direct correlation between these pathways and the two transmitters. For example, Ikeda and Sheardown (1983) examined inhibition that occurs in ganglion cells at the offset of an excitatory synaptic stimulus. They found that GABA was responsible for this inhibition in ON-center ganglion cells, and glycine in OFF-center ganglion cells. This was true for both transient and sustained cells. While no other laboratory has reported such a stark delineation, many have found that GABAergic inhibition is more prominent in the ON pathway. Belgium and colleagues (1984) found a different correlation; transient inhibition derived exclusively from glycinergic synapses. Transient glycinergic IPSPs were found in ON, OFF, and ON-OFF ganglion cells. Again, other experimenters found that glycine is preferentially, though perhaps not exclusively, involved in transient inhibition.

TABLE 23.1
Properties of retinal inhibitory receptors

	GABA Receptors*				Glycine Receptors	
	Ionotropic: Increase Cl ⁻ Conductance		Metabotropic: Modulate Voltage-dependent K ⁺ and Ca ²⁺ Channels		Ionotropic: Increase Cl ⁻ Conductance	
Receptor Subtype or Variety	GABA _A Fast activation and desensitization	GABA _C Slow activation and little desensitization	GABA _B Baclofen- sensitive	GABA _B CACA- sensitive	Glycine _{fast} Fast activation and desensitization	Glycine _{slow} Slow activation and little desensitization
Antagonists	Bicuculine SR95531, Picrotoxin	Picrotoxin I4AA, TPMPA, APMPA	CGP35348, CGP55845, Saclofen, Phaclofen		Strychnine	DCKA, Strychnine
Agonists	Muscimol, THIP, I4AA		Baclofen, 3AP, APMPA	CACA	Glycine	Glycine
Modulators	Suppressed by Zn and Ca, Enhanced by PKA	Suppressed by Zn and PKC	Suppressed by Ca	Enhanced by NO, cGMP	Enhanced by PKC, Bimodal effect of Zn	Suppressed by PKC

**Abbreviations:* APMPA: 3-aminopropyl(methyl)phosphonic acid; TPMPA: (1,2,5,6-tetrahydropyridine-4-yl)-methylphosphonic acid; I4AA: imidazole-4-acetic acid; THIP: 4,5,6,7-tetrahydroisoxazolo(5,4-c)pyridin-3-ol; 3AP: 3-aminopropylphosphonic acid; DCKA: 5,7-dichlorokynurenic acid.

While these two extreme models are clearly contradictory, a moderate interpretation is probably correct: GABA is more involved in inhibition of the ON pathway, and glycine is more involved in transient inhibition. A less restricted model has been presented by Frumkes and colleagues (1981) postulating a complex mixture of GABAergic and glycinergic interactions. One commentator noted that this model was so complex it must be right! While the retina is clearly not striving for simplicity, these models still beg the question why the retina uses two transmitter systems with such apparently similar properties when one might suffice. Part of the answer can be found in the receptors, particularly the GABA receptors.

Receptors

During the first decade of discovery, it was recognized that both GABA and glycine increase chloride conductance. The properties of the two receptors were uncannily similar, including not only ion selectivity, but also conductance. That similarity began to unravel in 1980 with the discovery of the metabotropic GABA_B receptor (Bowery et al., 1980). Retinal pharmacology was even more dramatically altered by the discovery of the rho subunit and its association with the GABA_C receptor (Cutting et al., 1991). Both the molecular subunit and the unusual receptor were first detailed in retina, although the link between the subunit and the receptor took a while to establish. Thus, there are at least three distinct types of ionotropic inhibitory amino acid receptor in retina (Table 23.1). This can be seen, for example, in the kinetics

of spontaneous IPSCs in mouse amacrine cells, where there is one type of glycinergic and two types of GABAergic synaptic responses (Frech et al., 2001).

IONOTROPIC GABA RECEPTORS The GABA_C receptor, like the GABA_A receptor, is an ionotropic receptor that is permeable to chloride. But the GABA_C receptor has several unique properties, including higher affinity for GABA, slower activation kinetics, and less desensitization (Feigenspan et al., 1993; Qian and Dowling, 1993) (Table 23.2). In rat bipolar cells, the GABA_C receptor has a main single channel conductance of 7.9 pS, compared to 29.6 for the GABA_A receptor. GABA_C receptors have an EC₅₀ of 4 μM; for GABA_A receptors the EC₅₀ is 27 μM. The mean open time of the GABA_C receptor is 150 ms, about sixfold greater than the GABA_A receptor (Feigenspan and Bormann, 1994a). These characteristics make GABA_C receptors ideal for the modulation of the slow, prolonged graded potentials found in retina. Thus, it is not surprising that the GABA_C receptor plays a particularly prominent role in the inhibitory feedback to the bipolar cell axon terminal (Lukasiewicz et al., 1994).

METABOTROPIC GABA RECEPTORS The GABA_B receptor is a G-protein-linked receptor that modulates voltage-dependent calcium and potassium channels. In some cases the modulation is through a direct action of the G-protein with the channel, in other cases a more complex second-messenger cascade is involved (Shen and Slaughter, 1998). It is likely to function as an autoreceptor in GABAergic

TABLE 23.2
GABA_A and GABA_C receptors

Relative Response Properties	
Activation Rate	GABA _A > GABA _C
Desensitization Rate	GABA _A > GABA _C
Mean Channel Open Time	GABA _C > GABA _A
Single Channel Conductance	GABA _A > GABA _C
Receptor Affinity	GABA _C > GABA _A
Retinal Distribution	GABA _A > GABA _C

TABLE 23.3
Metabotropic GABA receptors

Actions of Two GABA _B Receptors	
Baclofen-Sensitive	CACA-sensitive
Suppress L-type calcium channels in fish ganglion cells and in ~20% of amphibian bipolar cells	Suppress L-type calcium channels in goldfish Mbl bipolar cells
Enhance inward-rectifying potassium channels and L-type calcium channels in amphibian ganglion cells	Suppress L-type calcium channels in amphibian ganglion cells
Suppress N-type calcium channels in amphibian ganglion cells	

amacrine cells (Koulen et al., 1998). It is also an important postsynaptic receptor, suppressing bipolar cell transmitter release (Maguire et al., 1989) and altering the response properties of ganglion cells (Cook et al., 2000; Shen and Slaught-ter, 1998, 1999a; Zhang et al., 1997b).

The GABA_B receptor system in retina exhibits a variety that has not yet been found in the rest of the brain (Table 23.3). In fish retina, baclofen suppresses an L-type calcium channel in ganglion cells (Bindokas and Ishida, 1991). But in goldfish bipolar cells, GABA suppresses an L-type calcium channel through a baclofen-insensitive receptor. This receptor is a metabotropic GABA_B receptor, but its preferred agonist is cis-aminocrotonic acid (CACA) (Heidelberger and Matthews, 1991). These two GABA_B receptors are coex-pressed in amphibian ganglion cells, but have different actions (Zhang et al., 1997b). The baclofen-sensitive GABA_B receptors suppress N-type calcium channels but facilitate L-type calcium channels, whereas the CACA-sensitive recep-tors suppress the L-type channel. Thus, there is a diversity within the GABA_B receptors, which is compounded by a diversity of second-messenger mechanisms and effector targets.

GLYCINE RECEPTORS GABA release can activate metabotropic receptors and two subtypes of ionotropic receptor. Glycine receptors have not exhibited the same diversity. There are fast- and slow-activating ionotropic

glycine receptors that have some analogy with the GABA_A and GABA_C receptors (Han et al., 1997). In ganglion cells, rapid application of glycine produces a fast-rising chloride current that decays to a plateau. Nanomolar strychnine blocks the peak response but not the plateau, consequently leaving a slowly rising response with little desensitization. In contrast, 5,7 dichlorokynurenic acid (DCKA) inhibits this slow current but not the fast current. Thus, glycine produces two currents: one that activates and desensitizes rapidly, and another that activates and desensitizes slowly. Unlike the action of GABA at the fast GABA_A and slow GABA_C recep-tors, glycine is equally potent in eliciting both responses.

Among the major neurotransmitters in retina, only glycine lacks a metabotropic receptor. A possible explana-tion for this deficit is that glycinergic amacrine cells obtain their glycine from uptake instead of synthesis (Pow, 1998). This implies that there are relatively high ambient levels of extracellular glycine in the inner plexiform layer, making high affinity metabotropic glycine receptors impractical.

RECEPTOR VARIETY The molecular and pharmacological evidence for subdivisions within the GABA_A, GABA_B, and GABA_C receptors requires added terminology. For this chapter, we will use convention in referring to GABA_A, GABA_B, and GABA_C receptors as subtypes of the GABA receptor. Within these subtypes, receptors with different properties will be called *varieties*. We have alluded to varieties of the GABA_B receptor. There are also varieties of the GABA_C receptor, based on molecular composition and the action of various receptor antagonists (Gao et al., 2000; Qian et al, 1998; Shen and Slaught-ter, 2001). The GABA rho subunit can form a functional, homomeric receptor. Five rho subunits have been cloned from white perch retina, each with distinctive biophysical properties (Qian et al., 1998). The implications of this molecular diversity are yet to be explored. Even the original, GABA_A receptor comprises several varieties, based on subunit composition and the diverse effect of a series of GABA_A receptor antagonists (Frumkes and Nelson, 1995; Wang et al., 2000). Overall, there are at least two varieties of each of the three subtypes of GABA receptor.

There is a spatial distribution of receptor varieties that implies functional distinctions. The $\alpha 1$ subunit of the GABA_A receptor is expressed mainly in bipolar and hori-zontal cell layers, the $\alpha 2$ in the amacrine and ganglion cell layers, and the $\alpha 4$ in a subset of amacrine cells (Greferath et al., 1993). The GABA_A receptors in the proximal retina are sensitive to benzodiazepine, but those in the distal retina are not (Lin and Yazulla, 1994). There is a separation in glycine receptors as well, with the $\alpha 1$ found mainly in the distal inner plexiform layer (IPL), the $\alpha 2$ in the proximal IPL, and the $\alpha 3$ throughout the IPL (Greferath et al., 1994).

In light of these findings, the colocalization of glycine and GABA in the IPL no longer seems redundant. But then we come full circle with the finding that the rho-1 subunit, which creates such a distinctive response in the GABA_C receptor, can form heteromeric channels with the gamma-2 subunit of the GABA_A receptor or the α 1 or the α 2 subunit of the glycine receptor (Pan et al., 2000). So the molecular analysis has started to again blur the distinction between GABA and glycine receptors. Similarly, there appears to be a synergy between the actions of glycine and GABA in some retinal neurons, so that in combination the two transmitters produce a much larger response than the sum of their individual responses (Li and Yang, 1998).

Pharmacology of inhibitory receptors

THE GLYCINE RECEPTORS The pharmacology of retinal glycine receptors is thought to be comparatively simple. No metabotropic receptor has been identified, and the ionotropic receptor is blocked by strychnine. This contrasts with the differential distribution of alpha subunits across the retinal layers. The only evidence of pharmacological diversity is the work of Han, Zhang, and Slaughter (1997), which indicates that there are some glycine responses that are less sensitive to strychnine and are selectively blocked by DCKA (a potent blocker of the glycine recognition site on the NMDA receptor).

An issue that has lingered in the literature is whether there are glycine-like receptors activated by glycine but with selectivity for related compounds such as serine, alanine, or taurine. Taurine, in particular, has periodically been proposed as a neurotransmitter. But cross-desensitization experiments have provided no support for this hypothesis (Pan and Slaughter, 1995).

THE METABOTROPIC GABA RECEPTORS The GABA_B receptor is linked to a G-protein second-messenger cascade. The retina possesses the baclofen-sensitive GABA_B receptor that is similar to that described throughout the CNS; one that is sensitive to antagonists such as 2-hydroxysaclofen, CGP35348, and CGP55845. This receptor suppresses L-type calcium channels in amphibian bipolar cells (Maguire et al., 1989) and fish ganglion cells (Bindokas and Ishida, 1991), and N-type calcium channels in amphibian ganglion cells (Zhang et al., 1997b).

As mentioned above, there is another GABA_B receptor that is potently activated by CACA. CACA acts on a baclofen-insensitive GABA receptor through a G-protein cascade that may involve a cGMP pathway. In retina, this receptor has only been linked to suppression of L-type voltage-gated calcium channels (Heidelberger and Matthews, 1991; Zhang et al., 1997b). Unfortunately, an antagonist has not yet been found.

IONOTROPIC GABA RECEPTORS The GABA_A and GABA_C receptors have distinct pharmacological properties that permit their separation. The GABA_A receptor can be blocked by bicuculline and SR95531. The GABA_C receptor can be blocked by TPMPA, APMPA, and I4AA (the former seems selective, the other two are also agonists at the GABA_B and GABA_A receptor, respectively). GABA_{A&C} receptors are blocked by picrotoxin (except in rat retina). But TPMPA may not block all GABA_C responses, so the common experimental method of separation is to apply bicuculline to block GABA_A receptors, and then apply picrotoxin to measure the remaining GABA_C receptor response. This may be problematic, because I4AA blocks some GABA_C receptors that are not blocked by picrotoxin (Gao et al., 2000; Shen and Slaughter, 2001). There is also evidence that not all GABA_A receptors have the same sensitivity to bicuculline and to SR95531 (Frumkes et al., 1995; Lin and Yazulla, 1994).

Despite these ambiguities, pharmacological tools can be used to separate the subtypes of GABA receptor. In addition, subtle differences between antagonists suggest that it may be possible to distinguish receptor varieties, although that is not yet achievable. Nevertheless, it is evident that retinal circuits use inhibitory receptor diversity to process specialized components of the visual scene such as motion, edge enhancement, contrast, and gain.

Receptor modulation

Receptor modulation is an enormous field and can be viewed at several levels, from short-term effects such as phosphorylation to longer-term aspects such as protein expression and sorting. With respect to the former, both the glycine and GABA receptors are controlled by a number of mechanisms that have recently been explored. Modulators often alter the kinetics of the receptors, regulating several varieties in concert to produce a net change in the temporal properties of inhibition.

GLYCINE RECEPTOR MODULATION The glycine receptors are modulated by protein kinase A and protein kinase C (Han and Slaughter, 1998). There are fast and slow glycine responses, probably reflecting the responses of two receptor subtypes. The slow response is suppressed by protein kinase A, and the fast response is enhanced by protein kinase C. Thus, both phosphorylation pathways contribute to shifting the balance of the composite glycine response toward a more phasic signal. Because glycine is involved in transient inhibition, protein kinases can regulate this key aspect of glycine function in retina.

Zinc has a concentration-dependent, biphasic effect on the magnitude of the glycine response, but it only

influences the fast glycine response (Han and Wu, 1999). Low doses of zinc enhance this response; high concentrations suppress the fast glycine response. Zinc is a transmitter candidate, suggesting that it is used in retinal circuits to modulate glycine synaptic kinetics. Low concentrations of zinc may be synergistic with protein kinase C, both acting to increase the synaptic weight of the most phasic glycine signals.

GABA RECEPTOR MODULATION The GABA receptor is also modulated by phosphorylation and by zinc. Unlike the fast glycine response, the GABA_A receptor and the GABA_C receptor are only inhibited by zinc (Dong and Werblin, 1996; Li and Yang, 1999). Zinc's IC₅₀ for the GABA_A receptor is about 67 μ M, compared to about 2 μ M for the GABA_C receptor (Kaneda et al., 2000). Thus, low concentrations of zinc that enhance the fast glycine receptor also suppress the slow GABA_C receptor. Zinc can also increase the net kinetics of the GABA response, slowing the activation of the GABA_C receptor while accelerating that of the GABA_A receptor. Thus, low concentrations of zinc enhance the relative contribution of both fast glycinergic and fast GABAergic inhibition.

Protein kinases modulate GABA receptors, akin to the effect on glycine receptors. The GABA_A receptor response is enhanced by protein kinase A, a pathway that can be stimulated by dopamine (Feigenspan and Bormann, 1994b). Protein kinase C suppresses the GABA_C receptor (Feigenspan and Bormann, 1994c). Thus, protein kinase A enhances the fast GABA_A response and reduces the slow glycine response; protein kinase C enhances the fast glycine response but suppresses the slow GABA_C responses. The net effect is that fast inhibition is relatively greater after stimulation of either kinase system.

Internal calcium modulates ionotropic and metabotropic GABA receptors. The GABA_A receptor is suppressed by internal calcium released through ryanodine and IP₃ receptors (Akopian et al., 1998). Elevated calcium activates a calmodulin-dependent phosphatase that directly or indirectly suppresses the GABA_A receptor. The apparent affinity of the baclofen-sensitive GABA_B receptor is reduced by internal calcium release from ryanodine-sensitive stores that then activates calmodulin (Shen and Slaughter, 1999a). It is well known that one important function of GABA is to suppress transmitter release by inhibition of calcium channels (Pan and Lipton, 1995). But in retina there is a reciprocal pathway, whereby elevated internal calcium may abrogate this inhibition.

Anatomy of inhibition

INTERAMACRINE INHIBITION GABA and glycine are inhibitory in most neurons because of their negative chloride

reversal potential (around -60 mV). An exception is the horizontal cell, where both GABA and glycine produce a depolarization (Stockton and Slaughter, 1991), and the bipolar cell dendrite, at least in fish (Saito, 1981). This correlates with the K-Cl cotransporter found in ganglion cells (which extrudes chloride) and the Na-K-Cl cotransporter found in horizontal cells and ON bipolar cell dendrites (which accumulates chloride) (Vardi et al., 2000). Commonly, amacrine cells passively distribute chloride, resulting in silent inhibition, while the chloride reversal potential is more negative than the resting potential in ganglion cells, resulting in IPSPs.

Inhibitory amacrine cells feedback to bipolar cells, feedforward to ganglion cells, and also feed laterally to other amacrine cells. This lateral inhibition is often ignored although it is considerable. Anatomically, glycinergic amacrine cells frequently synapse on other amacrine cells (Pourcho and Owczarzak, 1991), and the majority of all synaptic input to glycinergic amacrine cells comes from other amacrine cells (Zucker and Ehinger, 1993). When examining inhibitory signals to ganglion cells, it is often observed that blocking either GABA or glycine receptors results in more inhibition rather than less (Zhang et al., 1997a). This paradox is due to serial lateral inhibition among amacrine cells (Marc and Liu, 2000). Blocking one of these receptors produces disinhibition of many other inhibitory amacrine cells.

INHIBITION OF GANGLION CELLS Feedforward inhibition is also considerable. All, or almost all, ganglion cells possess both GABA and glycine receptors. But commonly only one or the other set of inhibitory receptors is used (Miller et al., 1977; Protti et al., 1997). Ganglion cells are excited by glutamate input from bipolar cells and inhibited by both glycinergic and GABAergic amacrine cells. The balance favors inhibition. For instance, ON alpha ganglion cells in cat contain about 4400 synapses, 86% of which come from amacrine cells (Freed and Sterling, 1988). Of that amacrine cell input, about a quarter is from amacrine cells that take up glycine. Thus, the apparent glycinergic synapses alone are 1.5 times as numerous as the glutamatergic synapses. However, this may be an overestimate. Zucker and Ehinger (1992) found that only 56% of the synapses made by glycine-containing amacrine cells are onto postsynaptic elements that are glycine receptor immunoreactive. The implication is that these glycinergic amacrine cells also possess other neurotransmitters, which are released at almost half the synapses. If this statistic applied to the ON alpha ganglion cell, then glycinergic synapses would be nearly equivalent in number to the glutamatergic synapses. Nevertheless, when GABAergic synapses are considered as well, inhibitory synapses far outnumber excitatory synapses.

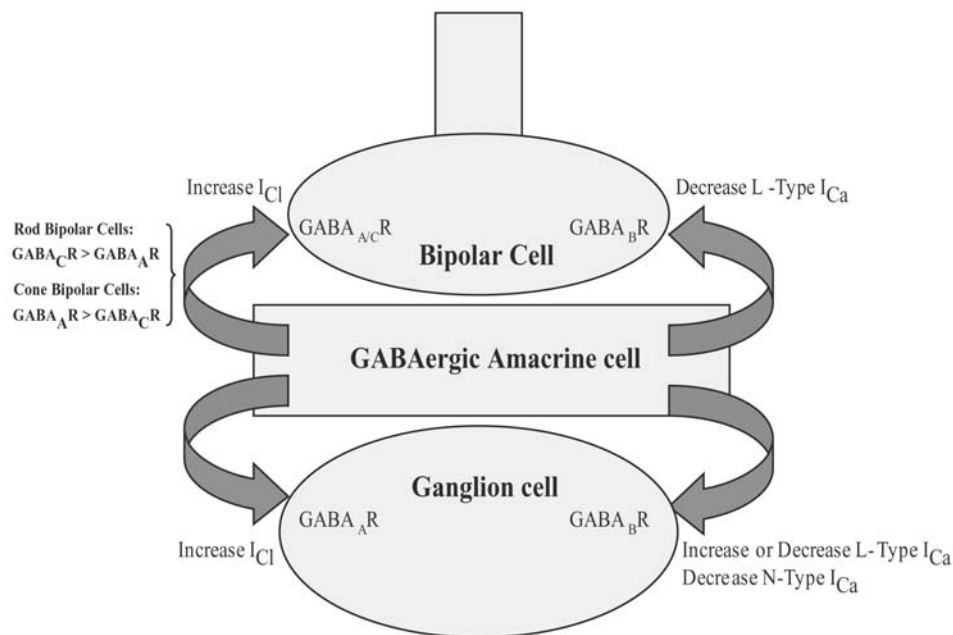

FIGURE 23.1. Actions of feedback and feedforward GABAergic pathways. GABA shunts responses of bipolar cells by activating $GABA_{A/C}$ receptors and also suppresses transmitter release by inhibiting L-type calcium channels. GABA also shunts responses in ganglion cells through $GABA_A$ receptors, while baclofen- and CACA-sensitive $GABA_B$ receptors have complex and sometimes opposing effects on several subtypes of voltage-gated calcium channel.

INHIBITION OF BIPOLAR CELLS GABA receptors are prominently involved in inhibitory feedback to bipolar cells (Fig. 23.1). Glycine seems to have a very limited role in this pathway. All three types of GABA receptors participate in this circuit, although their relative distribution varies markedly. In amphibian retina, Maguire and colleagues (1989) found that only about 20% of bipolar cells were responsive to baclofen and could be distinguished by having axon terminals near the middle of the IPL. The implication is that these are transiently responding bipolar cells and that $GABA_B$ receptors may be involved in motion detection. In the same retina, most bipolar cells express $GABA_C$ receptors (Lukasiewicz et al., 1994). $GABA_C$ receptors in the IPL seem to be localized exclusively at bipolar cell axon terminals. The ratio of $GABA_C$ to $GABA_A$ receptors varies in different types of mammalian bipolar cells, being highest in rod bipolar cells (Euler and Wässle, 1998; McGillem et al., 2000).

Morphology of inhibition

CENTRAL EXCITATION AND PERIPHERAL INHIBITION Whereas bipolar cells have compact dendritic and axonal terminals, the dendritic morphologies of amacrine and ganglion cells are extensive. Both amacrine and ganglion cells receive excitatory input from bipolar cells and inhibitory input from an array of amacrine cells. Consequently, the

excitatory input is compact whereas the inhibitory input sums over a larger receptive field. This disparity can be considerable; the inhibitory field may be 2 to 3 times the diameter of the excitatory field in amphibian ganglion cells (Lukasiewicz and Werblin, 1990). The inhibition is GABAergic and glycinergic; the latter has a slightly larger extent. A similar disparity between excitatory and inhibitory inputs is found in amphibian amacrine cells. Stimulation of the distal retina just above the amacrine cell produced mainly excitation, but stimulation 400 μm to the side produced only an inhibitory glycinergic response (Barnes and Werblin, 1987). Thus, the geometrical disparity between inhibitory and excitatory neurons produces an inhibitory surround response in the inner retina.

EFFECTS OF PERIPHERAL INHIBITION There is sometimes a correspondence between presynaptic input and postsynaptic receptor distribution. In amphibian amacrine cells, excitatory receptors are localized within 200 μm of the soma, and inhibitory receptors extend up to 300 μm (Cook and Werblin, 1994). Interestingly, calcium channels are prominent along the extremities of the dendrites in these wide-field amacrine cells, suggesting that synaptic output occurs near the tips of dendrites. Thus, inhibitory input synapses are located between the site of excitatory input and inhibitory output. This placement almost guarantees that inhibitory input will eliminate synaptic output

from the dendritic tips. This distribution of inhibition would effectively convert the neuron into a narrow receptive field cell.

A similar phenomenon is seen in the marmoset New World monkey, where glycine receptors were quantified based on an antibody to the α -1 subunit. In midget and parasol ganglion cells, the density of glycine receptors was about sixfold greater in distal dendrites as compared to proximal dendrites (Lin et al., 2000). This peripheral inhibition would exaggerate the difference between excitatory and inhibitory receptive fields resulting from the geometries of presynaptic inputs and shrink the ganglion cell's excitatory receptive field.

Inhibitory pathways

GABAergic and Glycinergic Neurons GABA and glycine are both found in amacrine cells, each in approximately 30% to 40% of these neurons (Ball and Brandon, 1986). There is only a small degree of overlap (~5%), probably representing one particular subset of amacrine cell (Yazulla and Yang, 1988). Glycine is found in some interplexiform cells (Marc and Lam, 1981), as is GABA. GABA is also present in some horizontal cells. Comparatively, GABAergic amacrine cells are more involved in feedback to bipolar cells, and glycinergic amacrine cells in interamacrine cell synapses. Overall, GABAergic amacrine cells may be more diverse. In the all-cone lizard retina, 23 different types of amacrine cell were discerned, of which 17 were GABAergic and only 3 were glycinergic. But in macaque amacrine cells, there are four dominant glycinergic types and four GABAergic (Kalloniatis et al., 1996). This section will provide a review of the retinal circuits where functional aspects of inhibitory amino acid receptors have been revealed.

The GABAergic horizontal cell has received much attention over the years, because it is believed to be responsible for the antagonistic surround response: the lateral inhibition of the distal retina (Mangel and Miller, 1987; Vardi and Sterling, 1994). However, this chapter will not discuss this pathway because it is unresolved. Hare and Owen (1996) found no evidence for GABAergic inhibition in formation of the antagonistic surround response in distal retina; Kamermans and colleagues (2001) observed that hemichannels, rather than a chemical synapse, produce this response. Therefore, the discussion of inhibitory circuitry will concentrate on inhibitory neurons of the proximal retina, primarily amacrine cells, with a brief commentary on interplexiform and bipolar cells.

DIRECTIONAL SELECTIVITY The circuit responsible for directional selectivity has received the most attention for the longest duration of any retinal inhibitory pathway. Barlow

and Levick (1965) analyzed the properties of directionally selective (DS) ganglion cells in rabbit retina, concluding that an unidentified asymmetrical inhibitory pathway provided the suppressive null direction response that is the hallmark of this phenomenon. This null inhibition pathway is GABAergic (Ariel and Daw, 1982b; Wyatt and Daw, 1975). The DS ganglion cells receive excitatory input activating nicotinic and NMDA receptors, and the GABAergic cells that mediate null direction inhibition are driven by kainate/AMPA receptors (Kittila and Massey, 1997). Unfortunately, the source of the asymmetrical inhibition is still an enigma.

One of the most perplexing components of the circuit is the cholinergic starburst amacrine cell. These cells form an array of mirror image neurons that contain and release GABA as well as acetylcholine (Brecha et al., 1988; O'Malley and Masland, 1989). They play a key role in encoding directionality, yet acetylcholine receptor blockers do not eliminate directional selectivity (Ariel and Daw, 1982a; Kittila and Massey, 1997). This suggests that their inhibitory action may be important in encoding directionality. Because these are the only neurons in retina that contain acetylcholine, their activity can be reliably monitored by measuring acetylcholine release (Massey and Neal, 1979a). Starburst amacrine cells possess GABA and glycine receptors (Zhou and Fain, 1995), which control acetylcholine release (Massey and Neal, 1979b; Massey and Redburn, 1982). GABA, but not glycine, suppresses basal release. The release of acetylcholine is inhibited by activation of either GABA_A or GABA_C receptors, although GABA_A receptor inhibitors block directional selectivity (Massey et al., 1997). The glycine inhibition involves a feedback loop that is itself suppressed by GABA acting through GABA_B receptors (Neal and Cunningham, 1995). How inhibition of the starburst cells contributes to directional selectivity in ganglion cells is unclear, and there is no evidence for asymmetry of the cholinergic neurons or in their inhibition.

Directional selectivity is reputed to be an intrinsic property of two classes of ganglion cells: the ON-OFF and ON DS cells. But activation of GABA_B receptors by baclofen uncovered directional selectivity in non-DS ganglion cells in amphibian retina (Pan and Slaughter, 1991). The tentative conclusion is that DS is a distributed property in retinal ganglion cells, but DS synaptic inputs have a greater weighting factor in DS ganglion cells. In non-DS ganglion cells, the directional signals are smaller and obscured by other inputs. Presumably, baclofen suppresses these other inputs, thereby unmasking directional signals.

INHIBITORY FEEDBACK TO BIPOLAR CELLS The output of bipolar cells is regulated by reciprocal synapses from amacrine cells. This is true of the rod and cone systems, and much of this feedback is GABAergic. For example, in cat rod

FIGURE 23.3. *A*, The channel mechanisms regulated by baclofen-sensitive GABA_B receptors in the formation of an intensity signal discriminator in ganglion cells. *B*, During weak light stimulation, GABA_B receptors open a small inward-rectifying potassium conductance that shunts small EPSPs, while the calcium-activated

potassium current is not significantly activated. *C*, With stronger light stimulation, GABA_B receptors suppress a larger inward-rectifying calcium-dependent potassium conductance allowing a potentiation of larger EPSPs, while the shunting inward rectifier current is not significant.

GABA_B receptor feedback to bipolar cells. Bipolar cell transmitter release is dependent on voltage-gated L-type calcium channels. In amphibian retina, about 20% of bipolar cells possess baclofen-sensitive GABA_B receptors that suppress these calcium channels and thus reduce transmitter release (Maguire et al., 1989). A proposed function of this selective inhibitory feedback is to create transient signals associated with motion detection (Werblin et al., 1988). The bipolar cells that are sensitive to baclofen are near the midline of the IPL, the presumed site where transient signals are formed. The proposed circuit includes narrow-field, sustained GABAergic amacrine cells that feedback to a subset of bipolar cells. The feedback makes that subset of bipolar cells release transmitter transiently (see Fig. 23.2).

It is curious that bipolar cells (the Mb1 cells) in goldfish retina contain baclofen-insensitive GABA_B receptors (Heidelberger and Matthews, 1991), although there are baclofen-sensitive GABA_B receptors in fish ganglion cells (Bindokas and Ishida, 1991). If there is commonality between these species, it would imply that some bipolar cells possess CACA-sensitive and others baclofen-sensitive GABA_B receptors. But CACA-sensitive bipolar cells have not been reported in any other species of retina.

A GABAERGIC BIPOLAR CELL The general flowchart of the retina includes excitation produced by glutamate-releasing photoreceptors and bipolar cells, modulated by inhibitory horizontal cells and amacrine cells. Yet it appears that a significant subset of bipolar cells may be inhibitory. For a while it was thought that many bipolar cells released glycine, but recent evidence suggests that these cells are

“contaminated” with glycine that diffuses into the bipolar cells from gap junction connections with glycinergic amacrine cells (Vaney et al., 1998). However, there is substantial evidence that about 10% of bipolar cells are truly inhibitory. These neurons have all the hallmarks, including being GAT immunopositive and taking up GABA (Yang, 1997; Yang and Wang, 1999). Furthermore, stimulation of bipolar cells produces an inhibitory response in ganglion cells when the excitatory (glutamatergic) bipolar cells are blocked. GABA-immunopositive bipolar cells are also found in human retina (Van Haesendonck and Missotten, 1993). The function of these inhibitory bipolar cells has yet to be determined.

GABA_B RECEPTOR CREATES A NEURAL DISCRIMINATOR

One of the functions of a sensory system is to discriminate between signals that are relayed to the brain and others that are suppressed. One obvious criterion is signal strength. The GABA_B receptor regulates two conductances in ganglion cells that combine to form an intensity discriminator (Fig. 23.3) (Zhang et al., 1998). The consequence is that small excitatory inputs to ganglion cells are suppressed, and larger EPSPs are enhanced. This phenomenon arises from the confluence of GABA_B receptor activation of a small potassium conductance (probably an inward rectifier) and the suppression of a high-voltage activated calcium-dependent potassium current (an outward rectifier). Thus, small EPSPs are thwarted by activation of the inward rectifying potassium conductance. Larger EPSPs normally activate a calcium-dependent potassium conductance, which is inhibitory. But the GABA_B receptor suppresses that calcium

FIGURE 23.4. Regulation of IPL surround inhibition. Transient glycinergic surround inhibition is reduced by GABAergic inhibition in dark adapted retina, becoming disinhibited and more prominent during light adaptation. Similarly, sustained GABAergic inhibition is suppressed during light adaptation.

current and the associated potassium conductance. Thus, the EPSP is enhanced. This system does not require extensive circuitry and the level of GABA_B receptor activation can regulate discrimination.

GLYCINE IN THE ON PATHWAY One of the best described and interesting inhibitory circuits is that of the AII glycinergic amacrine cell. The mammalian rod pathway uses the ON bipolar cell, predominantly or exclusively, yet there are both ON and OFF scotopic responses in ganglion cells. The ON responses are explained by the rod ON bipolar cell indirect excitation of ganglion cells, but the OFF excitation is more circuitous. The ON bipolar cell synapses with the AII amacrine cells, which in turn make glycinergic synapses with cone OFF bipolar cells. When the light is ON, the AII cell is depolarized and inhibits the OFF bipolar cell. When the light is OFF, the OFF cone bipolar cell is disinhibited, thereby producing the OFF response in ganglion cells. In sheer numbers, a majority of glycine receptors seem committed to this function. In macaque retina, 70% of the glycine receptors are found in strata 1 and 2 (based on an antibody to receptor $\alpha 1$ subunit), and most are associated with the AII amacrine cell (Grunert and Wässle, 1996).

The AII amacrine cell is inhibited by GABAergic amacrine cells, creating an OFF inhibitory surround (Bloomfield and Xin, 2000). This inhibition is another example of the cross-talk between these two inhibitory systems. In this case, it is generated by an ON amacrine cell, and this surround inhibition is blocked by tetrodotoxin, suggesting that it results from distant lateral circuits.

Besides this rod circuit, there is another glycinergic pathway from the ON to the OFF pathway. When the ON

pathway is blocked, responses in OFF ganglion cells are enhanced. This enhancement is blocked by strychnine, implying that the ON pathway inhibits the OFF pathway (Wässle et al., 1986). But there must be one other member of the circuit, because the ON system is quiescent when glycine is suppressing the OFF system. Presumably, a sign-inverting synapse is interposed, probably another example of serial amacrine cell synapses.

Inhibitory surround

As mentioned, the disparity in the spatial extent of excitatory and inhibitory inputs to ganglion cells contributes to formation of inhibitory surrounds. In amphibian retina, inhibitory IPL surround responses can be parsed into GABAergic sustained surrounds (evoked by a stationary windmill stimulus) and glycinergic transient surrounds (produced by a rotating windmill stimulus). In dark-adapted retina, the sustained surround is dominant, and the transient surround is weak or absent (Fig. 23.4). But with brief light adaptation, the sustained inhibition declines while the transient inhibition increases. The decline in the sustained surround is mediated by dopamine; the increase in the transient surround appears to be due to removal of GABAergic inhibition, mediated by GABA_C receptors (Cook et al., 2000; Cook and McReynolds, 1998). Thus, surround responses are a product of amacrine cell circuits and are modulated by interamacrine synapses.

A comparable process is seen in the surround responses of rabbit OFF ganglion cells. The ON surround response is absent in dark-adapted retina, but can be restored when glycine receptors are blocked (Jensen, 1991). This seems to be the converse of the amphibian circuitry, but once

again exemplifies the importance of cross-talk between inhibitory amacrine cells. The final product of these interamacrine cell circuits may be inhibition of ganglion cells or bipolar cells.

In *Xenopus*, the surround responses are eliminated in both ON and OFF bipolar cells when glycine (but not GABA) is applied to the retina (Stone and Schutte, 1991). But it is not clear whether this is a direct effect on bipolar cells, or is it more likely to be secondary to interamacrine effects?

Roska et al. (2000) examined three inhibitory surround mechanisms that sharpen the ganglion cell response in both time and space. In distal retina, an inhibitory surround is attributed to horizontal cells. Another is mediated by GABAergic amacrine cell feedback to bipolar cells, through GABA_C receptors. This feedback produces a time-delayed, spatial contraction of the image. The third level of surround is produced by feedforward inhibition of ganglion cells, through GABA_A receptors. This sharpens the response, both spatially and temporally. These three surround mechanisms combine to perform the classic role of surround inhibition in a neural network: correcting the signal scattering that occurs in the retinal layers.

GLYCINERGIC AND GABAERGIC INTERPLEXIFORM CELLS

While the best studied of the interplexiform cells contains dopamine, interplexiform cells in various species contain either GABA or glycine (Eldred and Cheung, 1989; Smiley and Basinger, 1988; Yang and Yazulla, 1988). Both of these inhibitory amino acids depolarize horizontal cells because of the unusually high chloride concentrations found in these neurons. The GABA effect may not relate to the function of interplexiform cells because horizontal cells release GABA. But the only source of glycine in the outer retina is the terminals of the interplexiform cell. Glycinergic IPSPs are also observed at bipolar cell dendrites, where they appear to be driven by OFF bipolar cell stimulation of interplexiform cells in salamander retina (Maple and Wu, 1998). Unfortunately, little is known about the function of interplexiform cells that contain inhibitory amino acids. It is not even clear if they are part of a centrifugal or centripetal pathway, because glycinergic interplexiform cells get input from horizontal cells and send output to GABAergic amacrine cells in the goldfish retina (Yazulla and Studholme, 1991).

GABA AND THE DOPAMINERGIC SYSTEM There is a mutual negative interaction between GABAergic and dopaminergic circuits. GABAergic neurons suppress dopamine release; glycinergic neurons do not. This is mediated primarily by GABA_A receptors, with a smaller contribution from GABA_B receptors (Boatright et al., 1994). The distinctions are even more eclectic, for $\alpha 3$ -containing GABA_A receptors are distributed throughout the dopaminergic amacrine cell dendritic tree, but receptors containing $\alpha 1$ GABA subunits are

only in the larger dendrites (Gustincich et al., 1999). Isolated dopaminergic neurons show bursting activity that is inhibited by GABA (Gustincich et al., 1997), suggesting that dopamine release is stimulated by disinhibition. In contrast, dopamine suppresses GABA_C receptors in both bipolar cells and horizontal cells, acting through cAMP (Dong and Werblin, 1994; Wellis and Werblin, 1995). In bipolar cells, where GABA_C receptors play a notable role in regulating transmitter release, dopamine can facilitate bipolar input to the inner retina (Matsui et al., 2001).

Summary

Inhibition in the IPL possesses a richness that is bestowed in part by circuitry, but more by receptor diversity. Recent studies have identified new inhibitory amino acid receptors and linked them to specific aspects of retinal function. Perhaps even more exciting is the inchoate evidence that receptor diversity is more extensive and this portends further specialization in encoding of visual information.

24 Anatomy, Circuitry, and Physiology of Vertebrate Horizontal Cells

IDO PERLMAN, HELGA KOLB, AND RALPH NELSON

S-potentials: the first intracellularly recorded photoresponses in the vertebrate retina

S-potentials were the first light-evoked electrical responses recorded with intracellular microelectrodes from nerve cells in the vertebrate retina (Svaetichin, 1953). As shown in Figure 24.1, S-potentials are negative-going changes in membrane potential that last for as long as the light stimulus is present. The graded character of the S-potential is evident in Figure 24.1A. The brighter the stimulus, the larger the amplitude of the S-potential until a saturation level is reached. In Figure 24.1B, the duration of a light stimulus of fixed intensity is altered to examine the effects of this parameter on the S-potential. For long stimuli, the S-potential changes in duration but the amplitude remains constant (the two leftmost responses in Fig. 24.1B). Further reduction in the stimulus duration causes a decrease in amplitude (Fig. 24.1B). This illustrates the temporal summation of the S-potential, following the psychophysical Bloch's law (Roufs, 1972). Up to a certain stimulus duration, the amplitude is directly related to the quantal *content* of the stimulus (quantal flux \times duration); while for stimuli of longer duration, the amplitude is related to the quantal *flux*. It is likely that S-potentials were named in honor of their discoverer, Gunnar Svaetichin, although S-potentials have come to mean slow potentials.

S-potentials evoked puzzlement among neurophysiologists of the late 1950s when they were first described. At that time, neurons were thought only to be depolarized (inside becoming more positive relative to outside) by excitatory synaptic inputs. If the depolarization was of sufficient amplitude, action potentials, or nerve spikes, were generated to transfer signals down the length of the axon. S-potentials, however, had neither light-induced depolarizations nor nerve impulses.

At first, the cell type of origin of S-potentials was not really known other than that they were recorded somewhere in the outer retina. In fact, initially S-potentials were thought to arise from cones, as indicated by the title of the 1953 article by Gunnar Svaetichin ("The cone action potential"). However, later intracellular marking techniques, in which dyes were injected from electrode tips into the cytoplasm of

the recorded neuron, revealed horizontal cells to be the source of the S-potentials (Kaneko, 1970; Werblin and Dowling, 1969). Since first described in fish retinas, S-potentials have been recorded from retinal horizontal cells in all vertebrate classes, including cold-blooded vertebrates (Byzov and Trifonov, 1968; Fuortes and Simon, 1974; Itzhaki and Perlman, 1984; Naka, 1976; Naka and Rushton, 1966, 1967; Normann and Perlman, 1979; Norton et al., 1968; Werblin and Dowling, 1969), mammals (Bloomfield and Miller, 1982; Dacheux and Raviola, 1982; Nelson, 1977; Nelson et al., 1975; Niemeyer and Gouras, 1973; Steinberg, 1969a, 1969b), and primates (Dacey et al., 1996; Dacheux and Raviola, 1990; Verweije et al., 1999). Horizontal cells have now been studied by numerous investigators using anatomical, biochemical, pharmacological, and electrophysiological techniques. In this chapter, we shall try to summarize our current knowledge of horizontal cells in the vertebrate retina.

Morphology and circuitry of horizontal cells

Horizontal cells are second-order neurons interconnecting photoreceptors laterally across the plane of the outer plexiform layer of the retina. These cell types were first described as huge bricklike structures occupying much of the inner nuclear layer in the fish retina (Yamada and Ishikawa, 1965). Early interpretations assumed these cells to be glial cells, mainly because they gave rise to hyperpolarizing slow S-potential responses rather than true depolarizing spikes like "real" neurons. Now we know horizontal cells to be true neurons that have synapses and exhibit most of the ultrastructural characteristics of neurons. Through Golgi staining, intracellular marking, and immunostaining techniques we have learned of the various morphologies horizontal cells can adopt in the retinas of different vertebrate species (Fig. 24.2) (Boycott and Dowling, 1969; Boycott et al., 1978; Cajal, 1892; Gallego, 1986; Kolb, 1970; Leeper, 1978a, 1978b; Peichl et al., 1998; Polyak, 1941; Sandmann et al., 1996a, 1996b; Stell and Lightfoot, 1975; Wässle and Riemann, 1978).

There are two morphological types of horizontal cell in the majority of vertebrate retinas, B-types with axons and

FIGURE 24.1. The S-potential of the fish retina. Light stimuli of fixed intensity but different durations (*A*) and light stimuli of fixed duration but different intensities (*B*) were used to elicit these potentials. Lower traces in *A* and *B* record light-stimulus duration and provide 100-msec tick-marks (from Svaetichin, 1953).

A-types that are axonless (see Fig. 24.2). In nonmammalian species, horizontal cells come in further axonless subtypes with color-specific cone connections (Fig. 24.2, axonless). Figure 24.2 shows the morphologies of these different types of horizontal cells in the various species indicated. Also shown are the spectral types of cone (red, blue, and green dots) that connect with the horizontal cells. Rod-dominated nonmammalian retinas like those of fish also have a horizontal cell type devoted only to the rods (not shown); rod-dominated mammalian retinas have adapted the axonal terminal portion of the B-type cell to connect purely with rods (Fig. 24.2, gray shaded areas over the axon terminal).

B-Type horizontal cells are concerned solely with light intensity changes and shaping adaptational and spatial responses of vertical pathway neurons. They are the luminosity type horizontal cells, which will be discussed later. B-Type cells can often be identified with antibodies against calcium-binding proteins (Cuenca et al., 2000; Wässle and Boycott, 1991; Wässle et al., 1989) and GABA neurotransmitters (Marc, 1999; Marc et al., 1978). In turtle retina, acetylcholine has been localized to H1-type horizontal cell dendrites, where they invaginate the cone pedicles (Cuenca et al., 2000). The dendrites of B-type horizontal cells in mammalian retinas are bushy and contact all cones in their dendritic field; while their axon terminals collect from large numbers of rods at some distance from the cone-connecting dendritic field. The length and thinness of the axon is believed to electrically isolate one portion of the cell from the other, thereby separating a cone photoreceptor-involved compartment of the cell from a rod photoreceptor-involved compartment (Nelson et al., 1975). In species where there are few rods (Fig. 24.2, turtle) the B-type cell's axon terminal has sparse contacts with red cones and the few rods present in this retina (Leeper, 1978a, 1978b).

A-Type horizontal cells in mammals are pure coneconnecting (most species have only green and blue cones). They

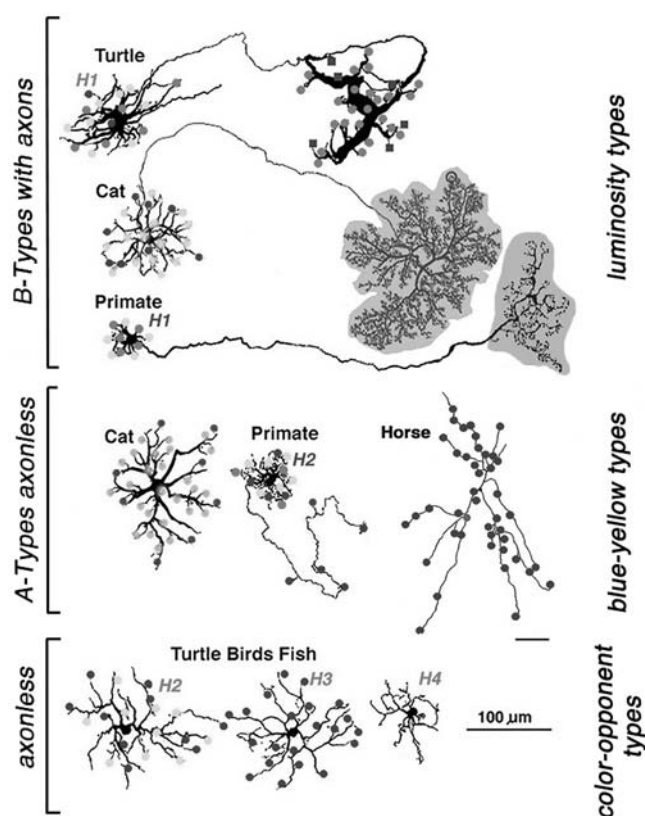

FIGURE 24.2. The morphologies of different types of horizontal cells and their known connectivities with rod and cone photoreceptors. The cells are drawn from Golgi-stained or Neurobiotin-filled retinal staining techniques and viewed in flat whole-mounted preparations. B-type cells with axons and axonless cell types exist in most vertebrate retinas. The physiological type that has been proved associated with the morphological type is indicated to the right of the figure; i.e., luminosity, blue-yellow, and color-opponent types. Red dots, red cones; green dots, green cones; blue dots, blue cones; black squares; or shaded gray areas represent rod inputs. (Horse image from Sandmann et al., 1996a.) (See color plate 9.)

have no connections with rod photoreceptors at all. Even in the case of the H2-type cell of the trichromatic primate retina, where one or more dendrites are elongated and axonlike, their connections are with cones and interestingly enough with blue cones. This may be a general theme for mammalian axonless horizontal cells that is only now being realized. In certain big cats (not yet confirmed in domestic cat), the elongated dendritic tips of A-type cells contact blue cones, and the dendrites closer to the cell body are in contact with both green cones and blue cones (Ahnelt et al., 2000). In horses the A-type cell is apparently only connected to blue cones (see Fig. 24.2) (Peichl et al., 1998; Sandmann et al., 1996a).

In turtles, birds, and fish, species with excellent color vision, type H2 and type H3 horizontal cells are large, stellate cells, lacking axons, and are concerned solely with cone pathways (Fig. 24.2, axonless, color-opponent types). Thus,

FIGURE 24.3. *A*, Electronmicroscopy of cat outer plexiform layer (OPL) shows an A-type horizontal cell's dendritic terminal entering an overlying cone pedicle to form a lateral element (le) at a ribbon triad. *B*, Light-adapted fish retina exhibits spinules (spin) on horizontal cell lateral elements in cone pedicles at synaptic ribbon (sr) synapses. (From DeJuan and Garcia, 2001.) *C*, High-magnification electronmicrograph of a gap junction between two A-type horizontal cell dendrites in the cat retina. *D*, Electronmi-

crograph shows the location of C \times 26 as revealed by immunocytochemistry (*asterisks*) in the hemi-gap junction (*arrow*) of the horizontal cell lateral element in the turtle retina. *E*, Electronmicrograph shows the location of C \times 26, as revealed by immunocytochemistry, in the full connexon extent of a gap junction between two H1 axon terminals (AT) in the turtle retina. (*D* and *E* from Janssen-Bienhold et al., 2001.)

in turtle (pentachromats) and fish (trichromats or tetrachromats), H2 horizontal cells connect to green and blue cones and H3 to blue cones (Fig. 24.2) (Fuortes and Simon, 1974; Leeper, 1978a, 1978b; Lipetz, 1978; Miller et al., 1973; Stell and Lightfoot, 1975). The C-type horizontal cells of the turtle can be labeled with antibodies to nitric oxide synthase and calcium-binding proteins (Cuenca et al., 2000), suggesting a role for nitric oxide in their functioning.

Horizontal cells always interact with photoreceptor terminals at what are known as lateral elements at presynaptic ribbons (Fig. 24.3*A*, le, *arrow*). In fish retinas, the horizontal cell connections with cones at the lateral elements are characterized by minute projections called *spinules* (Fig. 24.3*B*). Spinules are dynamic and change shape with the level of illumination. During background illumination, the spinules are stimulated to form, while darkness causes contraction

(Raynauld et al., 1979; Weiler and Wagner, 1984). These spinules are also under an endogenous circadian control but need centrifugal control from the brain via FMR-amide-like and gonadotropin-releasing hormone (GnRH)-like hormone-releasing hormones (Munz et al., 1982; Stell et al., 1984) acting on the dopaminergic interplexiform cell system in the retina (DeJuan and Garcia, 2001; Zucker and Dowling, 1987).

Retinal horizontal cells in all species are connected to their homologous neighbors by areas of gap junctions between their dendrites, their axon terminals, and occasionally between their dendrites and cell bodies. These areas of gap junction can be extremely large, appearing as plaques of electrical junction (Fig. 24.3C). First described in fish retinas by Yamada and Ishikawa (1965), gap junctions were considered “fused membrane structures” specialized for electrical transmission of stimuli. Procion yellow dye diffusion between morphologically similar horizontal cells was noted by Kaneko (1971) and indicated that the electrical junctions could pass small molecules freely through the so-called S-space of horizontal cells (Naka and Rushton, 1967).

Gap junctions are formed at closely applied plasma membranes (2 to 4 nm gap) of the two horizontal cell structures (Fig. 24.3C). Each half of the cell supplies connexons or hemichannels to complete the gap junction channel. These channels can consist of homomeric or heteromeric connexons, thus allowing a huge variety of gap junctions with slightly different properties to exist between various neurons of the nervous system. Each connexon channel contains six connexins (Cx) surrounding the channel pore. In fish and turtle retinas Cx43 and Cx26 (Fig. 24.3E) have been demonstrated to comprise the horizontal cell gap junction connexons (Janssen-Bienhold et al., 2001; McMahon et al., 1989). Not only dye molecules, but also ion and cytoplasmic molecules of small size can pass through the connexon pores of the gap junction, so changing horizontal cell activities and ionic properties. These ionic conductances are modulated by various agents, such as dopamine, nitric oxide, and retinoic acid. We shall deal with this aspect of horizontal cells in later sections of this chapter.

Physiological types of horizontal cell: luminosity and chromaticity

The vertebrate retina contains a mosaic of rod and cone photoreceptors that serve for dark- and light-adapted vision, respectively. Multiple cone types with visual pigments tuned to different regions of the visible spectrum provide vertebrates with the opportunity to discriminate colors. Most mammals are dichromats (having two different cone types); however, Old World monkeys, humans, and many cold-blooded species are trichromats (three different cone types) or even tetrachromats (four different cone types). In the

FIGURE 24.4. Photoresponses that were recorded from luminosity-type horizontal cells from the toad (Normann and Pochobradsky, 1976), rabbit (Bloomfield and Miller, 1982), and monkey (Dacheux and Raviola, 1990) retinas. In each case, photoresponses were elicited by light stimuli of different intensities.

retinas of birds, fish, and reptiles, a class of cones that are sensitive to ultraviolet light can also be found (Ammermüller et al., 1998; Goldsmith, 1980; Hughes et al., 1998) in addition to the red-, green-, and blue-sensitive cones. Because rods and cones of different spectral types are directly connected to horizontal cells, it is of interest to explore how horizontal cells integrate and process this richness of spectral information.

Two physiological types of horizontal cell are known to exist: luminosity and chromaticity. These cell types can be identified by their photoresponses to chromatic light stimuli. The luminosity (L-type) horizontal cells always respond with hyperpolarization to light stimuli of any wavelength within the visible range of the spectrum. The chromaticity (C-type) horizontal cells respond with different polarity to light stimuli of different wavelengths (Svaetichin and MacNichol, 1958).

L-type horizontal cells are found in every retina that has been studied, from cold-blooded vertebrates to mammals and primates. Figure 24.4 shows the photoresponses of luminosity-type horizontal cells from the toad (A), rabbit (B), and monkey (C) retinas. These cells respond with graded hyperpolarization to light stimuli of any wavelength. The amplitude and duration of the photoresponse depends on the intensity and duration of the light stimulus. In some species, two classes of L-type horizontal cells can be identified according to their anatomical structure and physiological properties. In the turtle retina, the L1 and L2 types are similar in their spectral sensitivity but differ in receptive field

FIGURE 24.5. Color opponency of S-unit in the fish retina. Responses were recorded as a function of wavelength covering the entire visible spectrum using light stimuli of different wavelength but similar quantal content. The responses elicited by light stimuli of wavelength close to the transition from hyperpolarizing to depolarizing pattern (denoted in the upper part of the figure by +4 to -4) are shown in faster time scale (Svaetichin and MacNichol, 1958).

size and in the kinetics of their photoresponses to red and green light (Perlman & Normann, 1979; Simon, 1973). Anatomically, these two L-type horizontal cells are, respectively, the soma and axon terminal of the H1 horizontal cell (see Fig. 24.2). In the rabbit retina, type A and B luminosity horizontal cells differ in morphology and in their major excitatory input but respond only with hyperpolarizations to light stimuli (Bloomfield & Miller, 1982; Dacheux & Raviola, 1982).

In 1958, Svaetichin and MacNichol first reported on wavelength-dependency of the S-potentials (Fig. 24.5). As shown in the figure, the photoresponses of this S-unit reverses in polarity at a wavelength of about 560 nm. The photoresponse to light stimuli of longer wavelength are depolarizing; stimuli of shorter wavelengths elicit hyperpolarizing responses. These color opponent S-units are called chromaticity, or C-type horizontal cells. C-type horizontal cells have been extensively studied in turtle and fish retinas (Ammermüller and Kolb, 1995, 1996; Asi and Perlman, 1998; Fuortes and Simon, 1974; Kamermans and Spekreijse, 1995; Kolb and Lipetz, 1991; Naka and Rushton, 1966; Saito et al., 1974; Spekreijse and Norton, 1970; Twig et al., 2001, 2002; Yazulla, 1976). C-type horizontal cells are

identified by the number of wavelengths at which response polarity reverses:

- no reversal—monophasic cells
- one reversal—biphasic cells
- two reversals—triphasic cells

The wavelength at which response polarity reverses is called the null wavelength. In fish retinas, two types of chromaticity horizontal cells have been described: biphasic and triphasic (Gottesman and Burkhardt, 1987; Kamermans and Spekreijse, 1995). In the bowfin retina, the null wavelength for the biphasic cells is around 640 nm; and for the triphasic cells, the null wavelengths are one in the region of 500 to 530 nm and the other in 650 to 670 nm (Gottesman and Burkhardt, 1987). The biphasic and triphasic C-type horizontal cells of the fish retina are identified morphologically as H2 and H3 types, respectively (see Fig. 24.2).

In the turtle retina, two classes of biphasic C-type horizontal cells have been identified (Asi and Perlman, 1998; Fuortes and Simon, 1974; Twig et al., 2002). Typical photoresponses of L-type and C-type horizontal cells in the turtle *Mauremys caspica* to light stimuli of different wavelength and intensity are shown in Figure 24.6. For each wavelength, a series of photoresponses to different intensities is shown. The L-type horizontal cell (Fig. 24.6, first row) responds to all stimuli with graded hyperpolarizations regardless of wavelength. The red/green C-type horizontal cell (Fig. 24.6, second row) responds with graded depolarizations to red light stimuli and with graded hyperpolarizations to yellow and blue stimuli. The yellow/blue horizontal cell (Fig. 24.6, third row) responds with depolarizations to red and yellow light stimuli and with hyperpolarizations to blue light stimuli.

To define the spectral properties of the horizontal cells, monochromatic light stimuli of dim intensities are used to elicit small amplitude (<1 mV) photoresponses. These photoresponses are within the linear range of the cells and can be used to calculate light sensitivities. The relationship between light sensitivity and wavelength is the action spectrum of the cell and describes its spectral properties. Figure 24.7 shows the action spectra of 8 L-types, 7 red/green types, and 6 yellow/blue types of horizontal cell (A, B, and C, respectively) from the turtle *Mauremys caspica*. These spectra clearly demonstrate that the L-type horizontal cells are most sensitive to long-wavelength stimuli, as expected since their major excitatory input is from red cones (Asi and Perlman, 1998; Fuortes and Simon, 1974). These cells receive additional excitatory input from green cones and to a lesser extent from blue cones (Asi and Perlman, 1998). The red/green C-type horizontal cells are characterized by reversal of response polarity around 600 nm (Fig. 24.7B). These cells receive excitatory input from green and blue cones and inhibitory input from red cones (Asi and Perlman,

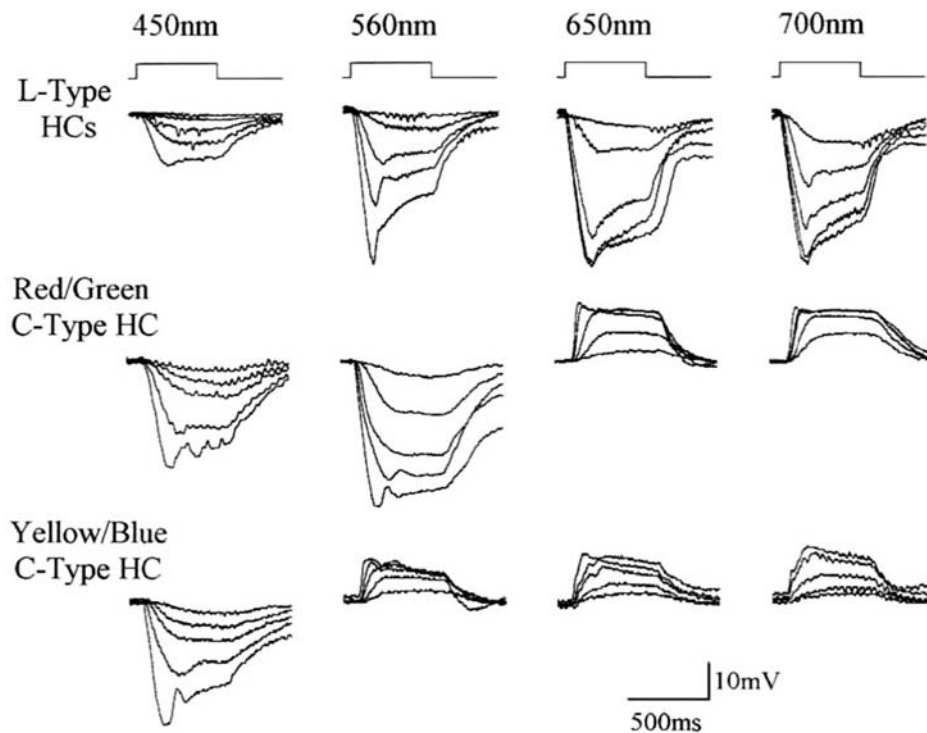

FIGURE 24.6. Wavelength dependency of the photoresponses from an L-type, a red/green C-type, and a yellow/blue C-type horizontal cells in the retina of the turtle *Mauremys caspica*. For each wavelength, several intensities were used.

1998; Fuortes and Simon, 1974). The yellow/blue C-type horizontal cells receive inhibitory inputs from green and red cones and excitatory input from blue cones (Asi and Perlman, 1998; Fuortes and Simon, 1974) and interestingly, also from UV cones (Ammermüller et al., 1998). Consequently, their photoresponses reverse in polarity around 540 nm (Fig. 24.7C).

Given the horizontal cell diversity from lower vertebrates, where the axonless types are chromatically opponent, it is surprising that in mammalian retinas, where the axonless horizontal cell type is also present, only L-type horizontal cell responses can be recorded (Nelson, 1985; Niemeyer and Gouras, 1973; Steinberg, 1969a, 1969b). For example, both cat A- and B-types are luminosity (see Fig. 24.2). Although dominated by red-cone input, low-level synergistic input from blue cones can be seen when tested using specific spectral stimulating and adapting conditions (Nelson, 1985).

In primate retina, horizontal cells also only occur as luminosity types (Dacey et al., 1996; Dacheux and Raviola, 1990). Some of these cells receive synergistic signals from long- and medium-wavelength cones (red and green cones), and others receive synergistic input from all three spectral types of cones; long- medium-, and short-wavelength (red, green, and blue cones) as shown in Figure 24.8. Anatomically H1-type horizontal cells tend to avoid the pedicles of blue cones (Fig. 24.8, *left*) (Ahnelt and Kolb, 1994a, 1994b; Dacey et al., 1996) and are therefore not responsive to blue

light stimuli (*E* in Fig. 24.8, *left*). On the other hand, large numbers of dendrites of H2-type horizontal cells make synaptic contacts with blue cone pedicles (outlined clusters, Fig. 24.8, *right*) (Ahnelt and Kolb, 1994a, 1994b; Dacey et al., 1996). The H2 cell is indeed very sensitive to the blue end of the spectrum (*E* in Fig. 24.8, *right*). Yet the responses of both horizontal cell types are only hyperpolarizing to the three wavelengths (Dacey et al., 1996). Thus, it appears that subsets of mammalian and primate L-type horizontal cells are devoted primarily to processing of either blue signals or red and green signals, but spectral opponency is not part of the processing regime (see Figs. 24.5, 24.6, and 24.7).

Rod and cone contributions to horizontal cells

ROD-CONE MIXING Steinberg (1969a, 1969b) was the first to record S-potentials in a mammalian retina. He made intracellular recordings from horizontal cells in the cat retina and saw the typical graded hyperpolarizing responses that depended on the intensity of the light stimulus. However, Steinberg's S-potential recordings revealed separate rod and cone contributions to the response, as might be expected in a rod-dominated retina. A very slow phase of membrane repolarization that was seen after termination of the light stimulus was identified as the rod contribution based on spectral adaptation. He called it the "rod after effect" (Fig. 24.9). The difference in offset kinetics for rod and cone signal

FIGURE 24.7. Action spectra of 8 L-type (A), 7 red/green C-type (B), and 6 yellow/blue C-type (C) horizontal cells in the turtle *Mauremys caspica* retina. Sensitivity data were calculated from photoresponses of small amplitude ($<1\mu\text{V}$). In order to compare the different action spectra, the spectrum of each cell was normalized to the peak sensitivity (Asi and Perlman, 1998).

components provides a convenient assay for rod and cone signal composition of S-potentials in rod-dominated mammalian retinas (Nelson, 1977; Nelson et al., 1976). In Figure 24.9, typical mixed rod and cone signals of all three horizontal cell structures in cats are shown (Nelson et al., 1976). In A- and B-type horizontal cell bodies, rod and cone signals are about equal in amplitude, whereas in the axon terminal of the B-type cell, the response has a slowly recovering waveform, characteristic of rod signals. The “rod after effect” is most evident with bright light stimuli (Fig. 24.9, bottom).

Further evidence for the mixing of rod and cone inputs to horizontal cells is seen during adaptation to background

lights. When retinas are light adapted by steady background lights, rod function saturates even at low levels of illumination and their contributions to the horizontal cell photoresponses decrease significantly. Meanwhile, the cones adapt to the conditions of ambient illumination and their input remains. These properties of rod and cone inputs are easily seen in the photoresponses of mammalian horizontal cells. The photoresponses of B-type horizontal cell axon terminals are virtually abolished by light adaptation, consistent with their rod-dominated physiology. In the horizontal cell bodies (A and B types) that receive mixed rod and cone inputs, light adaptation selectively reduces the rod contribution but large cone signals remain; therefore, these horizontal cell elements continue to respond well in the presence of background lights (Nelson, 1977).

We know that the axon terminals of the axon-bearing horizontal cells in the cat receive an excitatory feedforward input from rods, but the cell bodies of A-type and B-type cells contact only cones. So where does the large rod component of the S-potential in these structures of horizontal cells come from? Electron-microscope observations show that small gap junctions link rod and cone photoreceptors in the outer plexiform layer (Kolb, 1977; Raviola and Gilula, 1975). These electrical synapses introduce rod signals into cones and thence into horizontal cells. This rod-cone mixing in the photoreceptors is now considered a major pathway whereby rod-driven inputs pass to horizontal cells and to all subsequent second- and third-order cells in the retina (Smith et al., 1986; Sterling, 1990).

In other species, similar characteristics of rod-cone mixing can be found in horizontal cells. In the rabbit retina, as in the cat retina, rod-dominated input to the axon terminal is identified by waveform, sensitivity, and after-potentials (Dacheux and Raviola, 1982; Massey and Miller, 1987). Also, in primate retina, the axon terminals of the axon-bearing H1-type horizontal cells are connected to rods while the cell body is connected to cones (Dacheux and Raviola, 1990; Verweije et al., 1999). Similar to other mammalian retinas, the somata of primate H1-type horizontal cells receive rod input indirectly via gap junctions between rods and cones (Verweije et al., 1999).

Horizontal cells in cold-blooded vertebrates are also characterized by mixing of rod and cone signals. In the retina of the turtle *Chelydra serpentina*, the photoresponses of H1 axon terminals contain slow, low-amplitude components that are contributed by rod photoreceptors, despite their major excitatory input being from long-wavelength sensitive cones. The cell bodies of the same H1 horizontal cells receive input only from long- and medium-wavelength sensitive cones (Leeper and Copenhagen, 1979).

PASSIVE ELECTRICAL MODELS All vertebrate retinas contain one horizontal cell type that is an axon-bearing cell (see Fig.

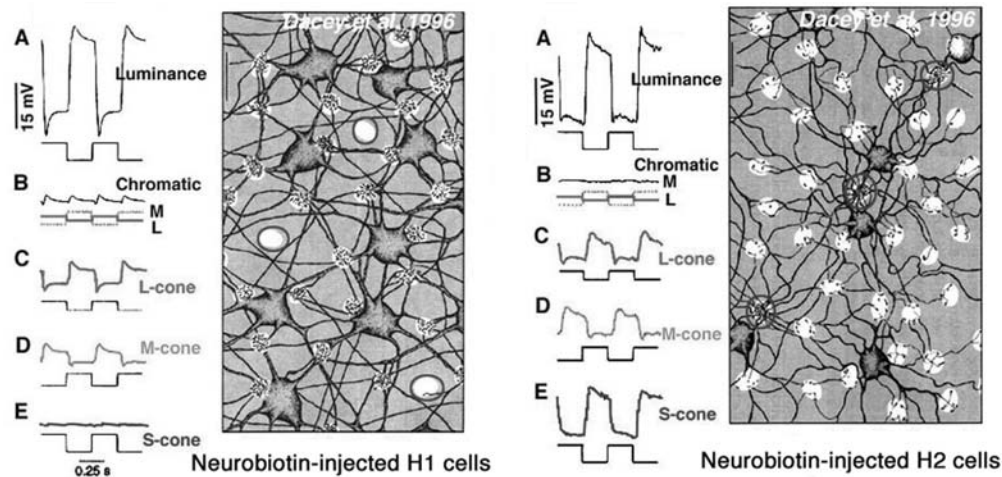

FIGURE 24.8. *Left*, Intracellular staining and chromatic responses of H1 cells in monkey retina. The H1 cells avoid having dendritic contact with blue cones (blue-outlined white circles), and the S-potential shows no response to stimulation with blue light (trace E). *Right*, Intracellular staining and chromatic responses of H2 cells in

monkey retina. The H2 cells send many dendrites to blue cones (blue-outlined cones) as well as to red and green cones. The S-potential is very large to stimulation with blue light (E). (Dacey et al., 1996). (See color plate 10.)

FIGURE 24.9. Rod-cone mixing in horizontal cells of the cat retina. Responses to light stimuli of different intensities were recorded from the cell bodies of A-type and B-type horizontal cells and from the axon terminal of the B-type horizontal cell (Nelson et al., 1976).

24.2, B type). The axon terminal and the somata of this horizontal cell type are connected by a long thin axon, but both parts behave as isolated physiological units. In the turtle *Pseudemys scripta elegans*, both axon terminal and somata receive excitatory input mainly from red cones, but they are characterized by different spatial properties and different kinetics to red and green light stimuli (Perlman and Normann, 1979; Simon, 1973). In the turtle *Chelydra serpentina*, the axon terminal receives excitatory input from red

cones and rods while the cell body dendrites contact red and green cones (Leeper and Copenhagen, 1979). In mammals (cat, rabbit) and in primates (monkey), the dendrites of the cell body receive input from cones while the terminals of the axon contact thousands of rods. No evidence has been found to indicate any synaptic or electrical interaction between the axon terminal and the soma of the same cell in any of these cases.

Where horizontal cell types have the dendritic portion of the cell much distant from the axonal ending (Fig. 24.2, B cells), calculations based on the anatomical dimensions and geometry of the neuron, and ohmic linear properties of cell membrane and cytoplasm, indicate that the axons are too long and thin to allow passive electrotonic conduction of signals from one end of the cell to the other (Leeper, 1978a, 1978b; Leeper and Copenhagen, 1979; Nelson et al., 1975). Such models tell us that signals in cell bodies of horizontal cells reflect the local synaptic inputs from cones and signals in axon terminals reflect the local synaptic inputs from rods. Indeed, the two portions of the same cell act as independent units (Nelson et al., 1975).

Ionic conductances in horizontal cells

LIGAND-GATED CHANNELS Photoreceptors make excitatory (sign-conserving) synapses onto horizontal cells. In darkness, the photoreceptors continuously release an excitatory neurotransmitter that opens cation channels with a depolarized reversal potential. Therefore, the horizontal cells are maintained at a relatively depolarized potential in darkness. When the photoreceptors are hyperpolarized by a light stimulus, transmitter release is reduced, the postsynaptic ligand-

FIGURE 24.10. *A*, The effects of L-aspartate and L-glutamate on the membrane potential and photoresponses of a horizontal cell in the rabbit retina (Bloomfield and Dowling, 1985). The photoresponses were elicited by diffuse light stimuli. *B*, The effects of L-aspartate, L-glutamate, and D-glutamate on the membrane

potential of a horizontal cell isolated from the carp retina (Lasater and Dowling, 1982). Each application pipette was filled with 500 μ M of drug. Current pulses are used to assess changes in membrane resistance.

gated channels close, and horizontal cells hyperpolarize. Transmitter release from photoreceptor terminals is calcium dependent. Thus, exposing the retina to solutions that interfere with calcium influx through voltage-dependent calcium channels causes block of transmitter release and horizontal cell hyperpolarization (Cervetto and Piccolino, 1974; Dowling and Ripps, 1973; Kaneko and Shimazaki, 1975).

Early experiments in intact retinas pointed to the excitatory amino acids L-glutamate and L-aspartate as putative candidates for the photoreceptor neurotransmitter (Bloomfield and Dowling, 1985; Cervetto and MacNichol, 1972; Marshall and Werblin, 1978; Negishi and Drujan, 1979; Normann et al., 1986). Exposing the retina to either L-glutamate or L-aspartate caused depolarization of the horizontal cells and loss of their photoresponses, as shown in Figure 24.10*A* for rabbit horizontal cells in the intact retina (Bloomfield and Dowling, 1985). In the experiment described in Figure 24.10*A*, 15 mM solutions of L-aspartate or L-glutamate were needed to induce depolarization of rabbit horizontal cells and loss of their photoresponses. These observations are consistent with the notion of an excitatory amino acid neurotransmitter being continuously released by the photoreceptors in the dark, and that light-induced electrical activity in the horizontal cells reflects the removal of the neurotransmitter from the synaptic cleft. Accordingly, exogenously applied neurotransmitter saturates the receptor sites in the horizontal cells, causing further depolarization. Because the horizontal cells are saturated with the neurotransmitter, modulation of endogenous trans-

mitter release by light stimuli have no effect on membrane potential and the photoresponses are eliminated. These and other studies raised two major questions: (1) Why were relatively high concentrations (millimolar range) of excitatory amino acids needed to exert the effects shown in Figure 24.10*A*? (2) Which of the two excitatory amino acids was the real neurotransmitter?

The first question was answered by the identification of efficient uptake systems for excitatory amino acids in retinal cells (Eliasof et al., 1998; Rauen et al., 1998). These uptake mechanisms remove the excitatory amino acids from the superfusing solution, thereby preventing the chemicals from reaching the cone–horizontal cell synapses. Thus, when nontransportable agonists of excitatory amino acids are used, considerably lower concentrations are needed to exert effects on horizontal cells (Massey and Miller, 1987; Yang and Wu, 1991a). This is illustrated in Figure 24.11 where the effects of 10 mM L-glutamate (*A*) are compared to those of 0.1 mM kainic acid (*B*). Kainic acid, a nontransportable agonist for glutamate-type receptors in vertebrate horizontal cells, exerts similar effects to those of L-glutamate at a concentration lower by 100-fold. In contrast, kynurenic acid, a nonselective antagonist of excitatory amino acid receptors (Mayer and Westbrook, 1987), induces the opposite effects (Fig. 24.11*C*). The horizontal cell hyperpolarizes and loses its photoresponses.

The identity of the neurotransmitter was a subject of debate for more than a decade. A variety of experiments in intact retinas were designed to decide between L-glutamate and L-aspartate, and conflicting conclusions were achieved.

FIGURE 24.11. The effects of L-glutamate (a), kainic acid (b), and kynurenic acid (c) on the membrane potential and photoresponses of L-type horizontal cells in the retina of the turtle *Mauremys caspica*.

It was not until the development of the isolated cell preparation that a clear answer to this question was obtained. Lasater and Dowling (1982), in their pioneering work, isolated horizontal cells from the carp retina and recorded their membrane potentials with sharp microelectrodes. The horizontal cells in culture were characterized by hyperpolarized resting potentials (close to the potassium equilibrium potential) because they were separated from the retina circuitry. Application of L-glutamate, but *not* of L-aspartate or D-glutamate, induced depolarization, indicating that specific receptors for L-glutamate existed in the horizontal cell membrane (Fig. 24.10B). With this experimental approach, a low concentration of L-glutamate was sufficient to induce effects, because in this preparation, removal of extracellular L-glutamate by uptake systems is negligible.

Voltage- and current-clamp techniques have been applied to isolated horizontal cells from a variety of species to reveal the properties of the glutamate-gated channels. These channels have a reversal potential around 0 mV, depending on the composition of the intrapipette and extracellular solutions (Hals et al., 1986; Perlman et al., 1989; Tachibana, 1985; Yang and Wu, 1991a). Pharmacological analysis of the properties of the glutamate-gated channels in horizontal cells, using specific agonists and antagonists, revealed them to be of the AMPA/KA type. They are specifically activated by α -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) or kainic acid (KA) and are antagonized by 6-

cyano-7-nitroquinoxaline (CNQX) or *cis*-2,3-piperidine-dicarboxylic acid (PDA) (reviews in Peng et al., 1995; Wu, 1994). When these ion channels are activated by the agonist kainic acid, the induced currents are considerably larger than those elicited by L-glutamate, even at higher concentrations (O'Dell and Christensen, 1989; Perlman et al., 1989). This effect has been attributed to fast desensitization of the AMPA/KA type channels by L-glutamate but not by kainic acid (Eliasof and Jahr, 1997; Schmidt et al., 1994). More recently, selective blockers of the glutamate-induced desensitization (e.g., cyclothiazide) have shown that the glutamate-induced currents are increased by severalfold, thereby concluding that horizontal cells express exclusively AMPA-type glutamate receptors (Blanco and de la Villa, 1999; Yang et al., 1998). Catfish horizontal cells, which express NMDA receptors in addition to AMPA/KA receptors, appear to be the lone exception to the above general conclusion (O'Dell and Christensen, 1989).

VOLTAGE- AND TIME-DEPENDENT IONIC CONDUCTANCES The photoresponses of horizontal cells from cold-blooded, as well as warm-blooded mammalian retinas, are shaped by voltage- and time-dependent ionic conductances in their plasma membrane (Lasater, 1986, 1991; Lohrke and Hofmann, 1994; Ueda et al., 1992). Five types of ionic currents—a sodium current, a calcium current, and three types of potassium current—have been identified in isolated horizontal

FIGURE 24.12. Voltage- and time-dependent ionic conductances in isolated horizontal cells. *A*, Current pulses to different voltage steps from a holding potential at -60 mV in horizontal cells from the rabbit retina (Lohrke and Hofmann, 1994). *B*, Current responses and I-V curves from four types of horizontal cells that were isolated from the retina of the white perch (Lasater, 1986).

cells of goldfish (Tachibana, 1983), catfish (Shingai and Christensen, 1986), white perch (Lasater, 1986), skate (Malchow et al., 1990), turtle (Golard et al., 1992), rabbit (Lohrke and Hofmann, 1994), and cat (Ueda et al., 1992).

Figure 24.12 shows the current responses to voltage steps of two types of horizontal cells from the rabbit retina (*A*) and four types of horizontal cells isolated from white perch retina (*B*). In rabbit horizontal cells, the inward sodium current is clearly evident during the first 10 ms of the current responses; at the steady state, a sustained outward potassium current is seen (Fig. 24.12*A*). The fish horizontal cells exhibit a more complex array of currents, as evident from the current pulses and transient and sustained I-V curves (Fig. 24.12*B*). All four types of fish horizontal cells exhibit similar ionic currents that differ only in relative magnitude. The sodium current is inward going and is seen during the initial 10 ms of the current pulses recorded when the horizontal cells are depolarized from a negative holding potential (about -70 mV) to around 0 mV. It is very similar to the regenerative sodium current typical of spiking neurons. The physiological role of this current in horizontal cells is not known because these cells do not respond with action potentials. Three types of potassium channel have been identified

by their voltage and time dependency and by their sensitivity to specific blockers. The inwardly rectifying channels conduct an inward current when the cells are hyperpolarized below potassium equilibrium potential. In some species, extracellular sodium ions also determine the reversal potential of these channels, making the currents functional at physiological potentials (Pfeiffer-Linn et al., 1995). The sustained outward potassium current (delayed rectifier) is activated at potentials more depolarized than the resting, dark potential of the horizontal cells. The outward transient potassium current (I_A) is activated by a fast depolarization from negative potentials. In the intact turtle retina, the outward transient potassium current is activated after termination of a bright light stimulus to enhance the recovery of the L-type horizontal cell potential back to the dark level. This effect allows the L-type horizontal cells to follow fast flickering stimuli and thus improves the frequency response curve of the cells (Perlman et al., 1993).

Gap junctions and spatial characteristics

GAP JUNCTIONS In all vertebrate retinas, including mammals, horizontal cells are characterized by large-

FIGURE 24.13. *A*, The syncytia of H2 cells of the turtle (*left*) and A-type horizontal cells in the rabbit (*right*) as revealed by Neurobiotin injection into one cell in each syncytium (Ammermüller and Kolb, 1996; Mills and Massey, 1994). *B*, The properties of the receptive field of turtle L-type horizontal cell as determined from

the photoresponses elicited by concentric light stimuli of different diameter (*left*). The peak amplitude, normalized to the response to full-field illumination, is plotted as a function of spot radius to derive the length constant (*right*) (Perlman and Ammermüller, 1994).

surface-area gap junctions (Fig. 24.3C and E) between each others' dendrites (Kolb, 1977; Witkovsky and Dowling, 1969). These junctions allow lateral flow of small molecules and ions within the horizontal cell network. Lucifer yellow or Neurobiotin injected into one horizontal cell in the layer spreads to hundreds of neighboring cells, forming striking images of the interconnected horizontal cell network (Fig. 24.13A and B) (Ammermüller and Kolb, 1996; Bloomfield and Miller, 1982; Kaneko, 1971; Mills and Massey, 1994; Teranishi et al., 1983; Vaney, 1994). Gap junctions are formed only between neighboring horizontal cells of the same physiological type, as shown in Figure 24.13. Networks of turtle H2 cells (Fig. 24.13, *left*) and of rabbit A-type cells (Fig. 24.13, *right*) are demonstrated by Neurobiotin injection into one cell of the network. The conductance of the gap junctions between horizontal cells and therefore dye coupling is influenced by the intracellular and extracellular milieu and by chemicals such as dopamine, retinoic acid, and nitric oxide that are released by other retinal cells (see later section).

RECEPTIVE FIELD PROPERTIES The gap junctions between horizontal cells are highly permeable to small ions and therefore serve as low-resistance pathways for electrical signals to spread laterally within the horizontal cell layer. Thus, horizontal cells receive excitatory input via chemical synapses from photoreceptors and via gap junctions from neighboring horizontal cells. The physiological consequences of the gap junctions between horizontal cells are that these cells have very large receptive fields that spread out to retinal regions outside the range of their immediate dendritic fields (Kaneko, 1971; Naka and Rushton, 1967).

Different procedures have been used to characterize the receptive fields of horizontal cells. The most common experimental procedures have been the application of a series of concentric spots of increasing diameter but fixed intensity, or moving a narrow slit of light across the retina. An experiment in which an L-type horizontal cell in the retina of the turtle *Pseudemys scripta elegans* was stimulated with a series of concentric spots of fixed intensity is shown in Figure 24.13B.

The first photoresponse to the left was elicited with a stimulus of supersaturating intensity that illuminated the entire receptive field of the cell. This is the maximal photoresponse of the cell. A series of six photoresponses that were elicited by light stimuli of fixed intensity and wavelength (650 nm) but different diameters are shown. The amplitudes of the photoresponses gradually decrease as the size of the illuminated retinal area is reduced (Fig. 24.13*B*, *left*). This diminution is not due to lesser summation of inputs from photoreceptors but to shunting of the direct input to the horizontal cell by neighboring horizontal cells. With full-field illumination, all the horizontal cells are evenly illuminated and are equipotential, and therefore no current flows between them. With small spot illumination, the membrane potential of nonilluminated horizontal cells is different from that of illuminated cells, causing electrical currents to flow between them and thus to shunt the responses of the illuminated cells.

The dimension of the horizontal cell receptive field can be quantified by the diameter of the spot that elicits a response that does not differ from that elicited by a full-field illumination or by the length constant (λ). The mathematical definition of λ and the ways of measuring it vary (Kamermans et al., 1996; Lamb, 1976; Lankheet et al., 1990; Nelson, 1977; Nelson et al., 1990; Owen and Hare, 1989). However, it is generally agreed that the receptive field size is directly related to λ and that λ is directly related to the membrane resistance of the horizontal cell and inversely related to the coupling resistance between the horizontal cells.

The relationship between peak amplitude of the photoresponse and the radius of the illuminated retinal area used to elicit it, while analytically given by a Bessel function (Lamb, 1976; Nelson et al., 1990), can be approximated by an exponential equation (Owen and Hare, 1989):

$$V_r/V_{ff} = 1 - [1 + (r/\underline{\lambda})]e^{(-r/\lambda)}$$

Where V_r and V_{ff} are the amplitudes of the photoresponses elicited by a light spot of radius r and by full-field illumination, respectively. $\underline{\lambda}$ is 0.81 of the one-dimensional length constant λ for the horizontal cell network (Hare and Owen, 1990). The relationship between peak response amplitude that was normalized to the amplitude obtained with full-field illumination and spot radius was constructed for the photoresponses in Figure 24.13*B*, *left* and is shown in Figure 24.13*B*, *right*. The continuous curve represents the best fit of the above equation to the data points with $\underline{\lambda} = 280 \mu\text{m}$ ($\lambda = 345 \mu\text{m}$).

Another common method for determining the length constant is to measure the photoresponses that are elicited by long narrow slits of light presented at different distances from the recorded horizontal cell (Nelson, 1977). The relationship between response amplitude and distance of the slit from the cell can be described by an exponential function. For slit stimuli much narrower than the length constant, the

length constant is approximately the distance between the slit of light and the recorded cell that elicits a response that is $1/e$ of that elicited when the slit directly illuminates the cell.

Horizontal cells have been classified according to their physiological type and according to the size and properties of their receptive fields. In the turtle retina, two types of luminosity horizontal cells have been described: L1 and L2 (Simon, 1973), or large receptive field (LRF) and small receptive field (SRF) horizontal cells (Perlman and Normann, 1979). The L1 (LRF) cells are characterized by receptive fields of large diameter ($>3 \text{ mm}$); the L2 (SRF) cells have a receptive field diameter of about 2 mm. These two L-type horizontal cells also differ with regard to spectral properties (Perlman et al., 1985) and responsiveness to surround illumination (Piccolino et al., 1981). The spatial properties of C-type horizontal cells in the turtle retina also depend on the color of the light stimuli (Kato, 1979; Twig et al., 2002). The waveform of the photoresponses of C-type horizontal cells may change dramatically when the spatial pattern of the light stimulus is changed, especially when the wavelength of the light is close to the zone where response polarity reverses (Twig et al., 2002).

The horizontal cell syncytium cannot be described by a simple array of resistors interconnected by coupling resistors. The resistances of the horizontal cell layer change with illumination and time; therefore, the size of the receptive field (magnitude of length constant) changes with light intensity and with time (Borenstein, 1999; Byzov and Shura-Bura, 1983; Kamermans et al., 1996). In general, the diameter of the receptive field (length constant) is directly related to the intensity of the light stimulus used to measure it (Lamb, 1976; Perlman and Ammermüller, 1994; Perlman et al., 1985; Pottek et al., 1997). When the irradiance of the ambient illumination is increased, the length constant first increases to a peak value and then decreases to a steady-state value (Borenstein, 1999; Kamermans et al., 1996; Nelson, 1977).

Feedback

Horizontal cells are postsynaptic to the photoreceptors, but in certain cold-blooded species they are also presynaptic to the photoreceptors. Horizontal cells send visual information back to cones through feedback pathways (Baylour et al., 1971; Burkhardt, 1977; Fuortes et al., 1973; Lasansky, 1981; O'Bryan, 1973; Wu, 1991). The effects of these pathways can be revealed by adjusting the properties of the light stimuli. In Figure 24.14, the photoresponses of a cone from the retina of the tiger salamander are shown (Lasansky, 1981). Each pair of responses was elicited by light stimuli of the same intensity but different size. The ON phase of each pair of photoresponses (initial hyperpolarization) is identical

FIGURE 24.14. The contribution of the feedback pathway from L-type horizontal cells to cone responses in the retina of the tiger salamander. Photoresponses were elicited by light stimuli of different intensities covering a small or a large spot (indicated) (Lasansky, 1981).

regardless of the size of the stimulus, but the later phases are considerably affected by the stimulus size. With a small spot stimulus, after the initial hyperpolarization, the cell slightly recovers toward the dark potential but the membrane potential is maintained at a hyperpolarized level for the entire duration of the stimulus. When a large spot stimulus is used, a significant depolarization is seen after the initial hyperpolarizing phase despite continuous illumination (Fig. 24.14, arrows). This late depolarizing potential reflects the activation of the negative feedback pathway from the horizontal cells.

In turtle retina, the feedback pathway from horizontal cells to cones can be revealed by experiments using light stimuli of different sizes and colors (Fig. 24.15). Red and green light stimuli of different diameters were used to excite a red cone (L-cone) and a green cone (M-cone). With small-field stimuli, the photoresponses of the red cone are very similar in shape (Fig. 24.15, upper left pair of responses). However, with large-field stimuli, the large excitatory input from the green cones to the L-type horizontal cells that is activated by the bright green light stimulus activates the feedback pathway and

causes the response of the red cone to the green light stimulus to become narrower (Fig. 24.15, lower left traces). In the green cone, the contribution of the feedback pathway from the L-type horizontal cells is more apparent and a depolarizing photoresponse is elicited with a large-diameter red light stimulus (Fig. 24.15, bottom traces). Blue cones (S-cones) also get feedback pathways from L-type horizontal cells (Itzhaki et al., 1992) as shown in Figure 24.15 (right-hand traces). A large-diameter red light stimulus was used to selectively isolate possible inputs that were mediated by feedback pathways from L-type horizontal cells to blue cones. In the dark-adapted state, a small depolarizing afterpotential was seen after the initial hyperpolarizing phase (Fig. 24.15, trace 1). During a red background light that selectively desensitized the L-cones, a pure hyperpolarizing photoresponse was elicited by the red light stimulus (trace 2), while the blue background augmented the relative contribution of the feedback pathway and, therefore, a depolarizing photoresponse was obtained (trace 3). These and other anatomical and physiological studies formed the basis for the theory that a feedback model between cones and horizontal cells underlied color opponency in nonmammalian retinas (Kamermans and Spekreijse, 1995; Stell and Lightfoot, 1975; Witkovsky et al., 1995; review in Piccolino, 1995).

The negative feedback circuit from horizontal cells to cones is thought to take place through the horizontal cell lateral elements invaginating the photoreceptor terminal at the triad ribbon synapse (see Fig. 24.3). The problem has been that no images of a synapse with vesicle clusters in the lateral elements have ever been seen, except for in human retina (Linberg and Fisher, 1988). Fish retinas have distinctive spinules on the dendritic endings of the horizontal cells' lateral elements in cone pedicles (Fig. 24.3bB). Spinules have been suggested to be the sites of feedback from horizontal cells to cones because they change shape and enlarge during background illumination when the effects of negative feedback are most apparent (Djamgoz et al., 1989; Downing and Djamgoz, 1989; Kirsch et al., 1990; Raynauld et al., 1979; Wagner, 1980; Weiler and Wagner, 1984).

GABA has been suggested as the candidate for the inhibitory feedback neurotransmitter between H1 cells and photoreceptors in some species (Cuenca et al., 2000; Marc et al., 1978). GABA-induced currents can be recorded from the terminals of red-sensitive and green-sensitive cones isolated from the turtle retina (Tachibana and Kaneko, 1984). Furthermore, color opponency in fish C-type horizontal cells is eliminated on exposure to GABA or its antagonists (Murakami et al., 1982a, 1982b). However, studies in other species have failed to show effects supportive for a role of GABA as the inhibitory neurotransmitter of the horizontal cell (Perlman and Normann, 1990; Stone et al., 1990). In L-type horizontal cells of turtle, GABA and related drugs induce depolarizations that are consistent only with the

FIGURE 24.15. The contribution of the negative feedback from L-type horizontal cells to the photoreponses of cones in the turtle retina. The red and green cones were stimulated with small-field and large-field stimuli of red and green light (Perlman et al., 1985).

The blue cone from the retina of the turtle *Mauremys caspica* was stimulated with a red (700-nm) light stimulus covering a large retinal area in the dark-adapted state (trace 1) and during red (trace 2) or blue (trace 3) background lights (Itzhaki et al., 1992).

activation of electrogenic GABA transporters in the horizontal cell membrane (Kamermans and Werblin, 1992; Perlman and Normann, 1990). Thus, the idea that GABA mediates the negative feedback of horizontal cells to cone photoreceptors has gone out of favor in recent years, although GABA could still have a feedforward action directly on bipolar cell dendrites.

A different approach to the question of horizontal cell feedback has been taken recently (Verweij et al., 1996). Using voltage-clamp recordings from cones during illumination with spots or annuli of light, these authors have suggested that negative feedback modulates the voltage dependency of the calcium channels in the cone pedicles. The idea takes off from an old electrical model (Byzov and Trifonov, 1968) and proposes that horizontal cells can initiate large extracellular current flow through hemi-gap junction channels at the lateral element synapse into the intercellular space at the triad synapse of the cone (Fig. 24.3D) (Janssen-Bienhold et al., 2001; Kamermans et al., 2001). During light stimulation, the L-type horizontal cells hyperpolarize and the magnitude of the extracellular current is reduced, so affecting the voltage-dependent calcium channels in the cone pedicle and its resultant membrane potential. The idea finds some support because when the hemi-channels are blocked with carbenoxolone (a specific gap junction blocker), the feedback signal in the cone is eliminated (Kamermans et al., 2001).

Modulation of horizontal cell physiology

The properties of horizontal cells can be modulated by a variety of chemicals that are released by retinal cells during

changing conditions of illumination. These chemicals are generally referred to as neuromodulators. They are believed to alter modes of information processing to adjust retinal function to any new state of adaptation. These chemicals can reach the horizontal cells either via direct synaptic interactions or via volume transmission. In the latter mode, intercellular communication is mediated by a chemical that is released into the extracellular space and reaches its targets by simple diffusion. The most extensively studied neuromodulator is dopamine, but in recent years nitric oxide and retinoic acid have also been studied. In this section, some effects of these neuromodulators on vertebrate horizontal cells will be discussed.

DOPAMINE Dopamine-containing neurons reside in the amacrine cell layer of the retina in most species. In some species (e.g., fish, where they were first demonstrated), dopaminergic cells are interplexiform cells (IPCs) that send long processes to the outer plexiform layer to make synaptic contact with horizontal cells at synapses. In other species (e.g., turtle), the dopaminergic cells are amacrine cells; therefore, dopamine has to reach the horizontal cells by volume diffusion through the inner nuclear layer. The action of dopamine on vertebrate horizontal cells has been extensively studied (see reviews in Dowling, 1991; Witkovsky and Dearry, 1991).

In cold-blooded vertebrates, dopamine has several influences on horizontal cells. (1) The size of the receptive field is reduced, as shown by dye coupling and by electrophysiological determination of receptive field size (Dong and McReynolds, 1991; Mangel and Dowling, 1985; Negishi and Drujan, 1979; Perlman and Ammermüller, 1994; Piccolino

FIGURE 24.16. The effects of dopamine on the physiology of fish horizontal cells. Photoresponses were recorded from a horizontal cell in the intact retina using light stimuli of fixed intensity but different diameter, under control conditions and after exposure to dopamine (*left*) (Mangel and Dowling, 1985). Voltage-clamp

recordings from isolated white perch horizontal cells (*right*) indicate dopamine-induced augmentation of kainate (KA)-induced current (compare lower and upper traces in *B*). Dopamine (DA) by itself (*A*) did not elicit any current (Knapp and Dowling, 1987).

et al., 1984; Teranishi et al., 1983). This effect reflects a reduction of gap junction conductance induced by activation of adenylate cyclase by dopamine at D1-type receptors (see Dowling, 1991 for review). (2) Dopamine induces the formation of spinules in fish horizontal cells in a manner similar to that seen with bright light background illumination (Djamgoz et al., 1989; Weiler et al., 1988). (3) In some species, the interaction between L-glutamate and its receptors on the horizontal cell membrane is modulated by dopamine so that the amplitude of the photoresponse is reduced to any given light stimulus (Mangel and Dowling, 1985; Yang et al., 1988). However, it is not clear that this happens in the turtle retina (Perlman and Ammermüller, 1994; Piccolino et al., 1984). (4) Dopamine changes the balance between rod and cone inputs to horizontal cells in *Xenopus* retina to augment the rod contribution in the dark-adapted state and the cone contribution in the light-adapted state (Witkovsky et al., 1989).

Figure 24.16 demonstrates the effects of dopamine on horizontal cells in the intact fish retina (*left*) in contrast to horizontal cells that were isolated from the fish retina (*right*). Light stimuli of constant intensity but different diameters were used to study the effects of dopamine on the receptive field size in the intact retina (Fig. 24.16, *left*). With small spot stimuli, the photoresponses that were recorded during superfusion with dopamine solutions were larger in amplitude than those recorded with the same stimuli under control conditions. The increase in the response to spot stimuli indicates less shunting by neighboring nonilluminated horizontal cells and is consistent with the notion that dopamine uncouples horizontal cells from the network (Lasater and Dowling, 1985). Another effect of dopamine is a reduction in the maximum amplitude of the photoresponses elicited

by light stimuli that illuminate the entire receptive field of the cell (Fig. 24.16, *left*). This was explained by the observation that dopamine modulated the interaction between L-glutamate and its receptors on the horizontal cell membrane itself (Knapp and Dowling, 1987). In Figure 24.16 (*right*), the effect of dopamine on the inward current elicited by a given dose of kainic acid is shown. Dopamine by itself evoked no current in the horizontal cell (Fig. 24.16*A*, *right*), but it significantly augmented the kainate-induced current (Fig. 24.16*B*, *right*). This was interpreted to mean that dopamine increased the affinity of the glutamate-gated channels on the horizontal cell membrane to its agonist. In the intact retina, the photoresponses of horizontal cells reflect the unbinding of glutamate from its receptors. If dopamine increases the affinity of glutamate for its receptors on the horizontal cell membrane, then unbinding during a light stimulus will be at a slower rate and the photoresponse is expected to be of smaller amplitude.

In the mammalian retina a similar but lesser magnitude of uncoupling of horizontal cells due to dopamine has been reported (Bloomfield et al., 1995; Mills and Massey, 1994). Similar to the findings in cold-blooded vertebrates, horizontal cell uncoupling in the mammalian retina is mediated by activation of cyclic AMP synthesis through the interaction of dopamine with D1-type receptors (Hampson et al., 1994).

NITRIC OXIDE Involvement of nitric oxide in physiological mechanisms is indicated by the presence of cells containing the enzyme nitric oxide synthase (NOS), which synthesizes nitric oxide from L-arginine (Nathan, 1992). Immunoreactivity to NOS isoforms or demonstration of NADPH-diaphorase activity has been seen in some populations of cells in every retina studied (Koistinaho and Sagar, 1995). In

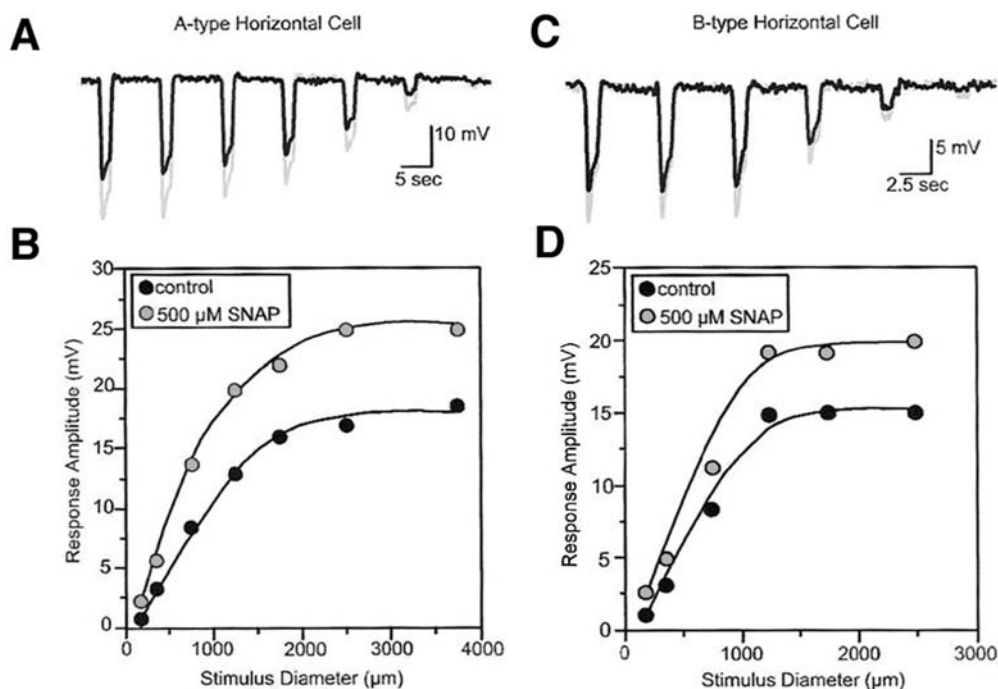

FIGURE 24.17. The effects of nitric oxide (NO) on the physiology of horizontal cells in the rabbit retina. The effects of NO were tested by adding SNAP, an NO donor, and testing its effects on the photoresponses elicited by light stimuli of fixed intensity but different diameters (black traces, control; gray traces, SNAP). The

relationship between response amplitude and stimulus diameter indicates that NO augments the photoresponses of the horizontal cell and reduces its receptive field size (Xin and Bloomfield, 2000).

all species NOS occurs in amacrine cells, but reports of NOS in photoreceptors, horizontal cells, bipolar cells, and Müller cells have also been published. In fish retinas, evidence for NOS in horizontal cells has been demonstrated by immunostaining and NADPH diaphorase histochemistry (Liepe et al., 1994; Ostholm et al., 1994; Weiler and Kewitz, 1993). In the turtle retina, n- and e-isoforms of NOS have been found in horizontal cell processes at the photoreceptor ribbon synapses and in the inner segments of the photoreceptors, in amacrine cells and in Müller cells (Blute et al., 1997; Cuenca et al., 2000; Haverkamp and Eldred, 1998; Haverkamp et al., 1999). In the rabbit retina, NADPH diaphorase activity in horizontal cells has been shown to depend on the state of adaptation and the activity of glutamatergic pathways. It is increased in the dark-adapted state (Zemel et al., 1996) or by activation of AMPA/KA type receptors (Zemel et al., 2001).

Regardless of the exact cellular source of nitric oxide, this molecule exerts profound effects on the physiology of horizontal cells. Raising nitric oxide level by either exogenous application (nitric oxide donors) or by addition of L-arginine reduces the size of the horizontal cell receptive field (Miyachi et al., 1990; Pottek et al., 1997; Xin and Bloomfield, 2000). This effect reflects direct action of nitric oxide on the gap junctions between horizontal cells. It is thought to be mediated through cGMP-dependent protein kinase pathways

(DeVries and Schwartz, 1989; Lu and McMahon, 1997; Xin and Bloomfield, 2000).

Figure 24.17 shows the effects of nitric oxide on A-type (A and B) and B-type (C and D) horizontal cells in the rabbit retina. The photoresponses were elicited by a series of light stimuli of fixed intensity and different radii, in control conditions and during exposure to SNAP (a nitric oxide donor). For every light stimulus, the photoresponse is larger during SNAP application (gray responses). This is better illustrated in Figure 24.17B and D, where the peak amplitudes of the photoresponses are plotted as a function of stimulus diameter. SNAP clearly causes augmentation of the photoresponses to large-diameter stimuli. Thus, nitric oxide acts in the distal rabbit retina to augment the photoresponses of the horizontal cells and to reduce the receptive field size (Xin and Bloomfield, 2000).

A similar augmentation of horizontal cell responses by nitric oxide has been seen in L-type horizontal cells of carp (Pottek et al., 1997) and turtle retinas (Levy, 2001). Nitric oxide's effect can reflect an action directly on the phototransduction process in the outer segments of the photoreceptors (Levy, 2001; Tsuyama et al., 1993) and/or on neurotransmitter release from the photoreceptors (Kurenniy et al., 1994). Furthermore, nitric oxide can modulate the interaction between L-glutamate and its receptors on the horizontal cell membrane (McMahon and Ponomareva,

1996) and thus, can alter the responsivity of horizontal cells independently of effects on the photoreceptors (Levy, 2001).

Nitric oxide, like dopamine, also induces cone contraction and horizontal cell spinule formation (Haamedi and Djamgoz, 2002).

RETINOIC ACID Retinoids are of great importance in the eye, having roles in both the photopigment cycle and in development of the eye. Retinoic acid is produced in the pigment epithelium as a side effect of the rhodopsin transduction process in bright illumination. In the form of a retinaldehyde, it is part of the rhodopsin molecule, the visual pigment of the vertebrate photoreceptors (Dowling and Wald, 1960; Wald, 1935); in the form of retinoic acid, it activates transcription factors that are important in the development of the eye (Dräger et al., 2001; Wagner et al., 1992). Most recently a third role for retinoic acid has been proposed, that of a neuromodulator linked to background adaptation affecting horizontal cells in particular (Pottek and Weiler, 2000; Weiler et al., 2001; Weiler et al., 1998).

Retinoic acid induces synaptic plasticity at the terminal dendrites of horizontal cells and promotes the growth of spinules in a pattern similar to that induced by background lights (Pottek and Weiler, 2000; Weiler et al., 1998). It exerts a pronounced effect on the electrical coupling between horizontal cells in mammalian and nonmammalian retinas and reduces the receptive fields of the horizontal cells (Weiler et al., 2001; Weiler and Vaney, 1999), as shown in Figure 24.18. Adding retinoic acid to retinal preparations of carp, rabbit, and mouse reduces the conductance of the gap junctions between neighboring horizontal cells, thus reducing the degree of dye coupling in a manner similar to that seen during background illumination (Fig. 24.18A). Intracellular recordings in horizontal cells also show that retinoic acid produces effects similar to those of light adaptation. The amplitudes of the horizontal cell photoresponses to full-field stimuli are increased by retinoic acid (Fig. 24.18B). The responses to stimulation with light annuli are reduced by retinoic acid, and those to spot illumination are increased (Fig. 24.18C). Thus, retinoic acid, like dopamine and nitric oxide, seems to modulate the physiological properties of vertebrate horizontal cells in order to adjust their function during background illumination.

Functional roles

The major functional roles of horizontal cells in the vertebrate retina are (1) creating spatially opponent receptive field organization for second- and third-order neurons in the retina, and (2) modulating the photoreceptor signal under different lighting conditions, a form of neuronal adaptation at the first synaptic level in the retina.

SPATIAL SURROUND ORGANIZATION Bipolar cells are the first visual neurons exhibiting spatial organization of their receptive fields. These cells respond with opposite polarity to light stimuli illuminating either the center or the surround (Dowling, 1970; Werblin and Dowling, 1969). Figure 24.19A shows a cartoon of the original model of photoreceptor and horizontal cell interactions with the bipolar cells that underlie spatial opponent organization of the latter (Werblin and Dowling, 1969). Specifically, direct input from photoreceptors is believed to contribute to the central response of bipolar cells, and the horizontal cells form the surround component. In experiments where horizontal cell membrane potentials are directly polarized by injections of current through an intracellular microelectrode, ganglion cell discharges characteristic of “surround responses” or “large-spot responses” are evoked (Mangel, 1991; Naka, 1971). This current-evoked response could reflect the negative feedback pathway from horizontal cells to cones and/or direct input from the horizontal cells to bipolar cells. Evidence for both possibilities has been reported. The glutamate agonist 2-amino-4-phosphonobutyrate (APB), selective for transmission between cones and ON-center bipolar cells, blocks the light responses of ON-center ganglion cells and also the current-evoked responses in ganglion cells (Mangel, 1991). Moreover, submillimolar concentrations of cobalt ions selectively block the feedback pathway from horizontal cells to cone photoreceptors, resulting in the absence of surround components in ganglion cells in proximal retina (Vigh and Witkovsky, 1999).

Horizontal cell feedback is not necessarily the only way of influencing bipolar cell receptive field architecture. Horizontal cells can impinge directly on bipolar cells, feeding visual information forward to these second-order retinal neurons. Direct horizontal to bipolar synapses have been described in several mammalian and nonmammalian species’ retinas (Dowling, 1970; Fisher and Boycott, 1974; Kolb and Jones, 1984). In one study using APB to block synaptic transmission from photoreceptors to ON-center bipolar cells, the light stimulus induced a hyperpolarizing response in the bipolar cell, thus supporting the idea of a direct excitatory input from horizontal cells (Yang and Wu, 1991b). The best candidate for the feedforward neurotransmitter is GABA (Wu, 1986).

There are exceptions to every model, though. Not all bipolar cells exhibit spatial antagonism. The ON-bipolar for the rod system and some OFF-center cone bipolar cells in cat retina appear to lack surrounds (Nelson and Kolb, 1983). Regardless of the exact neuronal pathway, whether feedforward or feedback, it is generally accepted that horizontal cells play an important role in spatial information processing in retinal neurons after the photoreceptors (Ammermüller and Kolb, 1995, 1996; Hare and Owen, 1990; Kaneko, 1970; Lasansky, 1978; Marchiafava and

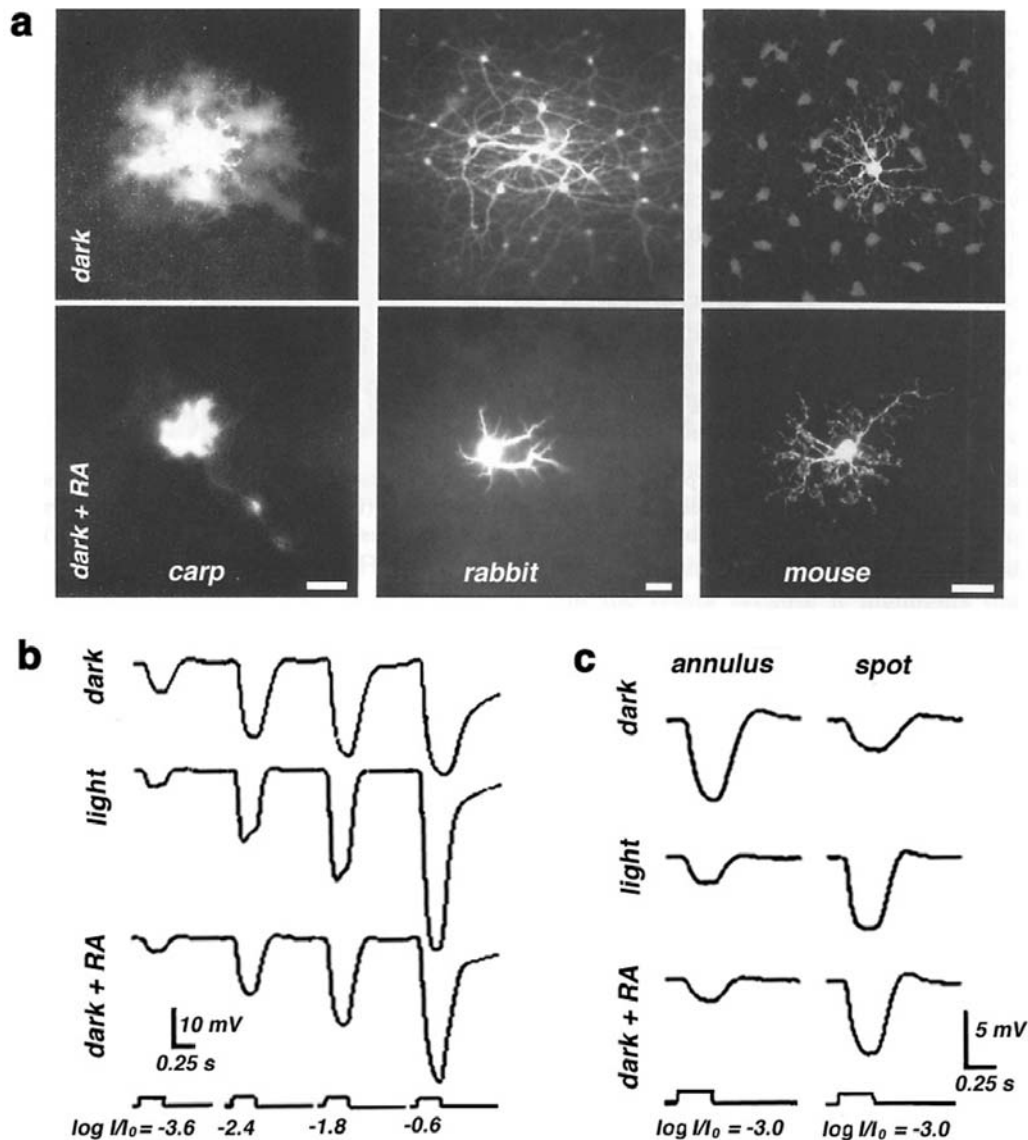

FIGURE 24.18. The effects of retinoic acid on the physiology of horizontal cells in different species. *a*, In carp, rabbit, and mouse retinas, retinoic acid added in the dark-adapted state reduces the extent of dye coupling. *b*, Retinoic acid added in the dark-adapted state exerts effects similar to those of light adaptation by aug-

menting the photoresponses of fish horizontal cells. *c*, Retinoic acid, like background illumination, reduces the response to an annulus stimulus and augments that to a spot stimulus in fish horizontal cells (Weiler et al., 2001).

Weiler, 1980; McReynolds and Lukasiewicz, 1989; Naka, 1971, 1976; Saito et al., 1979, 1981; Werblin and Dowling, 1969).

Horizontal cell feedback to bipolar cells probably also serves to generate color opponency in bipolar cells and therefore in ganglion cells. Figure 24.19*B* summarizes, in cartoon form, the manner in which single and double opponent bipolar cell receptive fields could be formed in the fish retina according to the cascade model of color opponency (Kamermans and Spekreijse, 1995; Stell, 1976; Stell and Lightfoot, 1975). The opponent surround of the single opponent cell is easy to model (Fig. 24.19*B*, *top*). This bipolar

cell receives an excitatory input from red cones only and therefore is defined as a red OFF-center cell. The negative feedback from the monophasic and biphasic horizontal cells oppose each other in the red range of the spectrum and strengthen each other in the green and blue range. If the degree of feedback from both horizontal cells is the same, then the bipolar surround will be of an ON pattern with spectral sensitivity highest in the green range of the spectrum. If the feedback from the monophasic horizontal cell is weaker compared to that of the biphasic horizontal cell, then the spectral response of the bipolar cell to surround illumination will be hyperpolarizing for red light and depolar-

FIGURE 24.19. Cartoon to show how the horizontal cell lateral inhibition on the cones helps to form the concentrically organized receptive fields of bipolar cells. *A*, A simple feedback from monophasic (L-type) horizontal cells onto cones can affect the hyperpolarizing OFF-center or depolarizing ON-center bipolar cells to provide the opponent ON- or OFF-surround, respectively. *B*, Possible models for the generation of color-opponent responses in bipolar cells are shown (Kamermans and Spekreijse, 1995). The

cartoon illustrates the manner in which biphasic (Bi) chromaticity horizontal cells and monophasic (Mono) luminosity horizontal cells can feedback through a single cone type to give the opponent color surround to a red OFF bipolar cell. In the lower cartoon, red cones provide excitatory input and green cone inhibitory input to produce a red OFF, green ON center double opponent bipolar cell. The red ON and green OFF surround is added by the chromatic (Bi) and luminosity (mono) horizontal cells.

izing for green light ($R-G^+$) (Kamermans and Spekreijse, 1995).

The double opponent bipolar cell (Fig. 24.19*B*, bottom) responds in its center with hyperpolarization to red stimuli and with depolarization to green and blue stimuli. This central color opponency is generated by different types of inputs from different types of cones: excitatory input from the red cones and inhibitory input from the green cones. If the monophasic and biphasic horizontal cells feedback onto both spectral types of cones (Kamermans and Spekreijse, 1995), the feedback through the green cones would work against the feedback through the red cones because of the different synaptic interactions. When the feedback pathways from each horizontal cell onto the red and green cones differ, color opponency can be generated by the feedback pathways. However, when the strength of the feedback from each horizontal cell to both types of cones is equal, the surround response can be achromatic. Under these conditions, color opponency in the surround of the bipolar cell can occur only through direct input from one or both horizontal cells to the bipolar cell itself.

PHOTORECEPTOR MODULATION UNDER DIFFERENT LIGHTING CONDITIONS Calcium entry into synaptic structures induces the release of neurotransmitter by promoting fusion of neurotransmitter-laden synaptic vesicles with the presynaptic membrane. Calcium entry occurs through specialized membrane channels regulated by both voltage and second messengers. In a simple model of horizontal cell modulation of gain at cone synapses (Kamermans et al., 2001; Verweij et al., 1996), depolarized, dark-adapted horizontal cells produce an electrical gradient in the extracellular space that reduces the rate of calcium entry into cone terminals. This, in turn, reduces the rate of neurotransmitter release. Background illumination, which hyperpolarizes horizontal cells, alters the extracellular currents, thereby shifting the voltage dependency of the calcium channels in the cone terminals and increasing the rate of transmitter release for a given potential of the cone.

This modulation also serves to complete the negative feedback loop between horizontal cells and cones, which regulates the horizontal cell membrane potential. When horizontal cells become depolarized, calcium influx into the cone

synapse is reduced, as is transmitter efflux from the synapse. The effect sends horizontal cell membrane potential in a hyperpolarized direction. The horizontal cell membrane potential becomes controlled by the network, rather than by factors intrinsic to the cell. Interestingly, bipolar cells perceive this negative feedback effect and synaptic gain modulation as a further spatial opponency effect. This is true for both ON- and OFF-center bipolar cells. The increase in transmitter release caused by horizontal cell hyperpolarization is just the reverse of the decrease in transmitter release that occurs as cones are hyperpolarized by small spots of light.

When horizontal cells are hyperpolarized by wide-field, bright light stimuli, cone signals evoked in second-order neurons both increase in amplitude and become quicker in time course. Such effects are commonly observed when small spots are flashed in the presence of large background fields (Chappell et al., 1985). Similarly, under dark conditions the horizontal cells can increase the sensitivity of both the rod and cone pathways by switching to a large receptive field organization and response characteristics of the scotopic range.

Horizontal cell modulatory effects on the cones can be utilized for interpretation of electrophysiological tests at the clinical level in human patients. A test known as suppressive rod-cone interaction (SRCI) is often recorded in clinical electroretinograms (Goldberg et al., 1983). In the SRCI, large, dim green stimuli, seen only by rods, cause observers to perceive focal, red stimuli, seen only by cones, as being brighter. Analogous physiological effects involving rod and cone signals occur in horizontal cells and bipolar cells themselves (Frumkes and Eysteinnsson, 1987; Nelson et al., 1990; Pflug et al., 1990). Flickering cone signals are evoked in cat horizontal cells by flickering red stimuli of various sizes. When the stimuli are small, flicker amplitudes can be increased by superimposing steady blue backgrounds, which selectively excite rods. Thus the amplitude of the cone flicker signals is modulated by wide-field, rod-driven horizontal cell stimulation, probably through increased gain at horizontal cell to cone synapses.

In the 50 years since Svaetichin first described S-potentials in the vertebrate retina, we have made significant progress in our understanding of the many ways that horizontal cells can influence the kinetics, plasticity, and spatial organization of the photoreceptor response. We have discussed most of these ways in previous sections of this chapter. They include rod-cone balance changes, differences in the horizontal cell's receptive field, often under neuro-modulatory control by dopamine and other neuroactive agents and biochemical second-messenger mechanisms. The horizontal cells are essential elements in visual information processing and play a crucial role in the genesis of the recep-

tive fields of inner retinal cells. Finally, the horizontal cells form an important link between inner and outer retina because this cell type is almost certainly under the influence of centrifugal input from within the retina and even from the brain itself.

Acknowledgements

We dedicate this chapter to the following scientists who have been very influential on us in the field of horizontal cell physiology. They include Elliot Simon, Mike Fuortes, Henry Wagner, Matthew Alpern, and Ken Naka. We thank other colleagues for their valuable advice and the National Institutes of Health (USA), Research to Prevent Blindness Organization (USA), and the Israel Science Foundation for continued support over the years.

25 Retinal Amacrine Cells

DAVID I. VANEY

Interneurons of the inner retina

Detailed studies of the neuronal interactions that occur at the terminal pedicle of cone photoreceptors have created a cohesive framework for understanding the complexity of visual processing in the outer retina and, in particular, the neuronal mechanisms that give rise to the parallel visual pathways mediated by the different types of bipolar cells (see Chapter 17, How Retinal Circuits Optimize the Transfer of Visual Information). By contrast, our understanding of how the visual signals are further processed in the inner retina has advanced comparatively little in the past decade, notwithstanding the detailed documentation of the neuronal diversity of both the amacrine and ganglion cells (see Chapter 26). In Ramón y Cajal's final paper addressing "the enigma of the amacrine cells," he pointed out that the functions of most types of amacrine cells remained unknown almost 50 years after their discovery (Cajal, 1933). Although our present understanding of amacrine cell function is now informed by the knowledge that these cells are primarily inhibitory neurons and that they make and receive synapses on their dendrites (Dowling and Boycott, 1966), anyone who has looked down a microscope at Golgi-stained or dye-filled amacrine cells can appreciate how Cajal was bewildered by these cells.

Amacrine cells first came to prominence in the late 1880s. Although Müller (1851) had recognized that the cells at the vitread margin of the inner nuclear layer formed a distinct sublayer (*spongöse schicht*), it was not until Tartuferi (1887) first applied the Golgi method to the retina that the detailed morphology of the spongioblasts was revealed. Shortly afterward, Cajal (1893) and Dogiel (1891) independently came to the conclusion that spongioblasts do not give rise to a classical axon, leading Cajal (1893) to name these inner retinal neurons amacrine cells, from the Greek *a-makrós-inos* meaning "without-long-fiber." Cajal also recognized that some spongioblasts in the bird retina do give rise to a short intraretinal axon; these cells he called association spongioblasts or association amacrine cells, to distinguish them from amacrine cells proper. In keeping with Cajal's broad view, this review encompasses all retinal interneurons that receive their primary input in the inner retina, including the amacrine cells of the inner nuclear layer, the "displaced" amacrine cells of the ganglion cell

layer, the association amacrine cells, and the interplexiform cells.

AI and AII cells: prototypical amacrine cells

In the mammalian retina, rod bipolar cells do not contact ganglion cells directly but, instead, their ribbon synapses are presynaptic to a pair of amacrine varicosities, typically arising from different types of amacrine cells, originally termed the AI and AII cells (Kolb, 1979; Kolb and Famiglietti, 1974). More informatively, the AII cell has also been called the rod amacrine cell because it is the third-order neuron in the scotopic pathway, and the AI cell has been called the reciprocal rod amacrine cell because the AI varicosities invariably make a reciprocal synapse back to the rod bipolar terminal. The AI amacrine cell is a wide-field GABAergic neuron, and the AII amacrine cell is a small-field glycinergic neuron, with each cell type being generally representative of the numerous other amacrine types with the same neurotransmitter. Thus, a detailed comparison of these two well-characterized cell types illustrates the diversity of structure and function shown by contrasting types of amacrine cells. The extensive literature on rod-signal circuits in the mammalian retina has been reviewed recently by Sharpe and Stockman (1999) and by Bloomfield and Dacheux (2001).

AMACRINE CELLS: SMALL-FIELD GLYCINERGIC NEURONS

The AII amacrine cells have a characteristic bilaminar morphology, with a stout vertically directed primary dendrite giving rise to a necklace of delicate lobular appendages in sublamina *a* of the inner plexiform layer, before branching to form a conical arborization in sublamina *b* (Famiglietti and Kolb, 1975). The AII amacrine cells receive extensive excitatory input from rod bipolar cells terminating deep in sublamina *b*, and the ON-signal in the AII cells is then fed into cone bipolar cells. In sublamina *a*, the lobular appendages make sign-inverting inhibitory synapses with OFF-center cone bipolar cells, whereas in strata 3 and 4 of sublamina *b*, the arboreal dendrites make sign-conserving electrical synapses with ON-center cone bipolar cells (Kolb, 1979; Sterling et al., 1988; Strettoi et al., 1992). Thus, the cone bipolar cells are both second-order neurons in the photopic pathway and fourth-order neurons in the scotopic pathway. In contrast to the cone signal, where the ON- and

OFF-pathways are established in the outer plexiform layer, the rod signal is not directed to separate ON and OFF pathways until the inner plexiform layer (see Chapter 18). The cone bipolar cells piggyback the rod signal, carrying it both to the ganglion cells and to the interposed circuitry that underlies complex visual processing in the inner retina (Strettoi et al., 1992).

Although the level of endogenous glycine in AII amacrine cells is relatively low compared to most glycinergic amacrine cells (Pourcho and Goebel, 1987; Wright et al., 1997), the AII cells clearly use glycine as their neurotransmitter because the glycine transporter GLYT1 is strongly expressed in the cell membrane (Vaney et al., 1998) and the output synapses on the lobular appendages are presynaptic to the $\alpha 1$ subunit of the glycine receptor (Sassoè-Pognetto et al., 1994). Correspondingly, application of the glycine antagonist strychnine blocks the scotopic light response in OFF-center ganglion cells, as would be expected if the ON response in the AII amacrine cells is sign inverted at a glycinergic synapse (Müller et al., 1988).

Under dark-adapted conditions, the AII amacrine cells show a strong center-surround organization of the receptive field, responding to center illumination with a transient-sustained depolarization and to surround illumination with a steady hyperpolarization (Dacheux and Raviola, 1986; Nelson, 1982). Under light-adapted conditions, the center responds to both the ONset and OFFset of light, apparently reflecting cone bipolar inputs mediated by both the heterologous gap junctions with arboreal dendrites (ON response) and ribbon synapses onto the lobular appendages (OFF response). It is unclear how the responses elicited under light-adapted conditions contribute to the processing of cone signals and whether these would degrade the acuity of the cone bipolar pathways (Dacey, 1999; Xin and Bloomfield, 1999).

There are over 500,000 AII cells in the retina of the cat or rabbit, accounting for ~11% of all amacrine cells (Vaney, 1985; Vaney et al., 1991). The dendritic-field size of the AII amacrine cells decreases with increasing density, which reaches a maximum of 5000 cells/mm² in the cat central area and 3000 cells/mm² in the rabbit visual streak. The lobular appendages of neighboring AII cells tile the retina with minimal overlap and therefore the lobular-appendage field is only ~20 μ m wide in the central retina. The arboreal dendrites spread further, typically showing a two- to four fold coverage of their dendritic fields. In the macaque retina, the AII amacrine cells have a peak density of ~5000 cells/mm² in the perifovea, suggesting that the central scotopic acuity is limited by the sampling density of the AII cells (Mills and Massey, 1999; Wässle et al., 1995).

In keeping with this interpretation, the receptive field of rabbit AII amacrine cells is only slightly larger than the

dendritic field under both dark-adapted and light-adapted conditions (Bloomfield et al., 1997). However, under intermediate conditions in the light-sensitized retina, the receptive-field center increases about sixfold in diameter, and this reflects increased electrical coupling through the homologous gap junctions that connect the arboreal dendrites of neighboring AII cells (Kolb and Famiglietti, 1974; Strettoi et al., 1992). Both the homologous and heterologous gap junctions are permeable to small biotinylated tracers, and this enables changes in the coupling to be assessed microscopically (Vaney, 1991). Bloomfield and colleagues (1997) showed that the changes in receptive-field size under different lighting conditions are closely mirrored by changes in the extent of tracer coupling. The homologous gap junctions between AII cells are uncoupled by exogenous dopamine (Hampson et al., 1992), and it has been proposed that endogenous dopamine underlies the constriction of the AII receptive field in the light-adapted retina, but it has yet to be demonstrated that dopaminergic antagonists affect either the receptive-field size or the extent of tracer coupling.

Two properties of the AII cells appear to be representative of the glycinergic amacrine cells in the mammalian retina. First, it appears that all glycinergic amacrine have small- or medium-sized dendritic trees, which show only limited dendritic-field overlap (Menger et al., 1998; Pourcho and Goebel, 1985; Wright et al., 1997). Second, the dendrites of glycinergic amacrine cells are not confined to a single stratum but typically connect bipolar cells and/or ganglion cells branching in two or more strata of the inner plexiform layer. In particular, most of the glycinergic amacrine cells have the capacity to integrate information between the ON- and OFF-sublaminae.

AI AMACRINE CELLS: WIDE-FIELD GABAERGIC NEURONS
Electronmicroscopy of the cat retina showed that the AI varicosities providing the reciprocal input to the rod bipolar terminals are connected by very fine intervaricose dendrites of ~0.1 μ m diameter (Kolb, 1979; Kolb and Famiglietti, 1974). Parallel Golgi studies identified the wide-field A17 amacrine cell as the probable morphological correlate of the AI amacrine cell (Kolb et al., 1981), and this was confirmed by electron microscopy of A17 cells that had been filled with horseradish peroxidase after their light responses were recorded (Nelson and Kolb, 1985). The A17 amacrine cell gives rise to a spray of fine beaded dendrites, which cover a field of 600 to 2000 μ m diameter (Fig. 25.1). Proximal to the soma, the dendrites spread diffusely throughout the inner plexiform layer but, more distally, they are essentially unistratified deep in sublamina *b*. Small round varicosities are located every 10 to 50 μ m along the dendrites and may number 1000 or more in a single cell.

The AI processes are homologically coupled by small gap junctions (Kolb and Famiglietti, 1974) and, following intra-

FIGURE 25.1 Reciprocal rod amacrine cells. *Top*, drawing of a Neurobiotin-filled AI (A17) amacrine cell in the cat retina. *Bottom*, somatic array of AI amacrine cells in the central area of the cat retina, labeled by homologous tracer coupling following the injection of Neurobiotin into two AI cells at the bottom-left and top-right of the field (D. I. Vaney, unpublished).

cellular injection with Neurobiotin, tracer coupling reveals the local population of A17 amacrine cells, whose density ranges from 300 cells/mm² in the far periphery of the cat retina to ~2500 cells/mm² in the central area (Vaney, 1996). The high cell density coupled with the large dendritic fields produces an extraordinarily high dendritic-field overlap: each point on the cat retina is covered by ~700 A17 amacrine cells and about 1 million of their varicosities are packed into each square millimeter of retina. This high density of varicosities is readily accounted for when it is considered that there are 40,000 rod bipolar cells/mm² in the central area and each rod bipolar terminal has ~30 ribbon synapses, some 75% of which are presynaptic to indoleamine-accumulating varicosities thought to arise from A17 amacrine cells (Freed et al., 1987; Holmgren-Taylor, 1982; McGuire et al., 1984).

Retinal amacrine cells that appear morphologically similar to the A17 amacrine cell have been described in a variety of mammals. In the rabbit retina, there are two distinct types of reciprocal rod amacrine cells, which have been termed S1 and S2 amacrine cells (Sandell and Masland, 1986; Vaney, 1986). Both types selectively accumulate indoleamines, and together they account for almost all of the varicosities that are reciprocal to the rod bipolar ribbons (Sandell et al., 1989). The S1 and S2 amacrine cells differ in their dendritic-field diameter, the initial course of their dendrites, and the form of their varicosities, but it is not clear which of the two cell types should be considered homologous to the A17 cell. The amacrine cells in the cat retina have not been investigated as systematically as those in the rabbit retina, and it is possible that the A17 amacrine cells may comprise more than one cell type; alternatively, the 25% of reciprocal varicosities that do not accumulate indoleamines in the cat retina may arise from a cell type—such as the A13 amacrine cell—that is homologous to one of the two types in the rabbit retina (Kolb and Nelson, 1996; Vaney, 1990).

The reciprocal rod amacrine cells (A17, S1/S2 cells) respond to light with a transient-sustained depolarization and the receptive field recorded at the soma is coextensive with the dendritic field (Bloomfield, 1992; Nelson and Kolb, 1985). These cells contain elevated levels of GABA (Osborne and Beaton, 1986; Pourcho and Goebel, 1983), and they appear to provide inhibitory feedback at the reciprocal synapse to the rod bipolar terminals, mediated predominantly by GABA_C receptors but probably also by GABA_A receptors (Bloomfield and Xin, 2000; Fletcher and Wässle, 1999; Hartveit, 1999). Although intracellular recordings indicate that the rod bipolar cells do not have a receptive-field surround generated in the outer plexiform layer, the inhibitory feedback from the reciprocal rod amacrine cells creates a surround at the level of the rod bipolar terminals, and pharmacological experiments

indicate that this is the source of the OFF-surround in the dark-adapted AII amacrine cells (Bloomfield and Xin, 2000).

There are interesting parallels between the neuronal circuits underlying the generation of the receptive-field surround in the photopic and scotopic pathways. In the photopic pathway, inhibitory feedback from horizontal cells to the cone photoreceptor terminal creates a surround before the OFF-center cone signal is split into separate OFF and ON pathways through the action of sign-conserving and sign-inverting glutamatergic synapses on the OFF- and ON-center cone bipolar cells, respectively (see Chapter 18). In the scotopic pathway, inhibitory feedback from the reciprocal rod amacrine cells to the rod bipolar terminal creates a surround before the ON-center rod signal is passed onto the AII amacrine cells and then split into the separate OFF and ON pathways through the action of sign-inverting glycinergic synapses and sign-conserving electrical synapses. It is not clear why two types of reciprocal rod amacrine cell are required in the rabbit retina, although the same can also be said for the two types of horizontal cells which, like the S1 and S2 amacrine cells, appear to differ primarily in the size of their receptive fields (Bloomfield and Miller, 1982; Hack and Peichl, 1999).

The AI amacrine cells are typical of other wide-field GABAergic amacrine cells in that they appear to rely on actively propagated sodium spikes to transmit synaptic signals along their dendrites and, consequently, the application of tetrodotoxin reduces both the receptive field of the AI amacrine cells and the surround response of the AII amacrine cells (Bloomfield, 1992; Bloomfield and Xin, 2000; Hartveit, 1999). Other wide-field amacrine cells usually branch in only one stratum of the inner plexiform layer and, therefore, the diffuse form of the AI cells appears atypical at first sight. However, electron microscope and physiological studies indicate that these cells are functionally unistratified, in that they interact directly with only one cell type in the vertical retinal pathways, namely the rod bipolar cells. The AI amacrine cells also receive input throughout the inner plexiform layer from other types of amacrine cells, but it is not known how this modulates the reciprocal interactions with the rod bipolar cells (Nelson and Kolb, 1985; Sandell et al., 1989).

RECIPROCAL CONE AMACRINE CELLS The ribbon synapses of cone bipolar cells are also presynaptic to a pair of processes, one of which is typically a GABAergic amacrine varicosity that makes a reciprocal synapse back to the cone bipolar terminal (Pourcho and Owczarzak, 1989). It might be expected that each type of cone bipolar cell would be served by a reciprocal amacrine cell with morphology comparable to that of the reciprocal rod amacrine cell, thus enabling the output of the bipolar terminal to be modulated

by the activity in surrounding bipolar cells of the same type. Moreover, it might also be expected that the reciprocal cone amacrine cells would come in paramorphic pairs serving the OFF- and ON-center cone bipolar cells in sublamina *a* and *b*, respectively. For example, one pair of amacrine cells could provide reciprocal input to the bipolar cells synapsing on transient alpha ganglion cells, and another pair could provide reciprocal input to the bipolar cells synapsing on sustained beta ganglion cells. However, the only well-characterized pair of GABAergic amacrine cells are the ON- and OFF-center starburst cells, which co-stratify with the ON-OFF direction-selective ganglion cells, but the starburst amacrine cells do not appear to provide reciprocal input to the bipolar cells that drive the neurons (Famiglietti, 1991).

Contrary to these expectations, the few reciprocal cone amacrine cells that have been identified are surprisingly heterogeneous in morphology, including some small-field and/or glycinergic types in addition to the expected wide-field GABAergic types (Kolb, 1997; Sassoè-Pognetto et al., 1994; Strettoi et al., 1992). However, the functions of the reciprocal cone amacrine cells appear to be different from those of the reciprocal rod amacrine cell, given that the surround of cone bipolar cells appears to be generated in the outer retina, and this will be reflected in differences in their morphology. Although it appears that spiking amacrine cells do contribute to the generation of the surround in retinal ganglion cells (Cook and McReynolds, 1998; Roska et al., 2000; Taylor, 1999), this may reflect feedforward inhibition onto the ganglion cells rather than feedback inhibition to the bipolar terminals (see Chapter 23).

Morphological diversity of amacrine cells

Cajal (1893) described three main categories of amacrine cells: the diffuse cells were subdivided into small and large varieties, and the stratified and bistratified cells were first subdivided according to their level of branching, and then by differences in their size and dendritic morphology. The Golgi-stained retinas were usually cut in vertical sections, making it impossible to trace the full extent of medium- and wide-field neurons. Thus, Cajal's original reports of the great neuronal diversity in the inner retina were not substantiated until the 1970s, when several researchers developed methods for staining whole-mounted retinas.

In these studies, the Golgi-impregnated neurons were sorted into separate types based on their dendritic branching pattern, stratification level, and dendritic-field size. Kolb and colleagues (1981) identified 22 different types of amacrine cells in the cat retina, and subsequent studies have identified as many as 26 types in the primate retina (Kolb et al., 1992; Mariani, 1990) and 70 types in the teleost retina (Wagner and Wagner, 1988). Moreover, Golgi staining is rather capricious, and some amacrine types were repre-

sented by only one or a few labeled cells; apart from the problems of characterizing a neuronal type with so few cells, probability alone indicates that some other types of amacrine cells would be missing from the sample. Because of the qualitative nature of these Golgi-impregnation studies, the extraordinary neuronal diversity that they revealed was not accepted widely until other means were found to validate individual types of amacrine cells, usually by methods that specifically stained a whole population of cells.

More recently, Masland and colleagues have developed a noncapricious alternative to Golgi staining in which a fluorescent product is created within an individual cell by focal irradiation of its nucleus (MacNeil and Masland, 1998; MacNeil et al., 1999). This "photofilling" technique had a 94% success rate when 261 amacrine cells in the rabbit retina were targeted systematically, with the only bias imposed by the oversampling of neurons with larger cell bodies. The photofilled neurons were then sorted by criteria similar to those used in Golgi studies, with no account taken of their relative frequencies. A total of 28 amacrine cell types were distinguished by this method, and almost all of these types could be identified in a parallel sample of 208 Golgi-impregnated amacrine cells (Fig. 25.2).

MacNeil and colleagues (1999) used the relative frequencies of the photofilled types to derive their cell densities and then calculated the retinal coverage of each type by multiplying the cell density by the mean dendritic-field area. This indicated that every type of small- and medium-field amacrine cell covered at least 80% of the retina and thus met an important criterion for a neuronal type established from previous studies on other classes of retinal neurons. This provided independent validation that the neuronal diversity of the amacrine cells had not been overestimated in the photofilled catalogue, but does allow for the possibility that some amacrine cell types with multiple coverage of the retina might actually comprise more than one natural type.

The 24% of the photofilled amacrine cells that had wide-field dendritic trees (>200 μ m diameter) were sorted into 10 types (MacNeil et al., 1999), but this should be regarded as a minimum estimate for two reasons. First, the photofilling technique poorly labels both the distal dendrites of wide-field cells and the very thin intraretinal axons produced by some cell types, making it difficult to appreciate fully the morphological diversity of the wide-field amacrine cells. Second, some types of wide-field cells account for only one amacrine cell in a thousand (Vaney, 1990) and could easily be missed in a random sample of 261 cells; this appears to be the case for the type 2 catecholaminergic cells found by Tauchi and colleagues (1990). The random injection of rabbit amacrine cells with Neurobiotin has revealed at least five types of wide-field amacrine cells that are not present in

FIGURE 25.2. Amacrine cells of the rabbit retina. Schematic drawing of the different types of amacrine cells identified by MacNeil and colleagues (1999) using the photofilling technique. The cells are drawn as they would be seen in vertical section, with the somata in the inner nuclear layer and the dendrites in the inner plexiform layer. The multiple types of wide-field amacrine

cells branching in each stratum are represented by a generic cell whose dendrites have been significantly truncated. Labels mark the rod amacrine cell (AII), the reciprocal rod amacrine cell (AI), and the OFF- and ON-starburst cells (SBa, SBb). (After Masland, 2001).

the photofilled catalogue (D. I. Vaney, unpublished). It seems possible, therefore, that the number of distinct amacrine cell types in the mammalian retina may yet approach 40 (Vaney, 1990).

All of the quantitative studies lead back to the qualitative conclusion that retinal neurons with distinct dendritic morphologies are likely to comprise different cell types, subject to three important caveats. First, it is necessary to avoid creating artificial cell types based on arbitrary criteria, for example, the presence of two or three primary dendrites (Rodieck and Brening, 1983). Second, it is essential to take into account changes in morphology with retinal eccentricity and cell density, as shown by Boycott and Wässle (1974) in their classic study of ganglion cells in the cat retina. Third, the retina contains imperfections like any natural system and a small minority of retinal neurons display aberrant morphologies or make aberrant connections that are not typical of the population as a whole. For example, there are about 300 serotonin-accumulating amacrine cells in the rabbit retina that send processes into the outer plexiform layer, but they are randomly distributed and their outer retinal processes cover only 6% of the retina (Sandell and Masland, 1989; Vaney, 1990). These neurons cannot be considered a natural type because they do not have a regular spatial distribution and a uniform dendritic coverage.

ASSOCIATION AMACRINE CELLS Although it has long been known that many types of amacrine cells produce depolarizing spikes (Werblin and Dowling, 1969), it has only become apparent in the past decade that amacrine cells giving rise to axonlike processes are a regular feature of the mammalian retina. Such association amacrine cells, which were first described by Cajal (1893) in the bird retina, were the only amacrine cells to which Cajal ascribed a definite function because they showed a clear dynamic polarization, receiving input from centrifugal fibers on their cell bodies and providing output through their short axons to other retinal neurons. In the last decade, Golgi-staining and dye-injection studies have revealed that the mammalian retina contains

~10 types of association amacrine cells (Famiglietti, 1992b; D.I. Vaney, unpublished) (Fig. 25.3). Two of these cell types have been studied in particular detail; one is the classic dopaminergic amacrine cell (Dacey, 1990) and the other is a distinctive type of polyaxonal amacrine cell whose somata commonly occupy an interstitial position in the inner plexiform layer (Dacey, 1989; Famiglietti, 1992a; Stafford and Dacey, 1997).

The dopaminergic amacrine cells were the first retinal neurons to be identified neurochemically, and they have been the focus of numerous studies in the past four decades (Witkovsky and Dearth, 1992). It is thus ironic that these cells are quite atypical amacrine cells in two important respects. First, they are present at very low density; in the rabbit retina, for example, the two morphological types each account for only one amacrine cell in a thousand (Tauchi et al., 1990; Vaney, 1990). Second, they give rise to both a sparsely branched dendritic tree and a much more extensive axonal arborization, which is formed by a single axon arising near the cell body (Dacey, 1990). In both respects, the dopaminergic amacrine cells resemble the type 1 nitroergic amacrine cells (Sagar, 1986; Vaney and Young, 1988b), although the multiple axons of the latter cells arise from more distal dendrites. The axonal arbors of the dopaminergic and nitroergic amacrine cells may extend for almost 10 mm across the retina, and this accounts for the extraordinarily rich plexus revealed by tyrosine-hydroxylase immunocytochemistry and NADPH-diaphorase histochemistry, respectively.

Intracellular recordings from the interstitial polyaxonal cells, termed the A1 amacrine cells in the monkey retina (Stafford and Dacey, 1997), showed that they produce large spikes over a receptive field that matches the relatively restricted dendritic tree, suggesting that the axonal arbor serves to transmit spikes distally from initiation sites near the soma. These cells probably have a global modulatory function like the dopaminergic amacrine cells, which are thought to facilitate the transition from scotopic to photopic vision, perhaps through the diffuse release of

FIGURE 25.3. Association amacrine cells. Drawing of six types of axon-bearing amacrine cells in the rabbit retina, labeled by the intracellular injection of Neurobiotin; each cell is correctly placed with respect to its retinal eccentricity from the horizontal visual

streak. Note that the axonal arbors of these cells may span almost 10 mm of retina, thus covering one-third of the visual field (D. I. Vaney, unpublished).

dopamine from the axonal arbor (Witkovsky and Deary, 1992). In some vertebrates, the dopaminergic axonal arbor extends to the outer plexiform layer (Dowling and Ehinger, 1975) but, in other respects, these dopaminergic interplexiform cells are clearly homologous to the dopaminergic amacrine cells found in other retinas. Thus the interplexiform cells should not be considered as a separate class of retinal neurons but rather as a subgroup of the association amacrine cells.

TRACER-COUPLING STUDIES Cell types that account for only a few amacrine cells in every thousand are encountered so infrequently by random labeling methods that other means must be found to characterize them. For example,

many of the association amacrine cells have comparatively large somata, enabling them to be preferentially targeted for intracellular dye injection. However, it is difficult to establish a cell type based on only a few labeled examples; therefore, any technique that selectively labels a whole population of amacrine cells greatly strengthens the legitimacy of the cell type. Biotinylated tracers readily pass through the gap junctions that connect retinal neurons (Vaney, 1991), and tracer coupling has proved to be a powerful tool for selectively labeling local arrays of many types of amacrine cells, both by homologous coupling following injection of a single cell and by heterologous coupling following injection of a ganglion cell or a different type of amacrine cell (Vaney, 1994a, 1999). In fact, more types of amacrine cells can be

selectively labeled by tracer coupling than by immunolabeling with presently available antisera.

The pattern of tracer coupling shown by each type of amacrine cell appears to be relatively stable in different species. For example, the dopaminergic amacrine cells show only weak homologous coupling in both cat and rabbit retinas, and the interstitial polyaxonal cells show heterologous coupling to ganglion cells in both rabbit and monkey retinas (Stafford and Dacey, 1997). Biotinylated tracers do not mask the antigenicity of intracellular epitopes in the coupled cells; therefore, a single preparation can be used to characterize the dendritic morphology, cellular array, and neurotransmitter content of a cell type (Wright et al., 1999).

Neurochemical diversity of amacrine cells

Retinal amacrine cells express a wide variety of neurotransmitters and neuroactive substances; this was critical to early progress in labeling individual populations of cells. The first retinal neurons to be identified neurochemically were several types of monoaminergic amacrine cells, which were labeled by the classic Falck-Hillarp method of formaldehyde-induced fluorescence (Ehinger, 1966; Häggendal and Malmfors, 1965). The first immunocytochemical studies were undertaken in the 1970s to study the retinal localization of neuropeptides (Brecha et al., 1979) and GABAergic markers (Lam et al., 1979). The scope of these studies was greatly extended with the development of techniques for localizing small amino-acid transmitters, both in glutaraldehyde-fixed sections and formaldehyde-fixed whole mounts (Agardh et al., 1986; Mosinger et al., 1986; Pourcho and Goebel, 1987; Pow and Crook, 1993; Pow et al., 1995). In the past decade, antisera against a range of regulatory proteins, including protein kinase C and various calcium-binding proteins, have proved valuable in selectively labeling diverse types of retinal neurons (Gábel and Straznicky, 1992; Negishi et al., 1988; Pasteels et al., 1990).

Almost all retinal amacrine cells contain elevated levels of GABA or glycine; most of the putative GABAergic cells express the GABA-synthesizing enzyme glutamic acid decarboxylase, and most of the putative glycinergic cells express the plasma-membrane glycine transporter GlyT1 (see Chapter 20). In rabbit retina, for example, a double-immunolabeling study showed that 32% of the cells in the amacrine sublayer express GABA, 62% express glycine, 2% express both GABA and glycine, and 4% express neither inhibitory transmitter (Wright et al., 1996) (Fig. 25.4). Many of the unlabeled cells are probably bipolar cells or displaced ganglion cells. Recent tracer-coupling studies have reinforced earlier evidence that different types of amacrine cells express characteristic levels of inhibitory transmitters (Pourcho and Goebel, 1985, 1987); for example, the DAPI-3 amacrine cells consistently show the

strongest glycine immunoreactivity in the rabbit retina whereas the AII amacrine cells are among the most weakly labeled of the glycine-immunopositive cells (Wright et al., 1997).

Although the glycinergic cells account for the majority of amacrine cells in the mammalian retina (Crooks and Kolb, 1992; Koontz et al., 1993; Pourcho and Owczarzak, 1991), the inner plexiform layer is dominated by the processes of GABAergic amacrine cells, which usually have much more extensive dendritic trees than the glycinergic amacrine cells (Menger et al., 1998). Correspondingly, the GABAergic cells account for 80% to 90% of the synapses made by all amacrine cells in the retina (Koontz and Hendrickson, 1990; Marc and Liu, 2000). Although inhibitory interactions in the retina are often represented as simple feedback or feedforward circuits, serial synapses between amacrine processes have long been recognized (Dowling and Boycott, 1966; Dubin, 1970). In fact, a quantitative study of the synaptic connectivity of GABAergic amacrine cells in the goldfish retina indicated that the majority of amacrine cell circuitries are relatively complex, involving nested feedback, nested feedforward, and chains of inhibition (Marc and Liu, 2000).

In many types of amacrine cells, the GABA or glycine is colocalized with another neurotransmitter, including dopamine, serotonin, acetylcholine, nitric oxide, and a diverse range of neuropeptides (Watt et al., 1984; Weiler and Ball, 1984). Such colocalization raised the exciting possibility that each cell type may be identified by a unique neurochemical signature (Lam et al., 1985), comparable to the chemical coding of enteric neurons (Costa et al., 1986). The signature hypothesis has been tested most rigorously by Marc and colleagues, who used postembedding immunocytochemistry and pattern recognition techniques to analyze quantitatively the amino-acid content of all cells in serial plastic sections of goldfish, monkey, and cat retinas (Kalloniatis et al., 1996; Marc et al., 1995, 1998). This analysis partitioned virtually all of the retinal neurons into as many as 15 "theme" classes that had statistically separable amino-acid signatures.

Although the amacrine cells in monkey retina could be divided into four GABA-dominated classes and another four glycine-dominated classes (Kalloniatis et al., 1996), this falls well short of accommodating the known morphological diversity of the amacrine cells. However, a recent study of the ganglion cells in rabbit retina showed that the seven theme classes identified from intrinsic amino-acid signals could be further divided into 14 classes, which may correspond to natural neuronal types, if both an excitation signal and soma size were also included in the parametric space (Marc and Jones, 2002). If the quantitative immunocytochemical analysis of the amacrine cells could be extended to include other parameters, including neuropeptides and the dozens of enzymes involved in neurotransmission, then it is possible

FIGURE 25.4. Almost all amacrine cells express glycine or GABA. Confocal fluorescence micrographs of a rabbit retinal whole mount immunolabeled for glycine and GABA, with the focus on the amacrine sublayer of the inner nuclear layer (L. L. Wright, unpublished).

that the number of theme classes extracted might yet approach the number of morphological types of amacrine cells.

STARBURST AMACRINE CELLS: EXCITATION AND INHIBITION
The principal cholinergic neurons in the retina are amacrine cells that have a distinctive radially symmetrical morphology, with the primary dendrites branching regularly and repeatedly to form numerous terminal dendrites that are studded with varicosities, thus giving the cells the appear-

ance of starburst fireworks (Famiglietti, 1983). The starburst amacrine cells are found throughout the vertebrates and comprise two paramorphic types, with the OFF-starburst cells stratifying in sublamina *a* of the inner plexiform layer and the displaced ON-starburst cells stratifying in sublamina *b* (Perry and Walker, 1980). The starburst amacrine cells contain and release both acetylcholine and GABA (Brecha et al., 1988; O'Malley et al., 1992; Vaney and Young, 1988a), but it is not known whether these fast-

acting excitatory and inhibitory transmitters are used at the same synapses.

In rabbit retina, the ON- and OFF-starburst cells stratify at precisely the same levels as the ON-OFF direction-selective ganglion cells (DSGCs) and, within each stratum, the dendrites of numerous overlapping starburst cells cofasciculate with those of the DSGCs (Vaney and Pow, 2000). The DSGCs receive a powerful cholinergic input (Masland and Ames, 1976), and the role of the starburst amacrine cells in the generation of direction selectivity has been the subject of many studies (Vaney et al., 2001; see also Chapter 28). The ON-OFF DSGCs comprise four subtypes that respond preferentially to image motion in one of the four cardinal ocular directions—upward, downward, forward, and backward (Oyster and Barlow, 1967). Each point on the retina is probably covered by four DSGCs of different subtypes, whereas DSGCs of the same subtype tile the retina in a highly territorial manner with little overlap of their dendritic fields (Amthor and Oyster, 1995; Vaney, 1994b).

The starburst cells receive bipolar and amacrine cell input over the whole dendritic tree, but their output to ganglion cells is confined to the varicose distal zone (Famiglietti, 1991). Vaney and Young (1988a) proposed that this proximodistal segregation of the input and output synapses could provide the spatial asymmetry necessary for the generation of direction selectivity, assuming that the dendrites on different sides of the starburst cells provided selective output to DSGCs with different preferred directions (Vaney et al., 1989).

Classic electrophysiological experiments revealed that the responses of DSGCs are both facilitated by image motion in the preferred direction and strongly inhibited by image motion in the opposite null direction (Barlow and Levick, 1965). The inhibition appears to be mediated by GABAergic amacrine cells because GABA_A-antagonists effectively abolish the direction selectivity of DSGCs (Wyatt and Daw, 1976). Given that the starburst cells contain both acetylcholine and GABA, Vaney and colleagues (1989) proposed that each DSGC could selectively receive either cholinergic input from starburst cells located on the preferred side of the ganglion cell or GABAergic input from starburst cells located on the null side (the preferred and null sides correspond to the flanks first encountered by preferred- and null-direction motion, respectively). If the two mechanisms operated together in a push-pull fashion, then a starburst dendrite pointing in one radial direction would both selectively excite a DSGC with a matching preferred direction and selectively inhibit an overlapping DSGC with the opposite preferred direction. Several related models of direction selectivity have been put forward, in which the spatial asymmetries underlying the different preferred directions are generated by a common radial amacrine cell (Borg-Graham

and Grzywacz, 1992; Grzywacz et al., 1997; Vaney, 1990; Werblin, 1991).

The experimental evidence that the starburst amacrine cells underlie the generation of direction selectivity is contradictory. In the rabbit retina, laser ablation of many ON-starburst cells on the preferred or null side of DSGCs indicated that the starburst cells facilitate the responses of DSGCs in either direction but do not mediate the null-direction inhibition (He and Masland, 1997; see also Vaney et al., 2001). In particular, the DSGCs remained unresponsive to null-direction stimuli following the laser ablation of null-side starburst cells. In the mouse retina, on the other hand, immunoablation of most starburst amacrine cells appeared to abolish direction selectivity, in that all recorded ON-OFF ganglion cells were directional in the control animals but nondirectional in the experimental animals (Yoshida et al., 2001). Moreover, the loss of retinal direction selectivity was reflected in the loss of the optokinetic eye reflex. The immunoablation experiments thus indicate that the starburst amacrine cells are central to the generation of direction selectivity, perhaps by providing the critical null-direction inhibition.

Borg-Graham and Grzywacz (1992) proposed that the terminal dendrites of a starburst amacrine cell would be activated more strongly by centrifugal image motion (away from the soma) than centripetal image motion (toward the soma). For example, a terminal dendrite on the right side of a starburst cell would be activated more strongly by a visual stimulus moving from left to right than in the opposite direction. Consequently, the release of transmitter from a terminal dendrite of a starburst amacrine cell would be directionally selective. Direct evidence for such a differential effect of centrifugal and centripetal image motion on the responses of the distal dendrites has recently been obtained from two-photon imaging of starburst cells filled with a calcium-indicator dye (Euler et al., 2002). If the dendrites on different sides of starburst cells connect selectively to DSGCs with different preferred directions, then the excitatory and/or inhibitory inputs to DSGCs should themselves be direction selective (Grzywacz et al., 1997).

Patch-clamp recordings from turtle DSGCs showed that the excitatory synaptic conductance was larger in the preferred direction than the null direction but, surprisingly, the inhibitory synaptic conductance of many of the DSGCs was also larger in the preferred direction (Borg-Graham, 2001). By contrast, patch-clamp recordings from rabbit DSGCs indicated that the synaptic inputs were almost balanced in the preferred and null directions; this result could be explained most parsimoniously if the component excitatory and inhibitory inputs were nondirectional (Taylor et al., 2000). However, more detailed studies of rabbit DSGCs now indicate that a larger excitatory synaptic conductance in the

preferred direction is coupled with a larger inhibitory synaptic conductance in the null direction (Taylor and Vaney, 2002). In addition to the presynaptic mechanisms that generate directional excitatory and inhibitory inputs, the OFF-responses displayed evidence for postsynaptic interactions between the inputs, by virtue of the fact that the inhibition was coincident with the excitation in the null direction but delayed in the preferred direction.

Fried and colleagues (2002) recently provided direct evidence that asymmetric inputs from starburst amacrine cells underlie the directional inhibitory inputs to DSGCs. They made paired recordings from a DSGC and a starburst cell and then examined how the ganglion cell responded to electrical stimulation of the amacrine cell. Their results indicate that null-side starburst cells inhibit the DSGCs but, surprisingly, that preferred-side starburst cells neither excite nor inhibit the DSGCs. Extracellular recordings had previously established that, although DSGCs cannot be driven by visual stimulation of starburst cells located beyond the dendritic tree of the ganglion cell, such stimuli do facilitate the responses produced by concurrent stimulation of the receptive-field center (Amthor et al., 1996; Yang and Masland, 1992). This led Vaney and colleagues (2001) to suggest that the glutamatergic input from the central bipolar cells somehow gates the cholinergic input from the starburst amacrine cells, either by acting presynaptically on the starburst terminals or postsynaptically on the ganglion cell dendrites. Thus it is possible that electrical stimulation of a preferred-side starburst cell might excite the DSGC if accompanied by concurrent stimulation of the central bipolar cells.

Therefore it is conceivable that the starburst amacrine cells could mediate the larger excitation in the preferred direction as well as the larger inhibition in the null direction. However, the push-pull starburst model of direction selectivity is challenged by several lines of evidence indicating that the starburst cells provide symmetrical cholinergic input to the DSGCs (reviewed by Vaney and Taylor, 2002). It is clear that the spatial and temporal characteristics of the excitatory and inhibitory inputs to DSGCs need to be examined in greater detail, using pharmacological methods to dissect the glutamatergic and cholinergic contributions to the excitation. The developmental mechanisms that would enable each of the four subtypes of DSGCs to receive spatially appropriate inputs from a single starburst cell are certain to be the subject of intensive investigation. When the cotransmission model of direction selectivity was first proposed, Vaney (1990) noted “the concept that pronounced functional asymmetries may be derived from the most symmetrical neurons in the retina is not without irony.” What is now clear is that the radial symmetry of the starburst amacrine cells is probably fundamental to generating the asymmetrical responses of DSGCs.

More structures than functions?

Although it is clear that the functional diversity of retinal amacrine cells is as broad as the morphological diversity, we are still faced with the problem that troubled Cajal (1933): namely, that there appear to be many more types of amacrine cells than required functions. Those amacrine types that have been studied in particular detail—including the AI, AII, dopaminergic, and starburst cells—perform quite distinct tasks, suggesting that the functions of other amacrine types are equally specialized (Masland, 2001). However, it is unclear whether the function of each amacrine type is narrowly restricted, even for cells that have been well characterized. For example, why are there two types of AI cells in the rabbit retina? What is the function of the AII cells in the light-adapted retina? Why do the dopaminergic cells contain GABA? Can the starburst cells excite ganglion cells in a paracrine fashion?

It is not even clear why half the amacrine cells use glycine and the other half use GABA, although it has been proposed that the diversity of inhibitory transmitters and their receptors may reduce cross-talk between adjacent synapses. This hypothesis is not compelling given that there does not appear to be significant cross-talk within the GABAergic circuitry that produces the directional responses of the four subtypes of DSGCs. However, the differences in the dendritic morphology of the glycinergic and GABAergic amacrine cells are clear enough. The glycinergic cells have small- or medium-field dendritic trees that typically occupy two or more strata of the inner plexiform layer; therefore, they can facilitate interactions between the parallel pathways established by the different types of cone bipolar cells. In other words, the glycinergic amacrine cells seem designed to mediate “vertical inhibition” in the retina (Roska and Werblin, 2001). The GABAergic amacrine cells, by comparison, seem designed to mediate the “lateral inhibition” that has normally been attributed to amacrine cells, either via the GABA_C-dominated feedback inhibition of bipolar cells or the GABA_A-dominated feedforward inhibition of ganglion cells and other amacrine cells (Roska et al., 2000).

Whether the inhibition is directed vertically or laterally, the potential connectivity of each type of amacrine cell is limited by its dendritic stratification, which alone imposes substantial functional diversity on the amacrine cells. However, no wiring diagram of the retina could predict the extraordinary morphological diversity of the amacrine cells, suggesting that many subtle aspects of amacrine structure and function have so far eluded us.
