26 Ganglion Cells in Mammalian Retinae

PAUL R. MARTIN AND ULRIKE GRÜNERT

IT IS CUSTOMARY to describe the ganglion cells as the output neurons of the retina. By this is meant that trains of action potentials in the axons of ganglion cells carry encoded messages from the eye to the brain. These messages give rise to conscious visual perception and also contribute to diverse, nonconscious aspects of visual function, including eye movements, modulation of attention, and entrainment of the circadian rhythm. This chapter gives an introduction to the basic morphological and functional properties of ganglion cells in the mammalian retina. Special attention is given to the dominant ganglion cell classes in the primate visual system.

Morphological properties

HISTORY Structural analysis of the eye began with the Greek and Arab anatomists, but identification of the cellular elements of the retina was dependent on the development of microscopic technology and histological methods in the eighteenth and nineteenth century. Polyak's historical review (1941) attributes to G. R. Treviranus (1836–1838) the first description of ganglion cells. Treviranus described a subset of “papillae” (presumed to be the photoreceptive terminals of the optic nerve fibers) on the vitreal surface of the retina. The major direction for retinal signal flow—from photoreceptors to the optic nerve—was substantially agreed upon by the end of the nineteenth century by the German and Italian anatomists led by Corti, H. Müller, and Kölliker. In these decades the retina became the object of intense scientific scrutiny, as proponents of the *neuronal* and *reticularist* schools attempted to answer “the basic problem of the intrinsic organisation of the nervous system: reciprocal or mutual relationship of the nervous elements” (Polyak, 1941, p. 169). The evidence and forceful arguments of Cajal prevailed, to give the first clear expression of the modern view: each ganglion cell is an independent functional entity, which forms the final link in a chain of synaptic connectivity beginning with the photoreceptors (Cajal, 1893; for qualifications to this view, see Chapters 17 and 25). Cajal's second major contribution to understanding ganglion cells was the delineation of diverse morphological types, with distinct patterns of dendritic arborization within the inner plexiform layer (Figure 26.1A). In this discovery is the germ of the modern view that the retinal ganglion cells comprise functionally distinct neuronal populations. The different types of ganglion

cells are specialized to encode, in parallel, signals about distinct aspects of the spatial, temporal, and spectral composition of the retinal image.

MORPHOLOGY AS A GUIDE TO FUNCTION Understanding the variety of morphologies presented by ganglion cells has been improved by assuming that there exist multiple natural types¹ of ganglion cell, each of which is present throughout the retina (Rodieck, 1972; Rodieck and Brening, 1983; Stone, 1983; see also Chapters 25 and 30). Members of a given cell type all show consistent features. Some of these features remain constant throughout the retina (e.g., the brain nucleus where the ganglion cell axon terminates); others show systematic variation (e.g., the size of the dendritic tree). Such variation can lead to systematic variation in functional properties and ultimately to variation in the visual functions that rely on the activity of that cell type.

A simplified catalogue of ganglion cell types defined in this way is nevertheless large. More than a dozen natural types of ganglion cell have been distinguished in the retinas of the mammalian species studied in detail (Boycott and Dowling, 1969; Kolb et al., 1992; O'Brien et al., 2002; Rockhill et al., 2002; Watanabe and Rodieck, 1989), and the extent to which homologies can be drawn between functional classes in species of different orders remains controversial (Shapley and Perry, 1986; see Chapter 31). But substantial insight has been gained by addressing two major questions. First, which properties of each ganglion cell type remain constant throughout the retina? Second, which properties are variable? The following discussion will focus on the primate retina as both exemplifying general principles and being most relevant to understanding the visual capacity of humans.

GANGLION CELL TYPES IN THE PRIMATE RETINA

Parasol and midget cells. Polyak (1941) distinguished, in Golgi studies of the primate retina, two types of ganglion cell,

¹The terms “type” and “group” are used according to Rodieck and Brening (1983), where a cell *type* occupies a unique position in a space defined by multiple parameters, whereas a cell *group* has one or more features in common but may contain multiple types. For example, in the following discussion the midget and parasol cells form separate *types*, but both belong to the *group* of ganglion cells with axons which project to the lateral geniculate nucleus.

FIGURE 26.1. *A*, signal flow in the retina (Cajal, 1893; modified from Fig. 34 in Polyak, 1941). Summary drawing made from observations of vertical (radial) Golgi-stained sections of bird retina. Rod (*R*) and cone (*C*) photoreceptors make contact with rod bipolar cells (*rB*) and cone bipolar cells (*cB*). Cone bipolar

cells are costratified with distinct types of ganglion cells (*G*) in the inner plexiform layer. *B*, *C*, ganglion cells in Golgi-stained vertical sections of macaque retina (modified from Fig. 70 in Polyak, 1941). *B*, parasol cell from the perifoveal region. *C*, midget cells at the fovea.

which he termed *parasol* and *midget* for the morphology of their dendritic arbour (Figure 26.1*B,C*). Subsequent studies using retrograde transport of injected tracer (Leventhal et al., 1981; Perry et al., 1984; Rodieck and Watanabe, 1993) showed that parasol cells form the dominant projection to the magnocellular layers of the lateral geniculate nucleus of the thalamus, whereas midget cells make up the dominant projection to the parvocellular layers. There can be little doubt that activity of these two cell types is the functional “front end” of most aspects of human conscious visual perception. Parasol and midget cells have been distinguished in the retinas of all primates studied so far (Boycott and Dowling, 1969; Ghosh et al., 1996; Leventhal et al., 1981; Perry et al., 1984; Polyak, 1941; Rodieck, 1988; Rodieck and Watanabe, 1993; Silveira et al., 1994; Yamada et al., 1996). Midget ganglion cells make up approximately 80% of the primate ganglion cell population, and parasol cells make up close to 10%.

Nonmidget, nonparasol cells. The proportion of nonmidget, nonparasol ganglion cells is small in relative terms (about 10%), but in absolute terms (probably about 100,000 cells in primate retina) they approach or outnumber the total complement of ganglion cells in most nonprimate retinas. For example, the retina of the cat probably contains about 120,000 ganglion cells (Williams et al., 1986). A wide range of morphologies is displayed by nonmidget, nonparasol cell populations; these populations are customarily described as wide field or diffuse because their dendrites are less densely branched and cover a larger region of the retina than the dendrites of parasol and midget cells at a given eccentricity

(for a summary of early morphological classification, see Rodieck, 1972, pp. 469–476).

Rapid progress has been made toward the goal of identifying natural types of ganglion cells from these other cell types. Two key technological advances have assisted this progress. First, retrograde labeling techniques allow identification of the central targets of ganglion cell populations. Each central retinorecipient nucleus gets input from only a few types of ganglion cell. The retrograde label thus acts as a “functional sieve” to reveal the morphology and mosaic properties of only a specific fraction of ganglion cells. Second, refinements to *in vitro* recording techniques allow combined functional and morphological measurements of individual neurons (Brown et al., 2000; Dacey and Lee, 1994; Demb et al., 2001; O’Brien et al., 2002). Common functional properties of a population of cells can then be tied to common morphological properties. These principles are well illustrated by the establishment of small bistratified ganglion cells as a natural type in primate retina, as follows.

Small-field bistratified cells. Delineation by Rodieck (1991) and Dacey (1993) of a parvocellular-projecting, bistratified ganglion cell type in macaque and human retina, with a dendritic arbor slightly larger than that of parasol cells, was closely followed by the discovery (Dacey and Lee, 1994) that the small-field bistratified cell corresponds to the “blue-ON” cell known from extracellular *in vivo* recordings in the retina and lateral geniculate nucleus (Derrington et al., 1984; Gouras, 1968). Small bistratified cells and blue-ON type responses have been identified in several primate species,

with the possible exception of the (nocturnal) owl monkey *Aotus*, suggesting that this functional system is common to diurnal primates (Dacey, 1993; Ghosh et al., 1996; Rodieck and Watanabe, 1993; Yamada et al., 1996). Direct correlation of morphology with function has only been made in macaque (Dacey and Lee, 1994). The basis of chromatic selective responses in small bistratified cells is treated elsewhere in this volume (see Chapter 64).

Other wide-field cell types. The central projections and morphological features of several distinct groups of wide-field ganglion cells in primate retina have been delineated (Boycott and Dowling, 1969; Kolb et al., 1992; Peterson and Dacey, 2000; Polyak, 1941; Rodieck and Watanabe, 1993; Telkes et al., 2000; Yamada et al., 1996), but their functional properties remain poorly understood, especially when compared to the analyses recently completed for essentially all ganglion cell types in cat and rabbit retina (O'Brien et al., 2002; Rockhill et al., 2002). One recent and important exception is the delineation of a wide-field class projecting to olivary pretectal nucleus in macaque (Gamlin et al., 2001); this cell shows nonadapting, sustained response to maintained illumination. It remains to be established whether this cell type, like the melanopsin-containing ganglion cell that projects to the suprachiasmatic nucleus (Hattar et al., 2002), attains nonadapting response to ambient light level by intrinsic phototransduction.

SYNAPTIC INPUT TO GANGLION CELLS Multiple types of bipolar and amacrine cells have been distinguished in all mammalian retinas studied so far (Chapter 25). The major excitatory neurotransmitter used by bipolar cells is glutamate, whereas amacrine cells use the inhibitory transmitters GABA and/or glycine. Glutamate, glycine, and GABA_A receptors are present throughout the dendritic tree of both midget and parasol ganglion cell types (Lin et al., 2002; Macri et al., 2000). Figure 26.2 compares the distribution of glutamate and GABA_A receptors on the dendritic tree of two parasol cells. Such light microscopic data are consistent with electronmicroscopic data suggesting parasol cells receive 80% of their synaptic input from amacrine cells and 20% from bipolar cells. By contrast, midget ganglion cells receive closer to 50% of their input from amacrine cells and 50% from bipolar cells (Calkins et al., 1994; Kolb et al., 1992).

Dendritic field stratification. Both Polyak (1941) and Boycott and Dowling (1966), in Golgi studies of primate retina, used the pattern of dendritic stratification in the inner plexiform layer as a defining characteristic for ganglion cell types. The pattern of dendritic stratification remains relatively constant throughout the retina (Watanabe and Rodieck, 1989). Because the absolute width of the inner plexiform layer varies with distance from the fovea, it is customary to express

FIGURE 26.2. Neurotransmitter receptors on ganglion cells. Computer reconstruction of the dendritic tree of Neurobiotin-injected parasol cells in marmoset retina. Retinas were processed for immunoreactivity to neurotransmitter receptor subunits: AMPA receptor GluR1 subunit (A); glycine receptor all subunits (B). Solid black circles show colocalized receptor clusters on the ganglion cell dendrites. Large gray circle shows the position of the cell somata. Both receptor types are distributed throughout the dendritic tree; the density of colocalized glutamate receptors is lower than that of colocalized glycine receptors. (Data from Lin, et al., 2000 and Lin et al., 2002.)

the depth of stratification as a percentage of the distance between the inner nuclear layer and the ganglion cell layer. In primate retina, midget cells form two subtypes, which stratify close to 15% and 75% depth; parasol cells form two subtypes, which stratify closer to the center of the inner plexiform layer around 33% and 66% depth (Calkins et al., 1994; Ghosh et al., 1996; Watanabe and Rodieck, 1989).

Wide-field ganglion cell types in primate retina display a variety of stratification patterns: some have dendrites restricted to a small range of depth in the inner plexiform layer, others have multiple layers of dendritic stratification, or dendrites that range in an apparently unconstrained way throughout the inner plexiform layer (Boycott and Dowling, 1969; Dacey, 1993; Kolb et al., 1992; Peterson and Dacey, 2000). Surveys of ganglion cell morphology in nonprimate mammalian retina (O'Brien et al., 2002; Rockhill et al., 2002) likewise show stereotyped patterns of dendritic stratification for each natural cell type. The functional significance of dendritic stratification is thought to lie in selectivity for synaptic input to ganglion cells from distinct classes of bipolar and amacrine cells.

Bipolar cell connectivity. Over 10 different bipolar cell types have been distinguished in primate retina (Boycott and Dowling, 1969; Boycott and Wässle, 1991; Kolb et al., 1992; Rodieck, 1988). The stratification level of bipolar dendrites is a natural constraint on the connectivity with ganglion cells. Polyak (1941) suggested that one-to-one connectivity between midget ganglion cells and midget bipolar cells in the fovea could be the anatomical substrate for high spatial resolution vision. Electron microscopic reconstruction of midget bipolar–ganglion cell pairs has confirmed that the great majority of bipolar synapses to each midget ganglion cell in the fovea derive from a single midget bipolar cell (Calkins et al., 1994; Kolb et al., 1992). Data from other cell types suggests that this “tidy” pattern of connectivity may be unique to the midget system in the foveal retina. Outside the fovea, the dendritic field diameter of midget cells encompasses the dendritic field of many midget bipolar cells. This implies neural convergence from midget bipolar cells to ganglion cells. Data from electronmicroscopic reconstructions of cat ganglion cells (see Chapter 17) also show divergence of bipolar to ganglion cell connections, so a bipolar cell may share its output among several ganglion cells. Electron microscopic analysis of parasol and small-field bistratified cells further shows that there is not unique connectivity between bipolar cells and ganglion cells (Jacoby et al., 2000). For example, the OFF-parasol cell derives synaptic input from two diffuse bipolar cell classes DB3 and DB2 (Jacoby et al., 2000). In summary, “type-to-type” costratification of ganglion cell dendrites with bipolar cell axon terminals gives strong probability of connectivity, but does not mean there is a devoted synaptic circuit.

ECCENTRICITY-DEPENDENCE OF MORPHOLOGY The idea that each natural ganglion cell type shows systematic morphological variation as a function of eccentricity, that is, distance from the retinal locus of highest cone receptor density, was first evaluated quantitatively by Boycott and Wässle (1974) in the cat retina. Figure 26.3 shows eccentricity-

dependent change in ganglion cell morphology for the primate retina. The dendritic field diameter of both midget and parasol cells shows systematic increase with distance from the fovea. This increase is associated with decreasing numbers of each cell type, so the sensorium is completely sampled by constant “coverage” of the retina by each class, albeit with decreasing spatial precision as eccentricity increases (Peichl and Wässle, 1981; Wässle et al., 1981; Yamada et al., 1996; see Chapter 29). Evidence for this principle is given in Figure 26.4 by comparing cells at the same distance from the fovea in nasal or temporal retina. Density is higher in nasal retina, and the dendritic field diameter of both parasol and midget cells is correspondingly smaller (Ghosh et al., 1996; Perry et al., 1984; Watanabe and Rodieck, 1989). This principle is also consistent with the less marked dependence of receptive field diameter on eccentricity for nonmidget, nonparasol cells, where larger dendritic field diameter is associated with a shallower central-peripheral density gradient (Perry et al., 1984; Peterson and Dacey, 2000; Rodieck and Watanabe, 1993).

Special case of the fovea. The special case of the fovea as a specialized region for high-acuity vision was recognized in early morphological studies (Boycott and Dowling, 1969; Cajal, 1893; Polyak, 1941). This specialization gives rise not only to gross changes in the structure of the retinal layers, but also to the characteristic morphology of midget cells as originally defined by Polyak (1941). Midget cells within 9° of the fovea in all diurnal primates described so far have uniform dendritic diameter (between 5 and 15 mm) (Kolb et al., 1992; Perry et al., 1984; Watanabe and Rodieck, 1989; Yamada et al., 1996). The dendritic fields of inner and outer subtypes are tightly packed in two or three sublevels within their respective zones of stratification (Calkins et al., 1994; Perry et al., 1984). These morphological features may reflect some lower limit on the size of a ganglion cell dendritic tree; there may be a requirement to “pack” a minimum number of bipolar and amacrine synapses onto the dendritic arbor. The fovea is also an exception to the general rule that the dendritic field diameter is close to the diameter of the excitatory (center) mechanism of the receptive field: the visual acuity of midget-PC pathway ganglion cells continues to increase toward the foveola but the dendritic field size does not change (Derrington and Lennie, 1984; Perry et al., 1984).

CENTRAL PROJECTIONS There is substantial segregation of central projections of distinct cell types. For most central nuclei studied so far, the functional properties of neurons in the target nucleus are dominated by the properties of the afferent ganglion cells. For example, the properties of most neurons in the magnocellular layers of the lateral geniculate nucleus (small receptive field, high sensitivity

FIGURE 26.3. Eccentricity dependence of ganglion cell morphology. Drawings from Neurobiotin-labeled ganglion cells in marmoset retina. Whole-mount view. Upper row, midget cells; lower

row, parasol cells. Dendritic field diameter of both cell classes increases with distance from the fovea. Arrows point to axons. (Modified from Ghosh et al., 1996, Fig. 5.)

FIGURE 26.4. Dendritic field diameter of parasol and midget cells in macaque retina. Data from horseradish peroxidase-labeled ganglion cells in macaque retina. At any given distance from the fovea the parasol cells have larger dendritic field than midget cells. Cells at a given eccentricity in nasal retina (filled circles) have smaller dendritic field diameter than cells at the same eccentricity in the temporal, upper, and lower quadrants of the retina (open circles). Regression line refers to parasol cells in temporal, upper, and lower quadrants. (Modified from Watanabe and Rodieck, 1989).

to achromatic contrast, high sensitivity to rapid movement) are also properties of the parasol ganglion cells, which project to the magnocellular layers (Croner and Kaplan, 1995; De Monasterio and Gouras, 1975; Derrington and Lennie, 1984; Lee et al., 1990; Wiesel and Hubel, 1966). The central target is thus key for delineating natural types of ganglion cells, but there is also imprecision in this wiring scheme. The axons of some ganglion cell types do branch to innervate more than one central nucleus, and some central nuclei receive afferent projections from more than one ganglion cell type. Two examples follow. First, the axons of the alpha ganglion cell class in cat retina branch to innervate both the lateral geniculate nucleus and the superior colliculus (Illing and Wässle, 1981). Second, the dominant input to the parvocellular division of the primate lateral geniculate is from midget cells, but a proportion of wide-field cells and some small-bistratified ("blue-ON") cells project to the parvocellular layers (Derrington et al., 1984; Leventhal et al., 1981; Perry et al., 1984; Rodieck and Watanabe, 1993; White et al., 1998). Definition of ganglion cell classes by their projection target alone (Shapley and Perry, 1986) should thus be regarded as a convenient simplification,

which applies to most but not all of the projection to any retinorecipient region of a given target nucleus.

Receptive field properties

Very soon after we started we were puzzled and greatly excited to find that uniform illumination of the retina was not the best way to influence the discharges of a ganglion cell; instead, a small spot of light was generally much more effective. Furthermore, the same spot of light could have opposite effects, depending on the exact position of the stimulus on the retina. All one had to do to convert excitation, or “on-response,” into inhibition, or “off-response,” was to shift the spot by a millimeter or less across the retina surface. (Kuffler, 1973, p. 795).

Kuffler’s statement encapsulates most of what today’s student of visual neuroscience must learn about the function of mammalian ganglion cells. First, the action potential discharge rate of each ganglion cell is directly influenced by photon flux in a restricted region of the retina. The *receptive field* of a ganglion cell thus corresponds to a region of visual space where presentation or withdrawal of light causes changes in the rate of action potentials (Barlow, 1953; Kuffler, 1953; Wiesel and Hubel, 1966). Second, the receptive field of most mammalian ganglion cells includes subregions that have opposite effects on the discharge rate of the cell. These subregions usually occupy more or less concentrically organized domains (“center” and “surround”). The rate of action potentials in the ganglion cell is determined by the balance of excitatory and inhibitory influences on the receptive field (Figure 26.5). Responses of such ganglion cells are best thought of as delivering to the brain a simple encoded signal about the local spatial derivative of photon

flux. Parallel studies by Barlow (1953) gave early evidence that there is also a rich variety of receptive field types, particularly in nonmammalian retinas, to which these simple principles do not apply. Such ganglion cells are cryptic, remaining silent until a trigger feature (or “releasing stimulus”) in the visual environment—for example, image movement in a certain direction—produces a burst of action potentials. Responses in such ganglion cells are better thought of as related to specific detection tasks for the visual system, giving rise to the idea of feature detection as a major task of retina ganglion cells (Barlow, 1953; Lettvin et al., 1959).

What have the studies of the intervening decades added to these fundamental observations? The remainder of this chapter summarizes the main advances in understanding receptive field properties of ganglion cells in mammalian retinas, with reference both to the underlying morphological features described above and to those aspects of visual function subserved by the major geniculate-projecting ganglion cell classes in primate retina. Key aspects of the functional properties of preganglion cell circuitry, the generation of ON- and OFF-type responses, and the generation of specialized properties such as direction selectivity are treated in other chapters in this volume (see Chapters 17, 18, 25, and 28). The following discussion treats ganglion cells as independent encoders of the visual scene, in which the encoded message is carried by the spike discharge rate. Evidence that correlated activity between ganglion cells and the fine structure of trains of action potentials may also convey useful additional signals to the brain is reviewed elsewhere (DeVries, 1999; Meister and Berry, 1999; Neuenschwander and Singer, 1996).

FIGURE 26.5. Receptive field map of a ganglion cell in cat retina made under direct ophthalmoscopic observation during intraocular recording. The area around the tip of the recording electrode defines three zones of the receptive field, where OFF-surround (oblique hatching), ON-center (crosses), and an intermediate zone where both ON- and OFF-responses were elicited. (Modified from Kuffler, 1953, Fig. 6).

CENTER-SURROUND ORGANIZATION Rodieck and Stone (1965) showed that responses of many ganglion cells in cat retina can be accounted for by assuming that the ganglion cell draws antagonistic input from concentrically organized regions with Gaussian distribution of sensitivity to photon flux. Despite well-recognized imperfections, the difference-of-Gaussians (DOG) model (Figure 26.6) remains most widely accepted as a simplified description of the majority of geniculate-projecting ganglion cells in primate retina.

In the midget-parvocellular and parasol-magnocellular cell types, the radius of the surround mechanism is typically 4 to 8 times larger than the radius of the center mechanism (Croner and Kaplan, 1995; Derrington and Lennie, 1984; Irvin et al., 1993; White et al., 2001). The surround mechanism increases in diameter together with the center mechanism, when passing from central to peripheral retina, so gradual uniform changes in illumination give little net response, regardless of the receptive field size or position in the retina (Croner and Kaplan, 1995; Irvin et al., 1993; White et al., 2001).

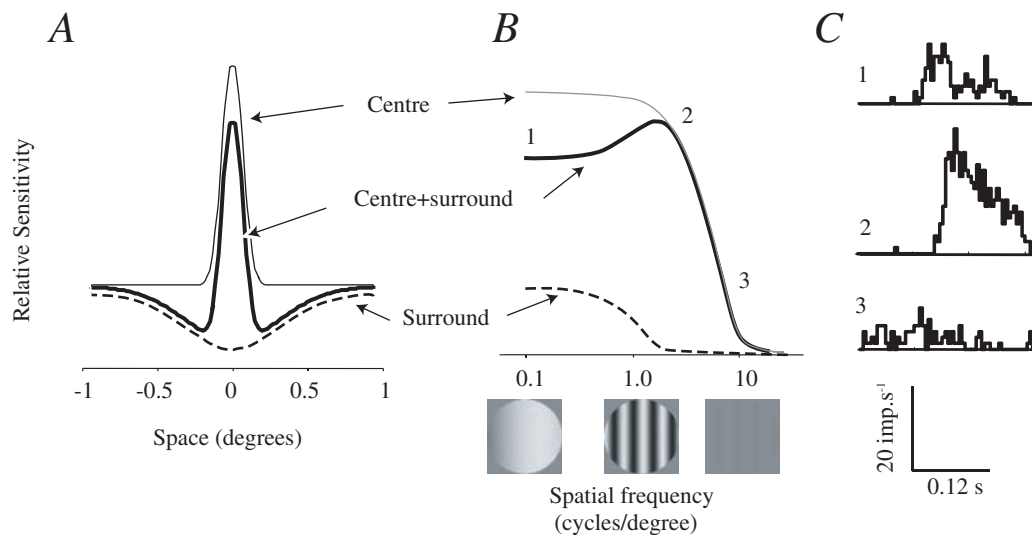

FIGURE 26.6. Difference-of-Gaussians analysis of center-surround receptive fields. *A*, space domain. Center and surround mechanisms are represented by two Gaussians with different contrast sensitivity and space constant. *B*, frequency domain. The center mechanism responds to higher spatial frequencies and is more sensitive than the surround. The frequency response curve

shows bandpass characteristic. *C*, sample peristimulus time histograms recorded from one midget-parvocellular pathway cell in the primate lateral geniculate nucleus. Responses to drifting sinusoidal gratings at the indicated spatial frequencies are shown. The peak response (2) corresponds to the lowest spatial frequency where only the center mechanism is active.

CONTRAST SENSITIVITY Spatial and temporal variations in image intensity cause variations in the discharge rate for the majority of ganglion cells. Sensitivity to such variations (expressed as the variation in discharge rate as a fraction of the variation in intensity, or contrast gain) varies between ganglion cell types. This leads to the idea that different ganglion cell types are tuned to different parts of the spatial and temporal spectrum of the retinal image (see Chapters 17 and 30). In the primate visual system, convergent results from several primate species show that achromatic contrast sensitivity of parasol cells in the retina, and of greater magnocellular cells in the lateral geniculate nucleus, is higher than the sensitivity of midget-parvocellular pathway cells. Responses of cells in the koniocellular division of the lateral geniculate nucleus are assumed to reflect predominantly the properties of nonmidget, nonparasol cells in the retina, and are more heterogeneous than the responses of parvocellular or magnocellular cells (Benardete et al., 1992; Derrington and Lennie, 1984; Irvin et al., 1993; Kaplan and Shapley, 1986; Lee et al., 1990; Norton et al., 1988; Purpura et al., 1988; Sherman et al., 1976; Solomon et al. 1999; Xu et al., 2001). Parasol-magnocellular pathway cells show response compression to high-contrast stimuli (Benardete et al., 1992; Lee et al., 1990; Purpura et al., 1988) indicative of the operation of contrast gain control mechanisms (Shapley et al., 1972). Figure 26.7 shows typical contrast-response relationships and average values for magnocellular, parvocellular, and koniocellular populations.

Two emerging general principles of concentric receptive field organization in mammalian retina are summarized

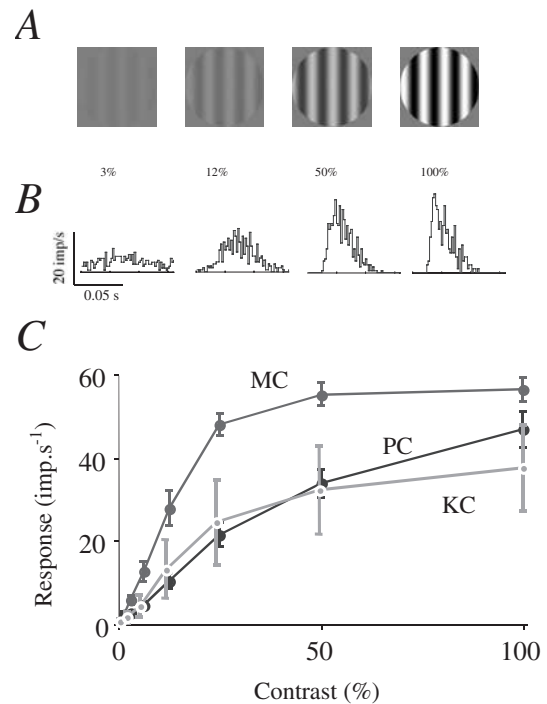

FIGURE 26.7. Contrast sensitivity. *A*, *B*, responses of one midget-parvocellular pathway cell (*B*) to drifting achromatic sinusoidal gratings at optimal spatial frequency at different contrasts (shown in *A*). *C*, average (mean \pm SEM) contrast-response functions of midget-parvocellular (PC), parasol-magnocellular (MC), and koniocellular (KC) pathway cells recorded in marmoset lateral geniculate nucleus. MC and KC cells show high-contrast sensitivity with saturated response to contrast above 50% (data from Solomon et al., 2002, and unpublished).

as follows. First, the contrast sensitivity of the surround mechanism is much lower than that of the center, but the surround integrates over a larger area (16 to 64 times the area of the center mechanism). Second, there is an approximately inverse relationship between area and peak sensitivity of both center and surround mechanisms, so the integrated “volume” of these mechanisms remains relatively constant throughout the retina (Croner and Kaplan, 1995; Irvin et al., 1993; White et al., 2001). The upshot of all this is that the influences of center and surround are rather well balanced (with the center mechanism usually dominating slightly), regardless of cell type or position in the retina. Small deviations from this general relationship confer slightly greater contrast sensitivity, especially for low spatial and high temporal frequencies, on ganglion cells in peripheral retina when compared to their central counterparts.

RELATION TO DENDRITIC FIELD AND SYNAPTIC INPUT The origin of the receptive field center is considered to lie in excitatory, glutamatergic input from bipolar cells (see Chapters 17, 18, and 21). Bipolar cell synapses are distributed

throughout the ganglion cell’s dendritic field (Cohen and Sterling, 1991; Owczarzak and Pourcho, 1999). Accordingly, there is good correspondence between the ganglion cell dendritic field and the size and shape of the receptive field center (Brown et al., 2000; Peichl and Wässle, 1981, 1983; see Fig. 26.8). However, the surround component probably originates at multiple levels of the preganglion cell circuitry. Center-surround interactions are already manifest at the level of the bipolar cell input (see Chapter 17), and direct inhibitory input from amacrine cells makes an additional contribution (Demb et al., 2001; Flores-Herr et al., 2001). Knowledge of the amacrine cells’ contribution to the inhibitory surround is still rudimentary; this is a consequence both of the morphological diversity of amacrine cells and the fact that most amacrine cell types make widespread connections within the retina (see Chapter 25). Recent data suggest that some of the inhibitory input to ganglion cells in rabbit retina depends on activation of voltage-sensitive sodium channels (“spiking” amacrine cells), and the majority of input from amacrine cells depends on GABAergic synaptic activity (Demb et al., 2001; Flores-Herr et al., 2001).

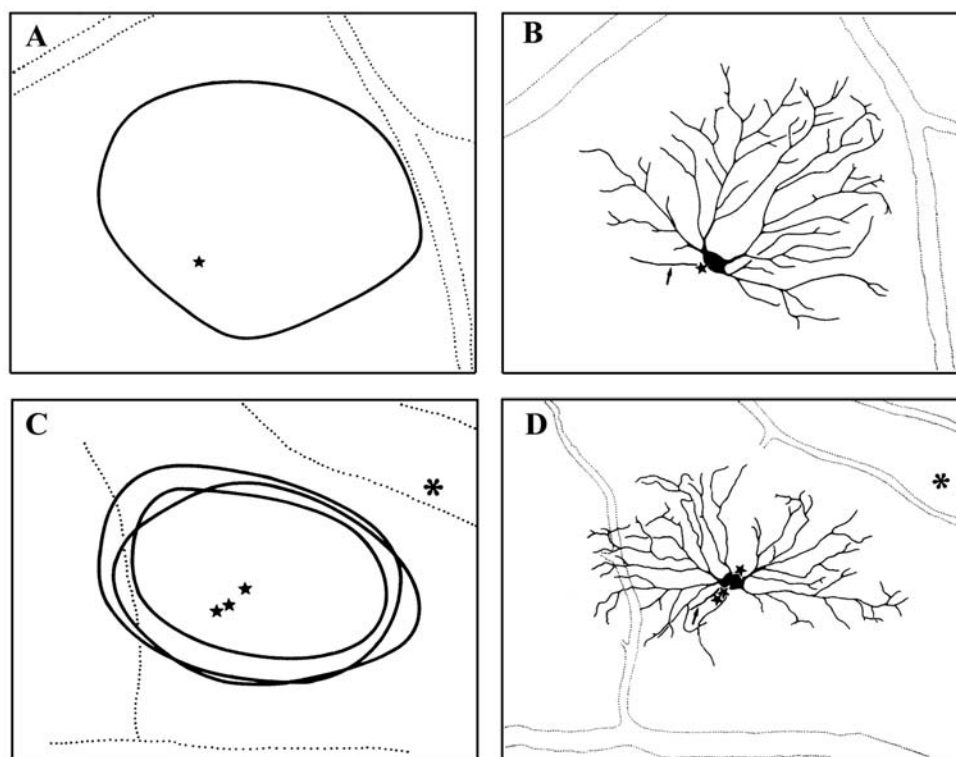

FIGURE 26.8. Correspondence of receptive and dendritic field in alpha cells in cat retina. *A, C*, solid lines show the border of the excitatory receptive field center for two alpha cells encountered in intraocular recordings. Three independent recordings were made from the cell shown in *C*. Stars mark the position of the tip of the recording electrode. *B, D*, drawings of alpha cells (identified postmortem by neurofibrillar stain of the whole-mounted retina) at

the recording sites *A* and *C*, respectively. Note the good correspondence between the size and shape of the dendritic tree and the border of the receptive field center for each cell. *Dotted lines* show borders of local retinal blood vessels. *Flower symbols* in *C* show position of an electrolytic marker lesion. (Modified from Peichl and Wässle, 1981).

LIMITATIONS OF THE DOG MODEL The DOG model may give a reasonable account of the response to spatial contrast for the many ganglion cells, but it is important to understand its limitations. First, there are many receptive fields (e.g., direction-selective cells; see Chapter 28) for which the DOG model simply does not capture the essential functional property of the receptive field. Second, even “ideal”—centrically organized, antagonistic—receptive fields may be more accurately described by *spatially finite* sensitivity functions such as the difference-of-raised-cosines (reviewed by Levick, 1996). Third, spatial sensitivity profiles of a good proportion of ganglion cells in cat, rabbit, and primate retina show deviations from the Gaussian prediction. Fine-grained analysis of the receptive field reveals that the center may contain multiple sensitivity peaks (Brown et al., 2000; Chichilnisky and Baylor, 1999; Cohen and Sterling, 1991; McMahon et al., 2000). Sensitivity within the center is only weakly correlated with the local dendritic branching density. This suggests that bipolar cell inputs, rather than local dendritic computation, create local variation in contrast sensitivity within the receptive field center (Brown et al., 2000; Cohen and Sterling, 1991). Parvocellular cells in the foveal representation in macaque geniculate show nonhomogeneous center sensitivity when assessed using laser interferometry, which bypasses the eye’s optics (McMahon et al., 2000). Because the foveal midget-parvocellular projecting ganglion cells receive input from a single midget bipolar cell, this raises the possibility that bipolar cell inputs may already have irregular receptive field structure.

ORIENTATION SENSITIVITY In the intact visual system, the sensitivity peaks arising from individual cones and bipolar cells are smoothed by combination of optical blur and by dendritic summation in the ganglion cell (Cohen and Sterling, 1991), leaving an overall mild circular asymmetry in most of the concentric receptive fields in ganglion cells and retinorecipient geniculate cells (Fig. 26.8; Leventhal and Schall, 1983; Levick and Thibos, 1982; Passaglia et al., 2002; Smith et al., 1990). In primate retina, the circular anisotropy (expressed as the length ratio of the major to minor axes of the best-fitting ellipse) is larger for midget cells (1.72) than for parasol cells (1.38); for both classes there is a tendency for the receptive fields to be oriented either radially (toward the fovea) or tangentially (Passaglia et al., 2002). These data partially corroborate morphological analyses showing only weak tendency for both midget and parasol cells to be oriented toward the fovea (Watanabe and Rodieck, 1989). The chief functional consequence of the elliptical receptive field is enhanced sensitivity to stimuli oriented along the major axis of the ellipse. Quantitative comparison of orientation bandwidth in subcortical and cortical neurons shows that subcortical orientation bias could account for the orientation

bias in the geniculorecipient layers of primary visual cortex, but that additional mechanisms are required to account for the much greater orientation selectivity of the majority of cortical neurons (Passaglia et al., 2002; Vidyasagar et al., 1996).

SPATIAL SUMMATION In contrast to the situation in many mammalian retinas, the great majority of primate ganglion cells show predominantly linear spatial summation (Kaplan and Shapley, 1982; Sherman et al., 1976; see also Chapter 17). Analyses of responses in nonprimate retina (Demb et al., 2001; Levick, 1996) give a general association of nonlinear summation properties with large receptive field dimensions. This implies that the low proportion of cells showing nonlinear spatial summation in primate vision could be a simple consequence of the dominance of midget cells, which have the smallest receptive fields described among mammalian retinas. A small proportion (<10%) of magnocellular and koniocellular pathway cells show nonlinear summation (Kaplan and Shapley, 1982; White et al., 2001, 2002; Xu et al., 2001), but within these populations there is no clear association of nonlinear response characteristic with larger receptive fields. There is evidence for multiple sites of nonlinear spatial interaction, including bipolar and amacrine cell inputs to ganglion cells (Benardete and Kaplan, 1997; Demb et al., 2001).

CHROMATIC CONTRAST SENSITIVITY Two kinds of interaction between photoreceptors can be identified in responses of ganglion cells. First, at mesopic illuminance levels there is functional interaction between synaptic inputs from rod and cone photoreceptors. These phenomena are described in detail elsewhere (see Chapter 55). There is unequivocal evidence for rod input at mesopic levels to parasol-magnocellular pathway ganglion cells (Lee et al., 1990; Lee et al., 1997; Purpura et al., 1988). Anatomical and physiological studies also suggest a smaller degree of rod input to midget-parvocellular pathway ganglion cells (Grünert, 1997; Lee et al., 1997); the degree of rod input to other ganglion cell types in primate retina may also be small (Dacey and Lee, 1994).

A second kind of chromatic interaction occurs between the different spectral classes (long-, medium-, and short-wavelength sensitive) of cone photoreceptors at photopic illuminance levels. Most of the midget-parvocellular pathway ganglion cells display opponent interactions between long- and medium-wavelength sensitive cones, whereas the small-field bistratified cells receive excitatory ON input from short-wavelength sensitive cones and antagonistic OFF input from the other cone types (Dacey and Lee, 1994; De Monasterio and Gouras, 1975; Derrington et al., 1984; Schiller and Malpeli, 1977; Wiesel and Hubel, 1966). The origin and nature of these interactions is discussed in

Chapter 64. Here it is important to note that for the midget ganglion cells these chromatic interactions are linked to center-surround antagonism, so the excitatory center mechanism derives input primarily from a single cone type, whereas the inhibitory surround mechanism derives input at least partly from the opponent cone type. By contrast, for small bistratified cells the chromatic interactions are generated through ON- and OFF-retinal pathways, so ON-excitation comes from short-wavelength cones and OFF-excitation comes from medium- and long-wavelength sensitive cones.

Receptive fields recorded in the geniculate include cells with inhibitory input from short-wavelength sensitive cones; these presumably reflect inputs from “blue-OFF” ganglion cells. Recent results from combined morphological and physiological recordings show a large, monostратified wide-field ganglion cell type may be the substrate of blue-OFF responses (Dacey et al., 2002).

Parasol-magnocellular pathway cells show some chromatic opponent interactions at low spatial and temporal frequencies (Derrington et al., 1984; Smith et al., 1992; Wiesel and Hubel, 1966), and nonlinear addition of medium- and long-wavelength sensitive cone inputs within the receptive field surround (Lee et al., 1989). Although these effects are small in comparison to the frank cone-opponent responses in midget-parvocellular and small bistratified cells, they render invalid the assumption that chromatic interaction at subsequent levels of visual processing is a definite sign of input from the midget and/or bistratified cell groups.

EXTRAClassical RECEPTIVE FIELD PROPERTIES The extraclassical receptive field is defined as a region of visual space where an appropriate stimulus can modulate the responses evoked from the classical receptive field (see Chapter 45). The effects of extraclassical stimulation are often termed facilitatory (or suppressive) to emphasize this distinction from frank excitatory (or inhibitory) effects on action potential discharge rates. Abrupt rapid movement of large targets outside the classical receptive field was first reported to produce facilitatory or frank excitatory effects in recordings from axons of cat ganglion cells by McIlwain (1964). Subsequent work on cat retina shows that both facilitatory and suppressive effects, originating in an extended region of the visual field, can influence both the evoked and maintained activity of ganglion cells (Barlow et al., 1977; Li et al., 1992; Passaglia et al., 2001). The influence on larger (brisk-transient, Y type spatial summation) receptive fields is generally greater than effects on smaller (brisk-sustained, X type spatial summation) receptive fields (Li et al., 1992). Fewer data are available on primate ganglion cells; recordings from ganglion cell targets in the lateral geniculate nucleus reveal both close-range suppressive and long-range facilitatory extraclassical receptive field regions (Felisberti

and Derrington, 2001; Marrocco and McClurkin, 1985; Solomon et al., 2002), but the extent to which these effects are already present in ganglion cell receptive fields in primates has not yet been established.

27 Retinal Ganglion Cell Excitability

ANDREW T. ISHIDA

RETINAS ARE GEARED to function as the first cell layers of the visual system by several sorts of signal generation and processing. In addition to transducing light and limiting light sensitivity, photoreceptors help reduce noise, differentially distribute signals to different bipolar cells, and adapt to changes in mean luminance (Sterling, 1998). Before driving retinal ganglion cells to “spike” (i.e., generate action potentials), interneurons help determine the spatial, temporal, and chromatic properties that produce changes in ganglion cell spiking at any moment, and help adjust the sensitivity and response kinetics of cells when the mean, range, and spatial distribution of light intensities change (Meister and Berry, 1999). Finally, the outcome of these processes is enriched by the variety of cellular teams that retinas devote to handling these tasks and, as described in other chapters of this book, this variety arises at least in part from differences in the combinations of bipolar and amacrine cells that converge onto ganglion cells, the synaptic arrangements and transmitter systems that make up the outer and inner plexiform layers, and the transfer and dynamic properties of these synapses.

In the midst of this, ganglion cells may seem to simply be on stand-by, generating a spike anytime some fixed threshold is reached. However, certain responses of the retina also entail changes in signal flow through synapses and single cells. The best known of these include shifts in the balance of rod and cone inputs to shared pathways, modulation of neurotransmitter-gated and voltage-gated ion channels, and changes in coupling at gap junctions (Akopian and Witkovsky, 2002; Barlow, 2001; Dowling, 1991; Vaney, 1999; Wässle and Boycott, 1991; Witkovsky and Dearry, 1991). Because some modulators have recently been found to regulate ion channels in ganglion cells, retinas seem set up to generate their outputs in part because stimuli change the synaptic inputs that drive ganglion cells, and in part because stimuli change the response of ganglion cells to their inputs. This chapter addresses two questions about how ganglion cells fit into an ensemble like this to form the retinal output. First, do all ganglion cells generate spikes in the same way? Second, do individual ganglion cells produce spikes the same way under all lighting conditions?

One reason for considering these possibilities is that they imply that retinas could be organized in different ways to respond to their inputs. A fixed mechanism of ganglion cell

“excitability” (i.e., spike generation) would suffice to send the retina’s output off to remote targets without it degrading along the way, but this would leave information-processing duties in the retina up to the outer and inner nuclear layers. Allowing different ganglion cells to generate spikes at different frequencies, at different moments, or in different temporal patterns could create different outputs for identical inputs, relieve other retinal cells from shaping these spiking patterns, or ensure that critical processing that started in the distal retina was maintained in the retinal output. Equipping individual ganglion cells with spiking mechanisms that change depending on the intensity, distribution, or other attributes of light could enable ganglion cells to modulate the retina’s output, and this could occur independently of or together with changes in the light responses of other retinal neurons.

A second reason for considering ganglion cell excitability is that it could factor into the range of inputs these cells respond to. For example, ganglion cell responses, measured in spike firing rate (i.e., spike “frequency”), saturate within a “dynamic range” of 2.5 log units (Barlow and Levick, 1969; Diamond and Copenhagen, 1995; Enroth-Cugell and Shapley, 1973; Green and Powers, 1982; Sakmann and Creutzfeldt, 1969; Thibos and Werblin, 1978), yet photon fluxes encountered under starlight and sunlight can differ by up to 10 log units (Rodieck, 1998). For ganglion cells to respond over broad ranges of stimulus values, retinas with fixed spike-generation mechanisms in all ganglion cells, or with different mechanisms in different cells, have at least three sorts of options. One is “range fractionation,” the use of different cells to respond to different portions of a parameter’s value range (cf. Albrecht and Hamilton, 1982; Ohzawa et al., 1985). A second way is “receptive field surround inhibition,” the reduction of responses to localized “center” illumination by light that falls within a slightly broader “surround” area (Barlow et al., 1957; Barlow and Levick, 1969; Donner, 1981; Enroth-Cugell and Lennie, 1975). A third would be “adaptation” or “gain control,” which adjust the response that cells produce per unit of input (Shapley, 1997; Shapley and Enroth-Cugell, 1984). Although none of these tactics necessarily entail differences or changes in ganglion cell excitability, differences in the range of inputs that ganglion cells respond to or the range of outputs that ganglion cells generate could contribute to range fractionation, and changes in excitabil-

ity could result from changes in either local or broad-field illumination.

One approach to take here would be to proceed through descriptions of light stimuli, cell types, light responses, mechanisms, and models. Unfortunately, although a number of different models of ganglion cell light responses have been built from comparisons of stimuli and responses, surprisingly few biophysical and intracellular signaling mechanisms that allow these models to work have been established by intracellular recording, imaging, or experimental manipulations. This chapter will therefore start by describing simple light responses of ganglion cells, those of dark-adapted cells to flashes of intermediate intensity. A number of cellular properties that have been found in ganglion cells by patch-clamp and immunocytochemical methods will then be reviewed, and related, where possible, to responses of light-adapted ganglion cells to light flashes and to randomly fluctuating intensities. Two of the main ideas considered here are that ganglion cell spike generation is not an “integrate-and-fire” process that can be described by voltage-gated ion current amplitudes, kinetics, and voltage sensitivities that are identical in all cells and constant under all conditions, and that changes in ganglion cell excitability help adjust the retinal output as the retinal input changes.

Excitability and light responses

DYNAMIC RANGE A number of studies have investigated the contribution of ganglion cell excitability to light responses by comparing light-elicited spikes with spikes elicited by current injections through intracellular electrodes. This was first attempted by measuring spikes with microelectrodes that penetrated ganglion cell somata (Fig. 27.1; Baylor and Fettiplace, 1979) and thereafter with patch-electrodes that sealed onto ganglion cell somata (e.g., Diamond and Copenhagen, 1995; Fohlmeister and Miller, 1997a; Kim and Rieke, 2001; Mobbs et al., 1992; Sheasby and Fohlmeister, 1999). To begin with, the transformation of current into spikes was studied from the spike frequencies elicited by exogenously injected constant current and by light flashes, and by comparing these with the amplitude of light-evoked whole-cell currents.

At spike frequencies ranging from around 2 Hz (spikes·sec⁻¹) to as high as 80 Hz, spike frequency was found to increase linearly with the amplitude of injected current (Baylor and Fettiplace, 1979; Diamond and Copenhagen, 1995; Mobbs et al., 1992; Robinson and Chalupa, 1997; Vaquero et al., 2001). Likewise, light-evoked spike frequency was found to increase linearly when plotted against the amplitude of light-evoked whole-cell current (Diamond and Copenhagen, 1995). Do these two types of plots coincide? Most studies so far have only measured one of these types of plots; of the plots published so far, some differ considerably in slope

(compare, for example, the data of Baylor and Fettiplace versus those of Mobbs and colleagues). It remains to be seen whether these differences are significant, because the data were collected with different methods and under different recording conditions. Fortunately, one study measured both plots in a single species, under the same recording conditions (Diamond and Copenhagen, 1995). These showed neither a significant difference in slope (both approximately 1 Hz/pA), nor a marked difference in position along the current axis. These similarities are consistent with the possibility that dendritic processing of input currents, if any, does not substantially contribute to light-evoked spike frequencies—a possibility that was recently confirmed by recording the whole-cell current that is activated by light and showing that spikes elicited by this light are similar in frequency and time-course to spikes elicited by injecting that current into somata (Fig. 27.2; Kim and Rieke, 2001).

These results suggest that, under the conditions that these measurements were made, ganglion cells can linearly transform current into spike frequency. Because there is no universal way that this is accomplished, one would like to know how ganglion cells are able to do this, and whether this contributes to ganglion cell function under various conditions. To begin with, these results predict that the dependence of ganglion cell spike frequency on light intensity should be similar to that of the cells that drive them to spike. Consistent with this, rod, cone, bipolar, and ganglion cells have been found to have similar dynamic ranges—around 2.5 log units. A measure of this similarity can be seen in studies that have fitted the Michaelis equation [$R = R_{\max}(I^n)/(I^n + \sigma^n)$] to plots of the amplitude of responses to local illumination against logarithm of light intensity; in this equation, R is response amplitude, R_{\max} is the maximum response amplitude, I is light intensity, and σ is the light intensity that elicits 0.5 R_{\max} (Naka and Rushton, 1966). These studies have found the coefficient “ n ” to be equal to, or not much different from, unity (for examples, see Ashmore and Falk, 1980; Baylor and Fuortes, 1970; Berntson and Taylor, 2000; Diamond and Copenhagen, 1995; Euler and Masland, 2000; Fain and Dowling, 1973; Guenther and Zrenner, 1993; Schneeweis and Schnapf, 1995; Thibos and Werblin, 1978). This does not argue that these fits are necessarily the best for all cells of these classes, but rather that similar dynamic ranges were found in the cells recorded from. At face value, this suggests that the linearity of current-frequency relations in ganglion cells allows their dynamic range to be governed by those of their presynaptic inputs, at least in the steady state.

HIGH VERSUS LOW SPIKE FREQUENCIES Monotonic increases in spike frequency with stimulus current intensity, particularly at low stimulus intensities, are not predicted by the Na⁺, K⁺, and leak currents described by Hodgkin and

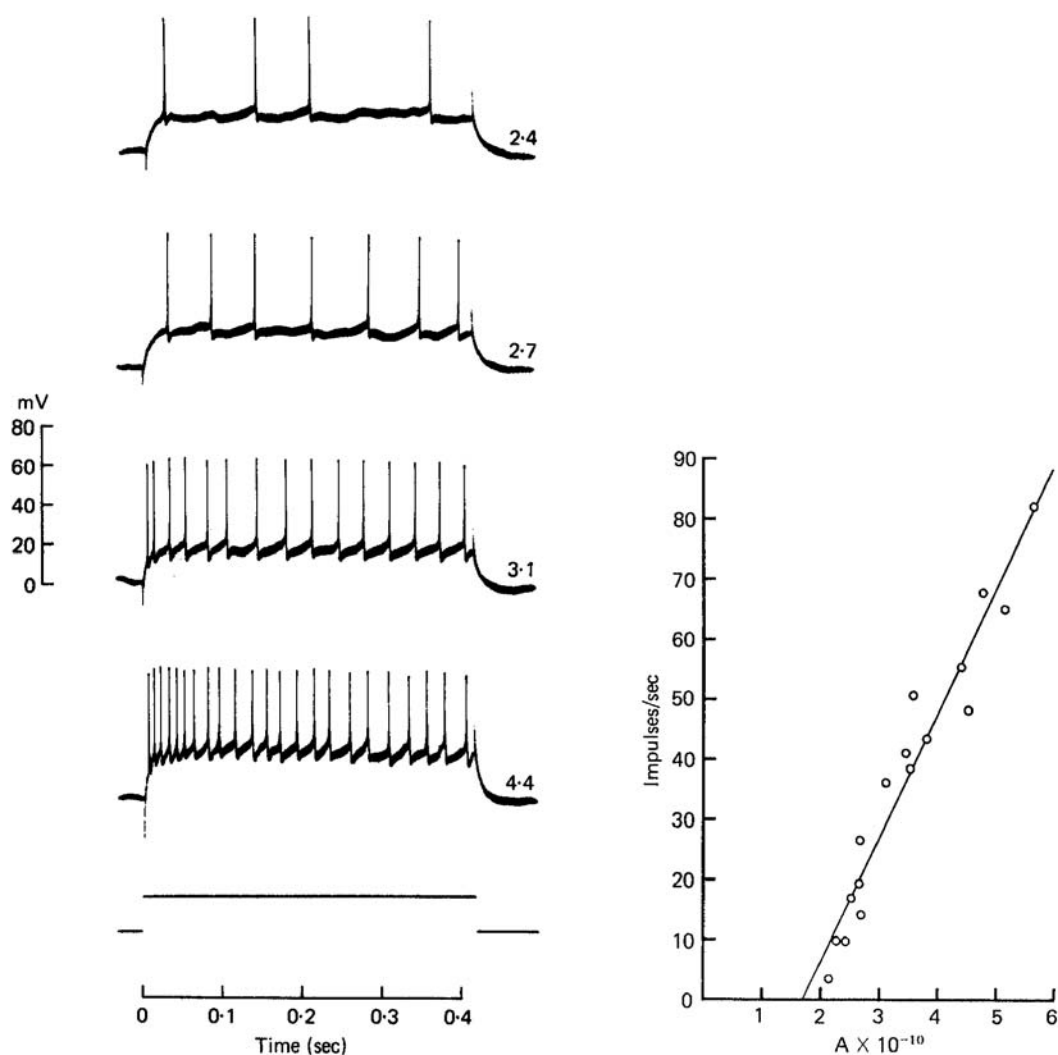

FIGURE 27.1. Responses of a retinal ganglion cell in turtle eyecup to constant current injections are shown at the left. The frequency of spikes elicited by several current injections into this cell are plotted at the right. The numbers next to each trace indicate the

current strength (in 10^{-10} A). The timing and duration of each injection are indicated along the bottom. Resting potential was -70 mV. From Baylor and Fettiplace (1979), with permission of The Physiological Society.

Huxley (1952), and therefore imply the presence of currents that have different properties. Recent studies of currents that facilitate ganglion cell spiking have been propelled by two different interests. One was to learn how, during responses to stimuli of different intensities, ganglion cells avoid large changes in the driving force for the nonselective cation current that bipolar cells activate in them (Diamond and Copenhagen, 1993, 1995; Freed et al., 1992). If, for example, ganglion cells depolarized by amounts that were proportional to light intensity, response amplitudes might increase so much to small inputs that ganglion cells saturate before their presynaptic inputs do.

A key observation was made in turtle ganglion cells that do not spike spontaneously in darkness. Here it was possible to show that dim light flashes elicit subthreshold excitatory postsynaptic depolarizations that sum linearly and that this

linear scaling stops when light flashes are bright enough to elicit spikes (Fig. 27.3; Baylor and Fettiplace, 1979). The recordings of that study, as well as recordings from toad and salamander ganglion cells (Copenhagen et al., 1990; Diamond and Copenhagen, 1995), showed that as light intensity increases, spike frequency increases and spike latency decreases, but the membrane potential that ganglion cells repolarize to between spikes is invariant, or nearly so. The interspike potential was around -50 mV in turtle, and around -40 mV in salamander. To explain this, Diamond and Copenhagen (1995) proposed that voltage-gated conductances “clamp” the membrane potential between spikes to a value that does not vary much with stimulus intensity (or, presumably, duration) and that this helps ganglion cells avoid response saturation due to nonlinear summation of synaptic potentials. The currents and current properties that

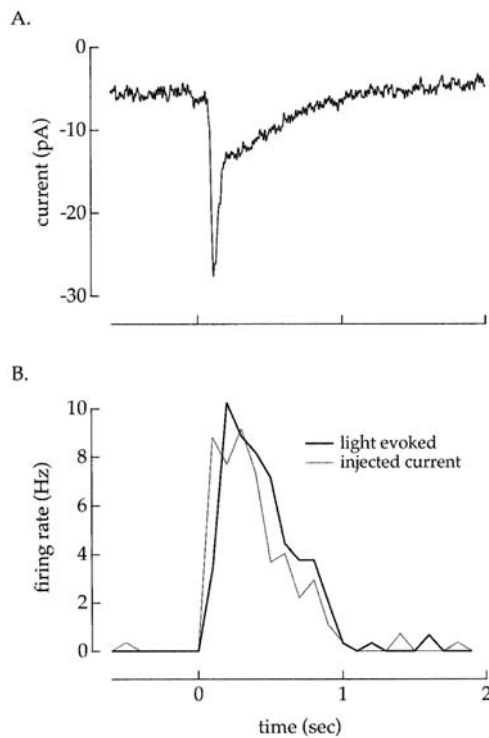

FIGURE 27.2. Responses of a ganglion cell in an isolated larval tiger salamander retina. *A*, whole-cell voltage-clamp current activated by a single flash (10 msec of 1000 photons $\cdot \mu\text{m}^2$ at 575 nm). *B*, poststimulus time histograms of spikes elicited by the same flash as in *A* (thick trace, averaged over 28 presentations) and by injection of the current shown in *A* (thin trace, averaged over 28 injections). produce this clamp remain to be identified. Nevertheless, this type of mechanism also seems to help buffer some cat and rabbit ganglion cells against saturation, at least during the first few hundred milliseconds of responses to bright flashes (Freed, 2000a; Fig. 1A of Bloomfield, 1996).

A second set of studies investigated how ganglion cells generate spikes at low frequencies, where the original Hodgkin-Huxley equations predict a discontinuity in response to small input currents. This work proceeded in two steps. First, it showed that Hodgkin-Huxley type equations can be modified to fit single spikes and intensity-frequency plots for salamander ganglion cells using five types of current—a regenerative Na^+ current; a high-threshold Ca^{2+} current; a low-threshold, rapidly inactivating K^+ current; a high-threshold, slowly inactivating K^+ current; and a K^+ current activated by increases in cytoplasmic Ca^{2+} concentration (Benison et al., 2001; Fohlmeister and Miller, 1997a; Sheasby and Fohlmeister, 1999). Next, it showed that incorporation of voltage-gated Na^+ channels into dendrites, and allowing retrograde current flow into these dendrites to dissipate charge, enable ganglion cell models to spike at low

FIGURE 27.3. ON responses of an ON-OFF ganglion cell in turtle eyecup to 6-msec flashes of 640 nm light. Between 3 and 5 traces are superimposed at each intensity. The numbers next to each trace indicate the intensity relative to 74.8 photons per μm^2 . The filled circles plot the response calculated from linear scaling of the response to the dimmest light (i.e., by multiplying the response to dim light, by the ratio of the test intensity to the dim intensity). Resting potential was -59 mV . From Baylor and Fettiplace (1979), with permission of The Physiological Society.

frequencies (Fohlmeister and Miller, 1997b). Although voltage-gated Na^+ channels are found in dendrites of various central neurons (e.g., Stuart and Sakmann, 1994), immunostaining of newt retina with a polyclonal antiserum directed against an amino acid sequence that is widely conserved among Na^+ channels did not reveal Na^+ channels in the inner plexiform layer (Cheon et al., 1998). Also, as mentioned above, a recent test for dendritic processing of input currents

in salamander ganglion cells showed no detectable amount (Kim and Rieke, 2001). On the other hand, patch-clamp recordings have shown that rabbit ganglion cell dendrites are endowed with Na^+ channels (Velte and Masland, 1999) and immunostaining studies have shown Na^+ channel-like immunoreactivity in the inner plexiform layer of cat, monkey, and goldfish retinas (Miguel-Hidalgo et al., 1994; Zenisek et al., 2001). As found recently in cerebellar Purkinje cells and cortical pyramidal cells (Caldwell et al., 2000), an antibody directed against certain Na^+ channel isoforms might help visualize Na^+ channels in salamander ganglion cell dendritic membranes.

TRANSIENT RESPONSES AND BURST FIRING The responses described above differ from those of other ganglion cells to the same stimuli, and from ganglion cell responses to other stimuli, in several respects.

1. Some ganglion cells can be hyperpolarized by light. These hyperpolarizations can be as large as 15 mV below the

membrane potential recorded in darkness (e.g., Ammermüller and Kolb, 1995). In dark-adapted retinas, the response to turning off lights that produce these hyperpolarizations is a step-wise increase in spike frequency (Fig. 27.4; Enroth-Cugell and Lennie, 1975; Jakiela et al., 1976; Müller et al., 1988; Thier and Alder, 1984; Yoon, 1972), leaving these cells to spike continuously in darkness.

2. In light-adapted retinas, depolarizing changes in light intensity elicit transient increases in spike frequency, rather than sustained ones. This can be seen in both the receptive field center and surround responses of ON- and OFF-center ganglion cells—for example, during brightening of ON-cell centers and OFF-cell surrounds, and darkening of ON-cell surrounds and OFF-cell centers (Figs. 27.4, 27.5, and 27.13; Enroth-Cugell and Lennie, 1975; Enroth-Cugell and Shapley, 1973; Jakiela et al., 1976; Lennie, 1981; Müller et al., 1988; Purpura et al., 1990; Thier and Alder, 1984; Yoon, 1972).

3. Maintained presentations of flickering checkerboards (i.e., arrays of squares that fluctuate in intensity and

position) elicit steady rates of spike firing (Brown and Masland, 2001; Chander and Chichilnisky, 2001; Smirnakis et al., 1997). Spatially uniform random flicker, however, elicit spike bursts (Fig. 27.6; Berry and Meister, 1998; Berry et al., 1997; Korenberg et al., 1989; Sakai and Naka, 1987; Sakanaga et al., 1987), meaning that there are both brief periods when cells do not spike (within each burst) and longer periods when cells do not spike (between bursts). These bursts, also called “events,” are preceded in ON-center ganglion cells by brief increases in mean light intensity, and in OFF-center cells by brief decreases in mean light intensity (Fig. 27.7; Meister and Berry, 1999). In response to repeated stimulus presentations over long recording times, the beginning of these events are temporally precise, cells spend relatively small amounts of time firing bursts, and spike-count variability is low (Berry et al., 1997; see also Kara et al., 2000).

4. Ganglion cell light responses can be reduced by increases in the mean light intensity and the amount by which intensity fluctuates relative to the mean (see Barlow and Levick, 1969; Chander and Chichilnisky, 2001; Enroth-Cugell and Shapley, 1973; Green et al., 1975; Kim and Rieke, 2001; Sakai et al., 1995; Sakmann and Creutzfeldt, 1969; Shapley and Enroth-Cugell, 1984; Shapley and Victor 1978; Yeh et al., 1996). These decreases follow various time courses and are commonly referred to as light adaptation and contrast gain control, respectively.

Do the light responses listed here differ from those described in the previous section due to changes in synaptic input alone, or do these responses suggest somehow that ganglion cells differ in excitability and membrane properties, and/or that light stimuli alter these properties? A number of observations are consistent with the latter. To begin with, the transition from sustained to transient spike

FIGURE 27.6. Intracellular recording of membrane potential (“response”) of a retinal ganglion cell in a catfish eyecup, during presentation of white-noise modulated full-field illumination (“light”). Differentiating the response gave the trace marked “difference.” An algorithm separating the response into analog and discrete signals gave the traces marked “slow” and “spike.” Mean luminance: $5 \mu\text{W}/\text{cm}^2$. firing that occurs during light adaptation of ganglion cells is not accompanied by parallel changes in the light responses of bipolar cells: depolarizing light responses from light-adapted rod bipolar, cone bipolar, and mixed rod-cone bipolar cells are sustained or consist of a transient peak followed by a sustained plateau (Berntson and Taylor, 2000; Dacey et al., 2000; Dacheux and Raviola, 1986; Euler and Masland, 2000; Kaneko et al., 1979; Saito et al., 1978). Furthermore, although transience in ganglion cell responses to input from these bipolar cells might result from a delayed presynaptic or postsynaptic inhibition by amacrine cells, light adaptation can change ganglion cell responses to small spots positioned carefully over the receptive field center from sustained to transient (Yoon, 1972; see also Jakiela et al., 1976).

Secondly, unlike some amacrine cells (Feigenspan et al., 1998), ganglion cells do not spike in the absence of synaptic input. This implies that spikes recorded from ganglion cells in darkness are generated by tonic excitatory synaptic input(s). This input produces as much as a 10-mV difference in the resting potential between ON- and OFF-center ganglion cells (Belgum et al., 1982; Coleman and Miller, 1989;

Saito, 1983), and also gives rise to fluctuations (“noise”) in the membrane potential recorded between spikes (Belgum et al., 1982; Bloomfield and Xin, 1997; see also Freed, 2000b). These inputs might be expected to affect the response of ganglion cells to depolarizing as well as hyperpolarizing inputs, because the voltage-gated and Ca^{2+} -sensitive ion currents that form ganglion cell spikes are subject to inactivation and modulation at these membrane potentials, and because noise would be expected to introduce some jitter in spike timing.

Thirdly, the responses of light-adapted ganglion cells to random fluctuations in the intensity of full-field illumination reflect additional complexities in spike firing mechanisms. In the dark-adapted ganglion cell responses discussed in the previous section, spike threshold appeared to be relatively constant, and there was no sign that the relationship between input current and steady-state spike frequency changed. These properties are consistent with the possibility that ganglion cell spike generation is a simple integrate-and-fire process, in which ganglion cells sum synaptic inputs and then spike whenever their membrane potential reaches a fixed threshold value. A number of modifications of this process have been proposed, for example, to account for the timing of spikes elicited by periodic stimuli in light-adapted ganglion cells (e.g., Reich et al., 1997) and for spike accommodation (e.g., Benison et al., 2001). Recent studies, however, have shown that responses of light-adapted ganglion cells to randomly modulated inputs differ from a simple integrate-and-fire process in at least two ways (Berry and Meister, 1998; Berry et al., 1997). First, these responses consist of spike “events.” Each event is comprised of a relatively fixed number of spikes that fire at a high rate (~ 100 to 200 Hz ; Fig. 27.7). Secondly, each of these events is followed by a relatively long period when cells do not spike. In response to repeated presentations of a randomly fluctuating input, spike events begin at times that vary from trial-to-trial by as little as 1 msec and by not more than 10 msec (Fig. 27.7; see also Berry et al., 1997). The spikes generated under these conditions have therefore been modeled by two signal processing stages (Keat et al., 2001; see also Chichilnisky, 2001; Korenberg et al., 1989), namely a linear filter that transforms light intensity into a generator potential, and a spike generator that starts a spike event when the generator potential exceeds spike threshold.

What cellular mechanisms equip ganglion cells to produce these light responses? Given the variety and complexity of spike-generating mechanisms in other central neurons, it should not be surprising that no complete answer to this question yet exists. However, numerous efforts have been made and are continuing to be made to identify such mechanisms. These efforts have explored how quickly ganglion cells can be depolarized by current injections, what ion channel properties enable ganglion cells to spike, and how

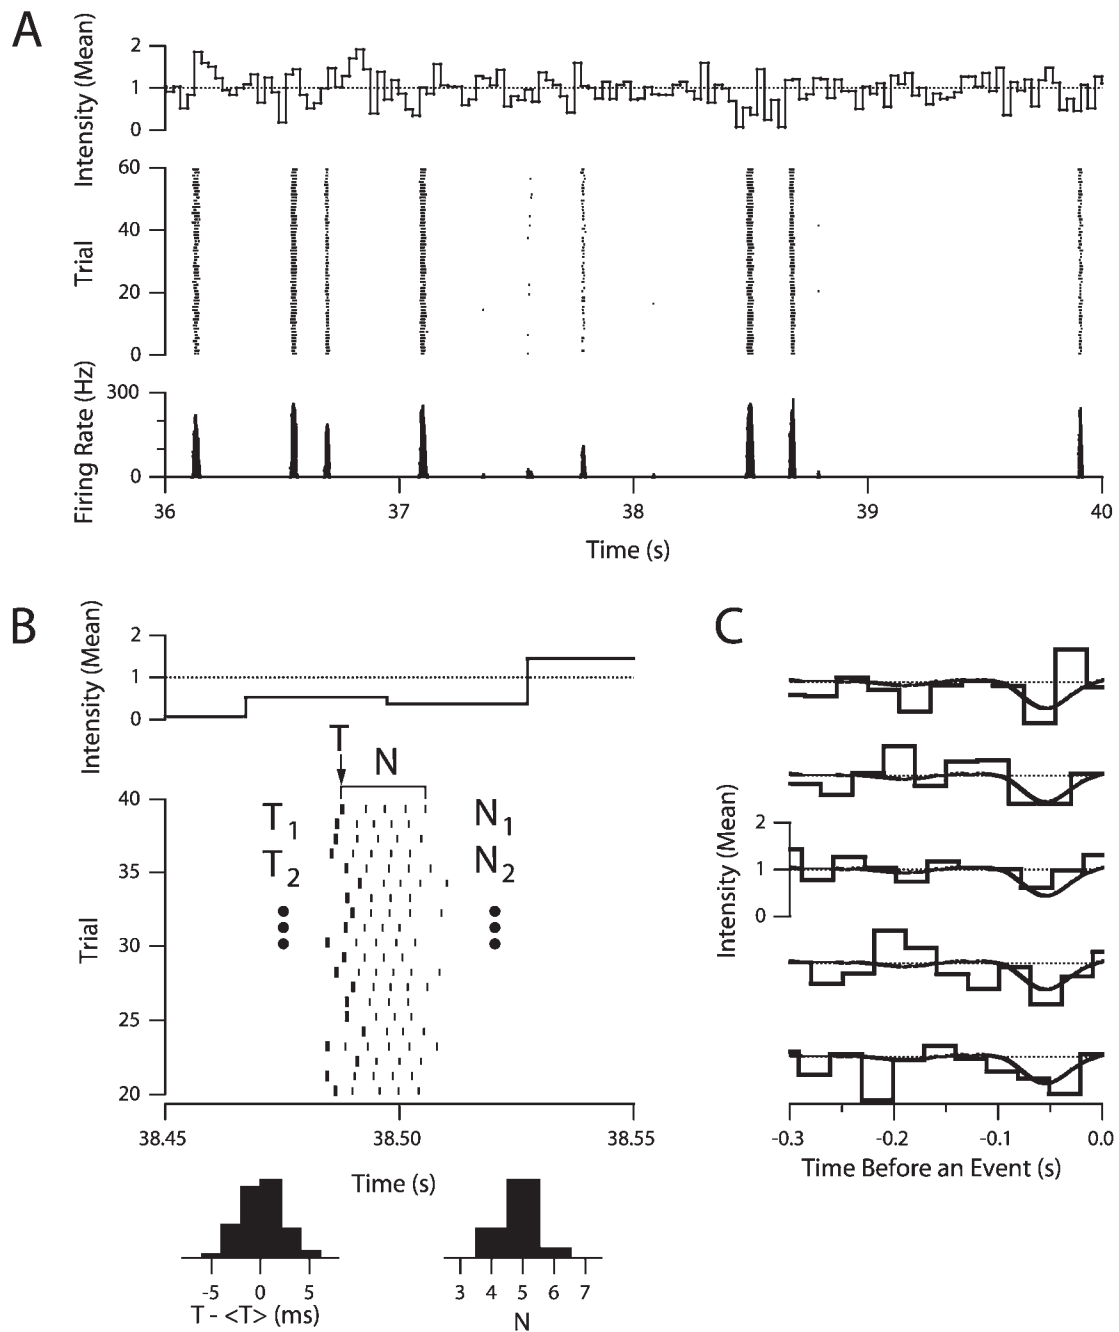

FIGURE 27.7. *A*, spike raster plots (*middle*) and firing rates (*bottom*), recorded from a ganglion cell in salamander retina, in response to 60 presentations of uniform illumination whose intensity was changed to a new value once per 30 msec, from a Gaussian distribution (*top*). Mean light intensity: $4 \times 10^{-3} \text{ W/m}^2$. Standard deviation: 35% of the mean. *B*, spikes comprising the “spike events” recorded during 20 trials, approximately 38.5 msec after the beginning of each trial. Histograms show the time of the first spike in

each event (T), relative to the value averaged across trials ($\langle T \rangle$). N gives the total number of spikes per event. *C*, plot of the intensity (thick line) during the 300-msec period that preceded spike events consisting of, on average, 1.8 to 2.2 spikes. The average intensity that preceded each event is plotted by the thin lines. From Meister and Berry (1999), with permission. Copyright 1999 by Elsevier Science.

these properties change under various conditions. The remainder of this chapter reviews the results of these studies, focusing on four particular areas: membrane time constant, differences in current-clamp and voltage-clamp measurements related to cell-type, modulation of excitability by sub-threshold voltage excursions, and modulation of excitability by dopamine. This will show that a dozen or so types of voltage-gated ion current have been found in ganglion cells so far, that roughly a half dozen conductances could account for ion permeabilities that have been detected around resting potential, and that certain light responses may involve the susceptibility of some of these conductances to modulation. These results begin to suggest that ganglion cells are packed with means to spike differently and to do so to various extents. For reasons given below, however, no attempt to calculate spikes from these data or to compare these data to existing spike models will be made.

Passive properties

MEMBRANE TIME CONSTANT When a pulse of depolarizing current is injected into a cell (either through an electrode or at a synapse), the membrane potential does not instantaneously rise to, or fall from, its steady-state value. The speeds at which these membrane potential changes occur have been measured in many cells, because they are thought to influence the temporal properties of spike firing and the integrative properties of neurons. Within a few mV of resting potential, these changes typically take tens of milliseconds to reach most of their steady-state value (see Spruston and Johnston, 1992).

Several studies have measured this property in ganglion cells. Some of the results are not formally equivalent because different methods were used. However, several values are the time in which membrane potential changed to 63% ($1 - \frac{1}{e}$) of its steady state value during a constant current injection. The values of these “membrane time constants” measured in different cells of the same species, and with similar methods in different species, can therefore be compared. The values reported so far fall into two sets. One was measured near resting potential. These results are summarized here to check for similarities without the complications of synaptic inputs, and in part to compare these values with what has been learned recently about ion permeabilities in resting cells. The second set of measurements give some idea of how time constants differ in cells that receive tonic synaptic inputs.

Using whole-cell patch-electrodes and fits of exponential time functions to membrane potential changes produced

by current injections, Lasater and Witkovsky (1990) found a value of 7 msec in turtle ganglion cells. By fitting single exponentials to similarly produced membrane potential changes, longer time constants have been reported for cat, mudpuppy, and tiger salamander ganglion cells. Robinson and Chalupa (1997) found mean time constants of 23 and 34 msec for beta and alpha ganglion cells, respectively; Lukasiewicz and Werblin (1988) found time constants ranging from 18 to 52 msec (mean: 41 msec), and Coleman and Miller (1989) found time constants ranging from 35 to 126 msec (mean: 68 msec). O’Brien and colleagues (2002) recently reported that the time constants peeled from 8 of 10 morphological types of cat ganglion cells ranged between 20 and 50 msec; that of alpha cells was closer to 5 msec, while zeta cells weighed in at 80 msec. Lastly, by modeling ganglion cells as somata attached to finite cables and fitting equations that describe these structures to the decay of capacitive current transients, Taylor and colleagues (1996) found time constants ranging from 27 to 270 msec (mean: 97 msec).

These data show a couple of trends. First, cells that responded differently to light (ON-center, OFF-center, and ON-OFF; linear vs. nonlinear spatial summation) were found to have similar time constants within individual studies (Coleman and Miller, 1989; Robinson and Chalupa, 1997). Because these types of ganglion cell differ in the level and size of their dendritic arborization, and in some cases the size of their somata (e.g., Wässle and Boycott, 1991), these results indicate that differences in cell shape and size produced no marked difference in time constant. The similarity in time constants reported by O’Brien and colleagues (2002) for the small, tightly branching beta cells and the more sparsely, broadly arborizing delta cells concurs with this; the marked difference between their measurements from alpha cells, beta cells, and zeta cells does not.

Secondly, two groups of cells that differed in sensitivity to current injections—the repetitively spiking “fast” and “slow” cells described by Fohlmeister and Miller (1997a)—had similar time constants. However, Fohlmeister and Miller (1997a) found that “medium” cells had shorter time constants than both slow and fast cells, and that plots of their spike frequency against current intensity were intermediate in slope and position. These data imply that neither of the measured properties depends on time constant. Similar data plots for other cells that have presented different time constants are not available. However, in the recordings of O’Brien and colleagues (2002), one finds (as one would

usually expect) that cells with the shortest time constants (alpha cells) spiked at the lowest rates for a given current intensity, and that cells with the longest time constant (zeta cells) spiked at intermediate rates at much smaller current intensities.

Thirdly, a wide range of time constants has been observed in some ganglion cells. Part of this may be due to species, as the value found in turtle was outside the range of values measured in salamander, mudpuppy, and cat. However, a wide range of values was found in salamanders and mudpuppies alone, even in cells classified for other reasons as single types (Coleman and Miller, 1989; Taylor et al., 1996). This might reflect normal differences in resting membrane resistance, and the ion conductances that determine these resistances. It is also possible that perfusion by the ruptured-patch whole-cell electrodes used to make these measurements altered these conductances in different ways, or to different extents, in different cells. Differences in "passive" membrane properties of the magnitude seen in ganglion cells have been caused in other neurons by this type of recording (Cuevas et al., 1997; Spruston and Johnston, 1992), and as described in the following section, more than one ion permeability in resting ganglion cells may be susceptible to these effects.

RESTING ION PERMEABILITIES A number of studies have shown that, as in other central neurons, the specific membrane resistance of ganglion cells (i.e., the ratio of their time constant to their specific membrane capacitance) is high (e.g., Coleman and Miller, 1989; Fohlmeister and Miller, 1997a; Freed et al., 1992; Taylor et al., 1996). Moreover, the ion permeabilities of resting ganglion cells appear to be "leak-like" because total membrane current amplitude shows no voltage- or time-dependent change when membrane potential is shifted under voltage-clamp around resting potential (i.e., between -65 and -75 mV; see Tabata and Ishida, 1996). One might not be surprised by either of these observations, until the ion permeabilities of resting ganglion cells were examined. To begin with, intracellular recordings suggest that resting ganglion cells are permeable to K^+ , Cl^- , Na^+ , and perhaps Ca^{2+} ions, because (1) increases in extracellular K^+ concentration depolarize dissociated ganglion cells (Bindokas et al., 1994), (2) the reversal potential of current measured just after shifting the voltage in whole-cell patch clamp recordings is K^+ -sensitive (Skaliora et al., 1995), (3) the reversal potential of current in the presence of Na^+ , K^+ , and Ca^{2+} channel blockers is Cl^- -sensitive (Tabata and Ishida, 1999), (4) a small amount of voltage-gated Ca^{2+} conductance resists inactivation at membrane potentials near resting potential (Lee, Hayashida, and Ishida, unpublished observation), and (5) the resting potential typically found in ganglion cells (-65 mV; e.g., Baylor and Fettiplace, 1979; Lukasiewicz and Werblin, 1988) is more positive than

the K^+ equilibrium potential (roughly -100 mV; Stys and Lopachin, 1996).

Recent studies have started to identify ion permeabilities in resting ganglion cells more specifically. Candidates for the resting K^+ and Cl^- permeability include TRAAK, found in ganglion cells by immunostaining and in situ hybridization (Fink et al., 1998; Reyes et al., 2000), and channels like $ClC-1$ (Rosenbohm et al., 1999) or $ClC-3$ (Kawasaki et al., 1994; cf. Stobrawa et al., 2001), because the Cl^- permeability is PKC-regulated (Tabata and Ishida, 1999). At least two non-synaptic routes for Na^+ influx into resting and slightly depolarized ganglion cells have been described: epithelial-type (amiloride-sensitive, voltage-insensitive) Na^+ channels (Matsuo, 1998; Mirshahi et al., 1999) and nonselective cation channels activated by cGMP (Ahmad et al., 1994). In addition to these, the activation and steady-state inactivation curves of Na^+ currents in ganglion cells overlap (Barres et al., 1989; Hidaka and Ishida, 1998; Inceoglu et al., 2002; Kaneda and Kaneko, 1991a; Lasater and Witkovsky, 1990; Lipton and Tauck, 1987; Lukasiewicz and Werblin, 1988; Skaliora et al., 1993), and a small fraction of the voltage-gated Na^+ conductance resists inactivation (Hidaka and Ishida, 1998). This might produce some Na^+ permeability in resting cells, because activation threshold can be as negative as -65 mV (Hidaka and Ishida, 1998). Lastly, "mixed-cation" channels also pass Na^+ ions in addition to K^+ ions, including those that pass the hyperpolarization-activated inward current I_h (Eng et al., 1990; Tabata and Ishida, 1996) and, guessing from the reversal potential measurements published for several preparations (Lasater and Witkovsky, 1990; Lipton and Tauck, 1987; Lukasiewicz and Werblin, 1988), those that carry a substantial fraction of the depolarization-activated outward current. It is not yet possible to state the relative contribution of any of these channel populations to resting membrane resistance (and potential), because the relative permeability of resting ganglion cells to K^+ versus other cations, and K^+ versus anions, has not been measured under physiological conditions. However, resting ganglion cells clearly have several ion permeabilities, and the control of some of these permeabilities by cytoplasmic messengers (e.g., TRAAK, the background Cl^- permeability, and the cyclic nucleotide-gated channels) suggests that membrane resistance (and, in turn, time constant) could be modulated.

MEMBRANE TIME CONSTANTS \pm SYNAPTIC INPUTS Given the high specific membrane resistances that have been found in unstimulated ganglion cells, the membrane time constant of ganglion cells would be expected to decrease when they are barraged by synaptic inputs. The full extent to which this occurs has not yet been worked out, but the three major conductances that might contribute to this effect are those gated by glutamate, inhibitory synaptic inputs, and voltage.

For example, Baylor and Fettiplace (1979) found time constants of 10 to 14 msec by fitting Lapicque's strength-duration equation to the latency of the first spike elicited by different current intensities. Although these measurements were made with sharp microelectrodes, one would also expect them to be shorter than most of those described above because they rely on spike latency, so that these measurements also reflect the effect of conductances that open at subthreshold voltages. A similar conclusion was reached by Coleman and Miller (1989). They reported that ON-center ganglion cells had monoexponential time constants, and that OFF-center and ON-OFF cells did not. By fitting sums of exponentials to the changes in membrane potential produced by stepwise current injections, they found that all cells had a similarly slow membrane time constant (for example, 70 msec for all the mudpuppy ganglion cells recorded from). The faster exponentials (<10 msec) were attributed to voltage-gated conductances activated in OFF-cells by tonically depolarizing synaptic inputs. Consistent with both of the above studies, Diamond and Copenhagen (1993) reported that blocking non-NMDA glutamate receptors in ON-cells, with CNQX, did not significantly alter membrane time constant. The total conductance due to NMDA-type receptors was estimated to be 1.5 times larger than that gated by non-NMDA receptors, suggesting that these conductances might not greatly alter membrane time constant either. These results, and those discussed in the previous section, imply that the ease with which ganglion cells can be driven to spike depends, in part, on the modulation of resting conductances, the voltage-sensitivity and kinetics of currents activating between resting potential and spike threshold, and the deactivation rate of high-threshold K^+ currents.

Voltage-gated ion currents

A number of studies have tried to identify voltage-gated conductances in ganglion cells using patch-clamp methods. Based on the effects of membrane potential changes, ion substitutions, and pharmacological agents, these studies have found that at least some ganglion cells possess a persistent Na^+ current, transient Na^+ current, transient Ca^{2+} current (I_T), conotoxin-sensitive Ca^{2+} current, dihydropyridine-sensitive Ca^{2+} current, toxin-resistant Ca^{2+} current, transient K^+ current (I_A), slowly inactivating K^+ current, one or two Ca^{2+} -activated K^+ currents, I_B (a K^+ current that remains after blocking the other K^+ currents listed here), and an inwardly rectifying cation current (I_h). These results show that in the species examined so far (rat, salamander, turtle, cat, goldfish, rabbit, and ferret), ganglion cells have as many as three "low threshold" ion currents that can be activated by depolarizations at relatively negative membrane potentials, as many as eight "high

threshold" currents that can only activate at more positive membrane potentials, and one current that is activated by hyperpolarization.

A number of questions emerge from these results. Are all of the voltage-gated ion currents listed above found in all ganglion cells? Are the properties of these currents identical among all cells? Have any differences in these currents been shown to account for any functional differences between ganglion cells? These questions have not yet been answered by testing for the presence of all of the currents listed above in any one or more types of cell. However, recordings from numerous cells in the species listed above have shown the following properties:

Na^+ CURRENTS All adult ganglion cells have a Na^+ current that is transient and relatively high-threshold. Some ganglion cells have also been found to have a persistent and low-threshold Na^+ current. The activation threshold of the transient Na^+ current is typically between -50 and -40 mV. Dividing the maximum current amplitude by the total cell capacitance yields a current density of at least 200 pA/pF (Barres et al., 1988; Hidaka and Ishida, 1998; Schmid and Guenther, 1998) consistent with the rise-time of spikes recorded from these cells (roughly 100–200 mV/ms). Complete current blockade is produced by 1 μ M tetrodotoxin (Hidaka and Ishida, 1998; Kaneda and Kaneko, 1991a; Lasater and Witkovsky, 1990; Lukasiewicz and Werblin, 1988; Taschenberger and Grantyn, 1995) consistent with the block of all spike output by tetrodotoxin (Byzov et al., 1970) and the lack of mRNA for tetrodotoxin-resistant Na^+ channels in rat ganglion cells (Fjell et al., 1997). The voltage-sensitivity of this current is complex in several respects. The current does not decline exponentially in amplitude during long (>30-msec) stepwise depolarizations (Hidaka and Ishida, 1998), consistent with the presence of channels that differ in rates of activation or inactivation (cf. Barres et al., 1989). The rate of recovery from inactivation depends on the duration of time spent at conditioning voltages (Kaneda and Kaneko, 1991a), consistent with the presence of multiple kinetic states or different channel subtypes. The voltage sensitivity of steady-state inactivation is susceptible to a left-ward drift in ruptured-patch whole-cell recording (Hidaka and Ishida, 1998), hinting at some sort of on-going regulation. The functional consequences of these complexities are not yet known for sure, but three possibilities are considered below.

"Persistent" Na^+ current—so-named because it resists steady-state inactivation—has been found in rat and goldfish ganglion cells (Hidaka and Ishida, 1998; Stys et al., 1993; Vaquero and Ishida, unpublished observation). The activation threshold of this current is around -65 mV, and at membrane potentials between -40 and -10 mV this current reaches a maximum amplitude that is <1% of the largest transient Na^+ current in the same cells (Hidaka

and Ishida, 1998). Although persistent and transient Na^+ current are both blocked by $1\text{ }\mu\text{M}$ tetrodotoxin, it is not known if they arise from the same channel populations in individual ganglion cells; they are listed here as separate currents because the persistent component has been found in some ganglion cells and not others. The function of this current in ganglion cells is not yet known, but it contributes to spike firing and signal processing in a variety of other cells.

Ca^{2+} CURRENTS All adult ganglion cells have high-threshold Ca^{2+} currents, and most (if not all) ganglion cells also have a low-threshold Ca^{2+} current. The low-threshold current (“T” type Ca^{2+} current or simply “ I_T ”) inactivates almost completely at resting potential (-65 mV ; Lee, Hayashida, and Ishida, unpublished observation) and therefore sizeable amounts of I_T can be activated only by depolarizations from more negative membrane potentials. During these depolarizations, I_T rises and declines in amplitude more slowly than transient Na^+ current, and the maximum current amplitude is typically small ($<10\text{ pA/pF}$). Although previous studies reported that I_T is absent in 25% of the ganglion cells recorded (Bindokas and Ishida, 1996; Guenther et al., 1994; Karschin and Lipton, 1989; Liu and Lasater, 1994a), Miller and colleagues (2002) have recently reported that current density is higher in ganglion cell dendrites than cell bodies. Because dissociations typically shear most or all the dendrites off of cells, this suggests that noticeable amounts of I_T may be present in more ganglion cells than previously reported and, more importantly, serve functions not previously considered.

High-threshold Ca^{2+} current appears to pass through two or three channel populations. One is modulated by dihydropyridine ligands—agonists that augment current at low doses and antagonists that reduce current (Akopian and Witkovsky, 1996; Bindokas and Ishida, 1996; Hirooka et al., 2000; Kaneda and Kaneko, 1991b; Karschin and Lipton, 1989; Liu and Lasater, 1994a; Taschenberger and Grantyn, 1995). Another is blocked by “conotoxins” from *Conus* snails and “agatoxins” from an *Agelenopsis* spider (Bindokas and Ishida, 1996; Hirooka et al., 2000; Karschin and Lipton, 1989; Liu and Lasater, 1994a; Rothe and Grantyn, 1994; Schmid and Guenther, 1998; Tabata et al., 1996; Taschenberger and Grantyn, 1995; Zhang et al., 1997). The third high-threshold Ca^{2+} current found so far is a toxin-resistant component in *Xenopus*, mouse, and rat ganglion cells (Akopian and Witkovsky, 1996; Rothe and Grantyn, 1994; Taschenberger and Grantyn, 1995). Since these current subtypes have been identified, it has become increasingly clear that they mediate the effect of numerous modulators and they do so in complex patterns. To begin with, high-threshold Ca^{2+} currents fuel increases in cytoplasmic Ca^{2+} levels in various subcellular regions of ganglion cells and these regulate nearby ion channels, transmitter receptors,

and signaling cascades (for examples, see Abdel-Majid et al., 2002; Ahljianian et al., 1990; Akopian et al., 1998; Bindokas et al., 1994; Henderson et al., 2001; Karschin and Lipton, 1989; Lipton and Tauck, 1987; Liu and Lasater, 1994a; Lohmann et al., 2002; Shen and Slaughter, 1998; Wang et al., 1998, 1999). These effects are then subject to modulations themselves. For example, GABA and dopamine can both differentially modulate the amplitude of Ca^{2+} currents (e.g., Liu and Lasater, 1994b; Shen and Slaughter, 1999), and glutamate and acetylcholine can exert opposite effects on Ca^{2+} currents (Akopian and Witkovsky, 1996; Baldrige, 1996; Shen and Slaughter, 1998). Thus, while the functions of Ca^{2+} currents obviously depend on their rates of activation and inactivation, it has become clear that these currents coordinate and regulate effects of pathways that converge onto ganglion cells and that this does not depend only on ganglion cell membrane potential. For further details, readers are referred to other chapters in this book and a recent review (Akopian and Witkovsky, 2002).

K^+ CURRENTS All ganglion cells are thought to possess low-threshold and high-threshold K^+ currents, and these have been attributed to as many as five channel populations. The low-threshold current was found in a single study (Lipton and Tauck, 1987) to start activating near -50 mV , inactivate fully around -40 mV , and be blocked by 4-aminopyridine (4-AP); this current was termed I_A . One other study (Guenther et al., 1999) has shown that the activation threshold of this current is around -40 mV . The second type of current reported by most studies has an activation threshold around -25 mV and is blocked by high concentrations of tetraethylammonium (TEA, 10 to 20 mM). A third current is resistant to block by 4-AP and TEA (Guenther et al., 1999; Lukasiewicz and Werblin, 1988; Sucher and Lipton, 1992; Tabata and Ishida, 1999). Although the activation threshold of this current is difficult to say from the published records, this current can be carried by Cs^+ (Tabata and Ishida, 1999) and be blocked by Ba^{2+} (Guenther et al., 1999; Sucher and Lipton, 1992). The two other K^+ currents are activated by depolarization and a concomitant rise in free intracellular Ca^{2+} concentration (Lipton and Tauck, 1987; Lukasiewicz and Werblin, 1988; Skaliara et al., 1995; Wang et al., 1998; see also Henne et al., 2000). These currents are termed BK_{Ca} and SK_{Ca} to signify that the former has a big single-channel conductance (118 pS in cell-attached mode) while that of the latter is small (22 pS). When the cytoplasmic face of these channels was exposed to solutions containing 1 and 10 nM Ca^{2+} , the opening probability and mean open time of BK_{Ca} increased more than those of SK_{Ca} (Wang et al., 1998). Depending on their voltage sensitivity and kinetics, K^+ currents either reduce or facilitate spiking in various preparations. Unfortunately, ascertaining the role of K^+ currents in ganglion cell excitability has been hampered by a number

of problems. One is that reagents commonly used to separate low- and high-threshold K^+ currents (4-aminopyridine and tetraethylammonium) nonselectively block K^+ currents in most, if not all, ganglion cells (Lasater and Witkovsky, 1990; Lukasiewicz and Werblin, 1988; Olson et al., 2000; Skaliara et al., 1995). This has also been found in a recent attempt to unravel K^+ currents and reveal a specific type of low-threshold K^+ current with other pharmacological strategies (Henne et al., 2000). Here, low TEA doses reduced both transient and sustained current (regardless of holding potential) and an agent denoted α -DTX (presumably dendrotoxin) reduced total K^+ current amplitude at membrane potentials above 0 mV but not to any noticeable extent at more negative voltages.

I_h Lastly, the inwardly rectifying cation current I_h has been found in some ganglion cells. The effect of ion substitutions and pharmacological treatments on voltage rectification provided the first evidence of this current in rat optic nerve (Eng et al., 1990). This current was subsequently separated from other currents and measured in goldfish ganglion cell somata (Tabata and Ishida, 1996). The activation threshold of this current is around -65 mV, and thus slightly more negative than that of I_h in photoreceptors. The function of I_h in ganglion cells is not entirely known yet and will certainly depend on its subcellular distribution and the properties of other currents. However, as in other retinal neurons, I_h tends to depolarize ganglion cells while they are hyperpolarized and for some tens of milliseconds after these hyperpolarizations cease (Tabata and Ishida, 1996). Cat ganglion cells have shown voltage rectification and posthyperpolarization spikes (Skaliara et al., 1993; see also O'Brien et al., 2002) consistent with activation of I_h ; recordings from turtle and salamander ganglion cells have shown no measurable amounts of I_h (Lasater and Witkovsky, 1990; Lukasiewicz and Werblin, 1988).

In summary, most studies have found that ganglion cells typically possess a large transient Na^+ current, two types of high-threshold Ca^{2+} current, transient K^+ current (I_A), tetraethylammonium-sensitive K^+ current, one if not two types of Ca^{2+} -activated K^+ current, and a K^+ current that resists block by TEA and 4-AP. The same studies have shown that persistent Na^+ current, transient Ca^{2+} current (I_T), toxin-resistant Ca^{2+} current, and inwardly rectifying cation current (I_h) are present in some ganglion cells and not in others.

SPIKE CALCULATIONS It would be natural to ask why few attempts to use current recordings to calculate ganglion cell spikes have been published so far (for an exception, see Benison et al., 2001). A major reason is undoubtedly that, of the currents alluded to above, the types actually recruited during light responses in specific types of ganglion cell are

unknown. A second reason is that the properties of ion channels in ganglion cell dendrites and axons have not been measured, except for the dendritic Na^+ current recordings of Velte and Masland (1999) and beyond a handful of whole optic nerve recordings and immunostainings (e.g., Boiko et al., 2001; Eng et al., 1990; Stys et al., 1993; Tang et al., 1979).

A third reason is that for most species the amplitudes, kinetics, and voltage sensitivities of the currents listed above have not been described in terms that can readily be incorporated into models. This is both a question of deriving kinetic schemes that describe these currents, and assessing whether data of sufficient quality are at hand. Unfortunately, the method that made it possible to identify and begin to characterize the currents listed above—whole-cell patch clamping in ruptured-patch mode with a continuous single-electrode voltage-clamp amplifier (Hamill et al., 1981)—can also be a source of two types of uncertainties. One is that this method does not provide membrane potential measurements while currents are measured and uncompensated series resistance can significantly distort the measurements of large-amplitude currents (see Armstrong and Gilly, 1992). The other is that rupturing the membrane between the cell cytoplasm and recording pipette solution has been found to confound measurements by changing cytoplasmic divalent cation levels, ion channel phosphorylation and redox states, and activities of signaling cascade components (see Marty and Neher, 1995; Ruppersberg et al., 1991; Tabata and Ishida, 1999; Vaquero et al., 2001; Vargas et al., 1999). Fortunately, perforated-patch recording (Horn and Marty, 1988) and discontinuous single-electrode voltage-clamp amplifiers (Finkel and Redman, 1984) have been developed to circumvent most of these problems. While it is too early to say how differently ganglion cell currents as a whole will look with these methods, a recent study measured voltage-gated Na^+ current in ganglion cells this way and found that the current kinetics and the voltage producing half-maximal steady-state inactivation differ significantly from values reported in previous studies (Inceoglu et al., 2002).

Heterogeneity

Can a case be made for differences in excitability among ganglion cells? If all ganglion cells received the same synaptic inputs, would they be expected to produce similar spike outputs? Can equations incorporating terms for the same currents describe spike generation in all morphological types of ganglion cells?

Baylor and Fettiplace (1979) originally showed that current injections elicit sustained spike firing in turtle ganglion cells even if their light responses were transient. They concluded that this transience could arise presynaptically, and subsequent current injections have also been

found to elicit sustained spike firing in most if not all salamander (Diamond and Copenhagen, 1995; Fohlmeister and Miller, 1997a; Sheasby and Fohlmeister, 1999), ferret (Wang et al., 1997), and goldfish (Vaquero et al., 2001) ganglion cells.

These results are contrasted by reports of transient spiking elicited by current injections into some postnatal rat ganglion cells (Barres et al., 1988) and some larval tiger salamander ganglion cells (Lukasiewicz and Werblin, 1988; Mobbs et al., 1992). While the basis for this transience has not been confirmed by a comparison of recorded spikes versus spikes calculated from recorded currents, a number of possibilities have been proposed. One is that after one or more spikes, the amount of Na^+ current available to produce additional spikes declines faster in transient cells than in sustained cells. This could be due either to steady-state inactivation at relatively negative membrane potentials, current activation at only relatively positive membrane potentials, slow recovery from inactivation, or a combination of these (Barres et al., 1988; Kaneda and Kaneko, 1991a; Skaliara et al., 1993; Wang et al., 1997). A second idea is that transience arises because the gradual inactivation of I_B promotes Na^+ current inactivation (Lukasiewicz and Werblin, 1988). A third idea is that the delayed activation of an outwardly rectifying K^+ current inhibits repetitive spiking (Henne et al., 2000).

A number of immunostaining and in situ hybridization studies have also found that different ganglion cells express different kinds and combinations of Shaker-, Shab-, and Shaw-type K^+ channels (Henne et al., 2000; Klumpp et al., 1995; Yazulla and Studholme, 1998) and different types of voltage-gated Na^+ channels (Fjell et al., 1997; see also Boiko et al., 2001). These results raise even further the possibility that ganglion cells spike in subtly different ways, not just transient versus sustained. However, the actual significance of these results will depend on the outcome of experiments that show the properties of currents carried by these channels and the properties of other currents in these cells.

One problem in understanding the differences summarized here is that all of the voltage-clamp measurements to date have been made either in ganglion cells of unknown subtype or at best, in only a few of the 10 to 20 types of ganglion cells that have been classified anatomically. For this reason, the study of O'Brien and colleagues (2002) is of keen interest, because it sampled excitability in 10 morphologically identified types of adult cat ganglion cell. Depolarizing current injections elicited different maximum spike frequencies, degrees of spike accommodation, and spike widths. This corroborates the observation that salamander ganglion cells differ in spike threshold and spike frequencies elicited by different amounts of current (Fohlmeister and Miller, 1997a; Sheasby and Fohlmeister, 1999), and shows that morphologically distinct cells possess more combinations of dis-

tinct spiking patterns, time constants, and amounts of inward rectification than any previous study suggested. Whether these differences allow different cells to generate outputs over different dynamic ranges, and the extent that these differences result from differences in cell morphology as opposed to the distribution and properties of specific ion currents, all remain to be worked out.

Response-dependent modulation

A number of changes in ganglion cells spikes differ from the simple integrate-and-fire behavior referred to above. Some of these are triggered by voltage changes in ganglion cells, and could therefore be called "response-dependent." Others are a consequence of changes in the chemical environment of ganglion cells, and could therefore be called "input dependent." Both are described below. Although these sections will show that some seemingly simple voltage responses are not readily explained by existing current recordings, comparing these currents and voltage behaviors suggest experiments that might be pursued. Response-dependent modulation is described first, starting with those showing effects of hyperpolarization, and following with those showing effects of depolarization.

PRIMING BY HYPERPOLARIZATION Hyperpolarizations can boost excitability, as evidenced by bursts of spikes seen after hyperpolarizing current injections are terminated (Eng et al., 1990; O'Brien et al., 2002; Skaliara et al., 1993; Tabata and Ishida, 1996). These spikes arise because hyperpolarization of ganglion cells below normal resting potential recruits inward current that can depolarize cells toward spike threshold after the hyperpolarization ceases.

One of these currents is I_h . This current is carried by both Na^+ and K^+ ions, reverses in polarity at voltages more positive than resting potential, and deactivates exponentially with a time constant of roughly 100 msec at resting potential (Tabata and Ishida, 1996). I_h can therefore depolarize ganglion cells until it deactivates, after the hyperpolarization that activates it is terminated. Two other currents that are affected by hyperpolarization are voltage-gated Na^+ current and I_T . Hyperpolarization does not activate these currents, but instead, increases the amount of current available for activation by subsequent depolarization. This occurs because resting membrane potential is positive enough to inactivate these currents—by as much as 25% of the maximum Na^+ current (e.g., Barres et al., 1989; Hidaka and Ishida, 1998; Inceoglu et al., 2002) and around 95% of the maximum I_T (Lee, Hayashida, and Ishida, unpublished observations; see also Bindokas and Ishida, 1996; Karschin and Lipton, 1989). After sufficient hyperpolarizations, the amounts of Na^+ and Ca^{2+} current that recover from inactivation and the I_h that activates would be expected to facil-

itate spiking, because the reversal potentials of all three currents are more positive than spike threshold. This might occur not only at the termination of hyperpolarizing steps of light intensity, but also during the hyperpolarizations that precede spike bursts elicited in OFF-center ganglion cells by randomly fluctuating light intensity (Sakai and Naka, 1987; see also Sakuranaga et al., 1987).

Although the sensitivities to hyperpolarization of I_T and I_h in ganglion cells resemble those of currents that contribute to the function and electrical properties of other central neurons and other tissues, there is little evidence at this time that the effects described above contribute to ganglion cell spiking *in situ*. For that matter, effects of this kind are difficult to reconcile with three observations. First, as noted above, the OFF response of dark-adapted ganglion cells consists of a step-like increase in spike frequency, rather than a transient one. Secondly, the amplitudes of I_T and I_h are typically small; in fact, some species have been reported to lack I_h (turtle: Lasater and Witkovsky, 1990; salamander: Lukasiewicz and Werblin, 1988) and I_T has been reported to be absent in some ganglion cells of all species examined to date (rat, turtle, goldfish, cat: Bindokas and Ishida, 1996; Guenther et al., 1994; Huang and Robinson, 1998; Karschin and Lipton, 1989; Liu and Lasater, 1994a). Thirdly, the membrane potentials that ganglion cells have been found to traverse during hyperpolarizing light stimuli are generally less negative than those that activate I_h and/or prime Na^+ and Ca^{2+} currents in the ways described above. The recordings of O'Brien and colleagues (2002) underscore this point, in that they show voltage rectification at -75 mV and more negative membrane potentials in theta and iota ganglion cells, but only during hyperpolarizations past -90 mV in beta, delta, epsilon, zeta, eta, and lambda cells. As clear as these disparities seem, they leave open the question why some ganglion cells possess I_h and I_T , and why others might not. To date, one study has found that the membrane potential changes calculated for cells assumed to have a leak permeability, I_h , and a depolarizing input that is either monosynaptic or push-pull in origin (Tabata and Ishida, 1996) resemble subthreshold membrane potential changes that occur during transient OFF responses (e.g., Saito, 1983). One might also note that all of the cell types that inwardly rectified in the study of O'Brien and colleagues (2002) spiked transiently after termination of hyperpolarizing currents.

One other current is thought to be primed in ganglion cells by hyperpolarization, namely I_A . This current is prototypically low threshold, transient, and inactivated by depolarization—in other words, it consists of a brief K^+ efflux that begins when cells are depolarized from relatively negative membrane potentials (Hagiwara et al., 1961). This current can delay spiking, and thereby reduce excitability (Connor and Stevens, 1971). The only evidence that this

occurs in ganglion cells is that, in rat, 4-aminopyridine accelerates the repolarizations that are recorded after terminating hyperpolarizing current injections (Eng et al., 1990) and reduces the amplitude of an outward current that is transient and low-threshold (Lipton and Tauck, 1987; see also Guenther et al., 1999). Spikes with very long latencies have been recorded in some rat ganglion cells during depolarizing current injections (Barres et al., 1988), and (as noted above) Shaker-type K^+ channel mRNA has been found in ganglion cells (Henne et al., 2000; Klumpp et al., 1995; Yazulla and Studholme, 1998). However, for reasons that are not yet known, the K^+ current that is transient and blocked by 4-aminopyridine in ganglion cells of all species beside rat begins to activate around -40 mV (salamander: Lukasiewicz and Werblin, 1988; turtle: Lasater and Witkovsky, 1990; cat: Skaliora et al., 1995; ferret: Wang et al., 1997; goldfish: Olson et al., 2000). The point here is not that this current is unusual (see Rudy, 1988), but that this current would work differently than low-threshold K^+ current. The function of 4-aminopyridine-sensitive currents in ganglion cells remains to be seen. So far, two studies have found that altering the properties of I_A included in Hodgkin-Huxley type equations does not affect ganglion cell spiking (Benison et al., 2001; Fohlmeister and Miller, 1997a).

ACCOMMODATION When ganglion cells are depolarized by constant current injections, the interspike interval increases during the first few spikes (Baylor and Fettiplace, 1979; Diamond and Copenhagen, 1995; Fohlmeister and Miller, 1997a; Mobbs et al., 1992; O'Brien et al., 2002; Vaquero et al., 2001; Velte and Masland, 1999). This increase—or the decrease in the “instantaneous” frequency calculated from the inverse of these intervals—is termed “accommodation.” Practically speaking, a decline in spike frequency is termed accommodation if the frequency does not decline to the baseline level (or zero), to distinguish it from “transient” spike firing (Cleland et al., 1971; see also Bieda and Copenhagen, 2000). Although accommodation lowers the spike frequency averaged over the duration of long depolarizations below that measured either during brief depolarizations or during the initial portion of long depolarizations, relatively little is known about what causes it. Simulations of dissociated cells have suggest that a gradual build-up of intracellular Ca^{2+} can lead to accommodation (Benison et al., 2001); accommodation observed under conditions that block voltage-gated Ca^{2+} influx (Vaquero et al., 2001) implies that other mechanisms can also produce accommodation.

CALCIUM-MODULATED SPIKING Another effect of depolarization on ganglion cell excitability is due to depolarization-activated Ca^{2+} influx. Nearly all studies have found that pharmacological agents that reduce high-threshold Ca^{2+}

currents reduce spike frequency. These agents include D_1 -type dopamine receptor agonists, $GABA_B$ -type GABA receptor agonists, Co^{2+} , Cd^{2+} , and the *Conus* toxins ω -MVIIC and ω -GVIA (Liu and Lasater, 1994b; Rothe et al., 1999; Zhang et al., 1997). Because all ganglion cells are thought to have Ca^{2+} -activated K^+ currents, it seems likely that the effects of blocking Ca^{2+} current are due, in part, to reducing Ca^{2+} -activated K^+ currents. If so, then one might expect spike frequency to be decreased by toxins that block these currents. However, two toxins of this sort (apamin and charybdotoxin) have been found to increase spike frequency (Fohlmeister and Miller, 1997a; Wang et al., 1998). Attempts to account for the effect of Ca^{2+} by modeling have led to two different conclusions. One model predicts that blocking Ca^{2+} and Ca^{2+} -activated K^+ currents should increase spike frequency (Fohlmeister and Miller, 1997a). A more recent model (Benison et al., 2001) predicts that Ca^{2+} currents by themselves will not affect spike frequency. These models were formulated differently, in a number of ways, particularly in how they model cytoplasmic Ca^{2+} levels. Figuring out which factors are significant will therefore depend on the outcome of further studies of the cells modeled, particularly their cytoplasmic Ca^{2+} levels and the sensitivity of K^+ currents to Ca^{2+} and voltage.

ADAPTATION INDUCED BY TEMPORAL CONTRAST A very different effect of depolarization has been studied by Kim and Rieke (2001). Their results are the first to have shown that the excitability of at least some ganglion cells is modulated by “temporal contrast” (defined in their study as the ratio of the standard deviation of the photoisomerization of long-wavelength-sensitive cones to the mean rate). This was done in two ways. First, spikes and whole-cell current were measured in response to 8% and 21% contrast in full-field illumination. These responses were used to describe how ganglion cells convert light to whole-cell current in terms of one linear filter and a static nonlinearity, and how ganglion cells convert the whole-cell current to spikes in terms of another linear filter and static nonlinearity. Increasing contrast reduced spike generation more than the conversion of light to current, and did so in the linear filter rather than the static nonlinearity. Secondly, current that fluctuated randomly within a 0 to 50 Hz bandwidth (i.e., Gaussian noise) was injected into ganglion cells. When the modulation depth of the injected current was changed from a value induced by 8% contrast to that induced by 21% contrast, spike frequency declined. Because this reduction did not occur in the presence of a Na^+ channel toxin (tetrodotoxin), while it persisted in the presence of agents that block Ca^{2+} current and some K^+ currents (Cd^{2+} , Ba^{2+} , and apamin), temporal contrast adaptation appeared to be mediated by effects of current variance on Na^+ channels (Fig. 27.8).

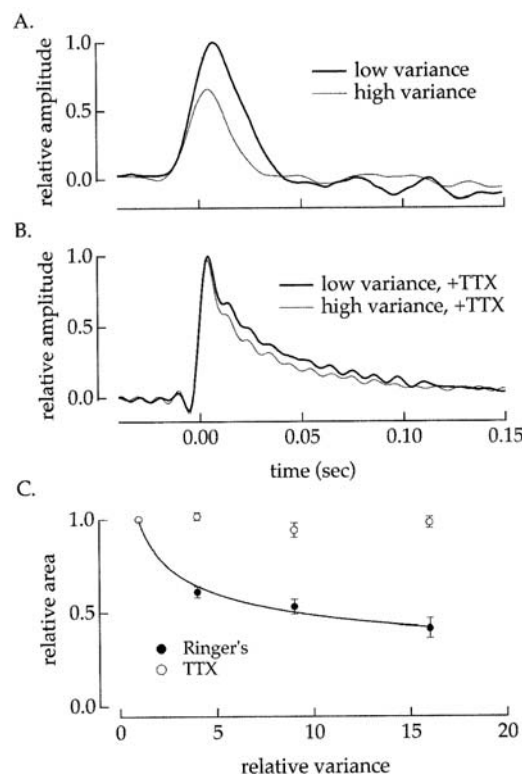

Figure 27.8. Responses of a ganglion cell, in an isolated larval tiger salamander retina, to injections of randomly fluctuating current. Current variance (in the bandwidth 0 to 50 Hz) was set to values recorded in response to low-contrast or high-contrast illumination (16 or 144 pA^2 , respectively). Responses show the change in spike firing rate, calculated as the output of a linear filter in a sandwich model, from cross-correlating the injected current with the spikes recorded, and dividing by power spectrum of the current. Control response (A) decreased on increase in current variance. This decrease was not observed in the presence of 100 nM TTX (B). C, plot of area of response in responses to different current variances, in presence and absence of TTX. From Kim and Rieke (2001), with permission. Copyright 2001 by the Society for Neuroscience.

Kim and Rieke (2001) suggested that increases in current variance increase spike threshold by decreasing the fraction of Na^+ channels that are available for activation. Specifically, Kim and Rieke suggested that this component of adaptation may occur because Na^+ channels recover slowly from inactivation after being activated at subthreshold membrane potentials by increased stimulus contrast. Other effects could also have come into play. For example, because Na^+ current measurements from ganglion cells of the species studied by Kim and Rieke show that activation threshold is -40 mV (Lukasiewicz and Werblin, 1988), contrast might have raised spike threshold because Na^+ channels inactivated without activating. This would be interesting to check in ganglion cells because Na^+ channels in a number of tissues enter, and recover from, this type of inactivation somewhat slowly (e.g., Rudy, 1978), and because a portion of the effect found by

Kim and Rieke is slow in onset and recovery. Also, other studies have shown that, before declining, spike frequency increases sharply just after contrast is increased (Brown and Masland, 2001; Chander and Chichilnisky, 2001; Smirnakis et al., 1997). Therefore, increases in contrast might induce other kinds of slow Na^+ channel inactivation, for example, one that follows fast inactivation during volleys of spikes (e.g., Fleidervish et al., 1996). One further possibility is that increases in contrast reduce excitability because a K^+ conductance is activated by the increased spiking that occurs just after the contrast increment, as found in ferret V1 neurons (Sanchez-Vives et al., 2000). Temporal contrast adapts these cells by activating a Na^+ -dependent K^+ current and, in various preparations, this current is blocked by tetrodotoxin, and not by Cd^{2+} , apamin, or low concentrations of Ba^{2+} (Constanti and Sim, 1987; Koh et al., 1994; Schwindt et al., 1989). It may only be a coincidence, but this pharmacology matches the one found by Kim and Rieke (2001).

Regardless of mechanism, the extent that decreases in ganglion cell excitability account for contrast adaptation remains to be worked out. Earlier studies found contrast adaptation that was relatively broad ranging and attributable to feedback from processes in the inner plexiform layer (Shapley and Victor, 1978). More recent studies have found contrast adaptation that is localized (Brown and Masland, 2001; Donner et al., 1991; Smirnakis et al., 1997) and persists after blocking GABA and glycine receptors (Brown and Masland, 2001; Donner et al., 1991; Rieke, 2001). Moreover, changes in contrast have been found to adapt some bipolar cells more than others (Rieke, 2001). These results imply that adaptation might arise in different ways or to different extents in different ganglion cells (Chander and Chichilnisky, 2001; Donner et al., 1991; Kim and Rieke, 2001).

Input-dependent modulation

Various substances (e.g., dopamine, serotonin, somatostatin, enkephalin, vasoactive intestinal peptide, substance P, and nitric oxide) have been found to affect spontaneous firing rates, light responses, and/or voltage-gated currents of ganglion cells (e.g., Hirooka et al., 2000; Zalutsky and Miller, 1990). These substances are generally termed “neuromodulators” because they exert their effects by altering the amplitude, voltage-sensitivity, and/or kinetics of ion currents, and also because their effects typically take seconds to develop. Of the substances that are thought to act as neuromodulators in the retina, dopamine has been studied the most extensively (Dowling, 1991; Witkovsky and Deary, 1991), and among the many effects that dopamine is known to exert, two recent studies have found that dopamine alters the excitability of dissociated ganglion cells (Liu and Lasater, 1994b; Vaquero et al., 2001). These studies showed that dopamine and SKF-38393 (a D1-type dopamine receptor

agonist) reduce spike frequency, truncate sustained spike firing, and increase spike latency, and that these effects occur without a change in resting potential (i.e., without producing a response opposite in polarity from the response to excitatory transmitters). Two of these effects are observed in ganglion cell responses to light flashes when dark-adapted retinas are light adapted by full-field background illumination. In particular, plots of spike frequency versus stimulus intensity shift rightwardly and spike firing becomes “transient” (as only a few spikes are elicited just after the beginning of constant current injections). The following sections describe what is known about how dopamine might produce these effects.

MECHANISMS OF INHIBITION Three intermediate steps between the release of dopamine by background illumination and modulation of ganglion cell excitability have been identified. First, light elevates cyclic 3',5' adenosine monophosphate (cAMP) levels in ganglion cells (Fig. 27.9; Vaquero et al., 2001). Secondly, dopamine increases cytoplasmic cAMP levels in ganglion cells (Liu and Lasater, 1994b) by activation of D1-type dopamine receptors, and thirdly, the elevated level of cAMP appears to activate a cAMP-dependent protein kinase (PKA; Vaquero et al., 2001). The evidence for these latter two steps is that a D1-type dopamine receptor antagonist (SCH-23390) blocks increases in ganglion cell cAMP levels by exogenous dopamine, that the inhibition of spikes by SKF-38393 is counteracted by a PKA inhibitor (Rp-5,6 DCl-cBIMPS; Fig. 27.10), and that a membrane-permeable cAMP analog that can activate PKA (8-bromo cAMP) also inhibits ganglion cells (Vaquero et al., 2001). As would be expected if light stimulates intraretinal dopamine release and if this dopamine activates D1-type receptors in ganglion cells, SCH-23390 diminishes cAMP levels in light-adapted ganglion cells, whereas sulpiride (a D2-type dopamine receptor antagonist) does not (Vaquero et al., 2001). In concert with these results, cAMP immunoreactivity has been found in the ganglion cell layer somata of light-adapted rat retinas (Vaquero and Ishida, unpublished observations), forskolin increases cAMP immunoreactivity in turtle (Liu and Lasater, 1994b) and rat (Shen et al., 1999; Traverso et al., 2002) ganglion cells, and antisera directed against adenylyl cyclase isoforms immunostain somata throughout the ganglion cell layer of rat and mouse retinas (Abdel-Majid et al., 2002).

The electrophysiological details of how dopamine-activated PKA reduces ganglion cell excitability remain to be worked out. D1-type receptor activation inhibits ganglion cells even after voltage-gated Ca^{2+} influx is blocked by replacing most of the extracellular Ca^{2+} with Mg^{2+} (Fig. 27.11; Vaquero et al., 2001). This suggests that dopamine inhibits ganglion cells by modulating other voltage-gated currents involved in spike generation, for example, voltage-

FIGURE 27.9. Transretinal cryosections of goldfish retinas, immunostained with a polyclonal antiserum directed against cyclic 3',5' adenosine monophosphate (cAMP) and imaged on a confocal laser microscope. Dark-adapted retinas were isolated and fixed under infrared illumination, 3 hrs after sunset (*a*), or from fish transferred to complete darkness for a 3-hr period that began 3 hrs after sunrise (*d*). Light-adapted retinas were isolated and fixed under room light 3 hrs after sunrise (*c*), or from fish exposed to roomlight for a 3-hr period that began 3 hrs after sunset (*b*). Level of photoreceptors (onl), outer plexiform layer (opl), inner nuclear layer (inl), inner plexiform layer (ipl), and ganglion cell layer (gcl) indi-

cated along left side of figure. The intensity of fluorescence that passed through a 590-nm long-pass filter is displayed in grayscale, with the brightest fluorescence appearing white. cAMP-like immunoreactivity is most vivid at level of cone photoreceptor inner segments in dark-adapted retinas and in ganglion cell layer in light-adapted retinas. cAMP-like immunoreactivity in photoreceptors is reduced in light-adapted retinas. Arrows point to some of the ganglion cell somata in each section. Magnification is identical in all panels; calibration mark in *d* is 30 μm . From Vaquero et al. (2001). gated Na^+ current and/or voltage-gated K^+ currents. What changes in these currents could explain the inhibition by dopamine? One possibility is that the primary effect of dopamine is like that found in hippocampal pyramidal neurons. Here, dopamine decreases the voltage-gated Na^+ current amplitude and decreases spike frequency (see Fig. 4a in Cantrell and Catterall, 2001). These effects are not thought to involve a change in Na^+ current inactivation (Cantrell et al., 1999).

Dopamine could also reduce ganglion cell excitability and truncate repetitive spiking by modulating outward K^+ current(s). One possibility is that K^+ current deactivates rapidly in the absence of dopamine, so that spike repolarization is short lived and ganglion cells can spike again when they are depolarized; if K^+ current deactivation was then slowed in the presence of dopamine, depolarization back to spike threshold would be postponed, Na^+ current inactivation could accumulate, and spiking would become transient. Although D1 receptor activation is not known to inhibit cells in any tissue this way, this is one way that somatostatin inhibits hippocampal pyramidal neurons (Moore et al., 1988).

Aside from these possibilities, it was originally proposed that dopamine inhibits turtle ganglion cells by decreasing the amplitude of a high-threshold Ca^{2+} current (Liu and Lasater, 1994b). The basis of this suggestion was that spikes are blocked in ganglion cells by other pharmacological agents

that block Ca^{2+} currents. This remains an interesting possibility because it suggests that dopamine might excite some ganglion cells, specifically those whose Ca^{2+} current amplitudes are increased by dopamine (Liu and Lasater, 1994b). One way to resolve this would be to demonstrate that dopamine reduces Ca^{2+} currents in cells that it inhibits, and increases Ca^{2+} currents in cells that it excites.

FEEDFORWARD INHIBITION Regardless of the mechanism(s) underlying the effect of dopamine on ganglion cells, the ability of dopamine to inhibit ganglion cells in the absence of their synaptic inputs implies that this inhibition does not require a decrease in excitatory synaptic inputs to ganglion cells, or a decrease in ganglion cell responses to this input in situ. This constitutes an inhibitory input to ganglion cells that is anatomically feedforward.

What cells and pathways produce this inhibition? A large number of anatomical, immunostaining, release, and electrophysiological studies suggest that dopaminergic input to ganglion cells can be activated by various presynaptic circuits. To begin with, endogenous dopamine and/or tyrosine hydroxylase have been found in processes ramifying in the most distal sublayer ("s1") of the inner plexiform layer in all of around 45 different species examined to date; similar processes also ramify in the middle and most proximal sublayers of most species (Djamgoz and Wagner, 1992; Ehinger, 1983; Frederick et al., 1982; Gustincich et al., 1997;

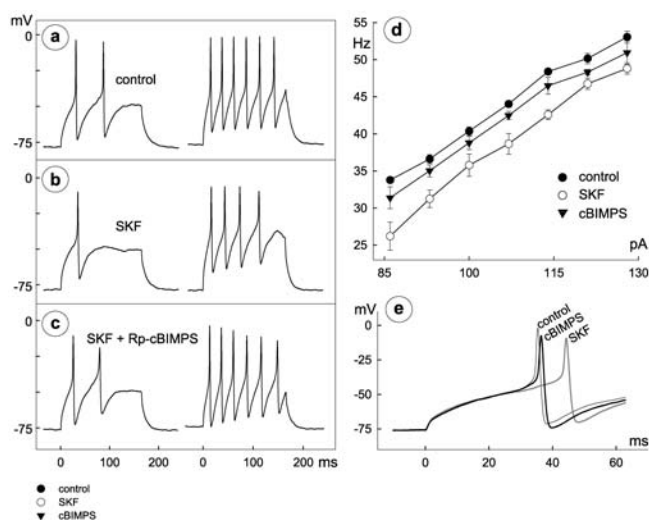

FIGURE 27.10. Intracellular recording of membrane potential of a ganglion cell dissociated from goldfish retina. Spikes are elicited by 165-msec, constant-current injections of 72 and 107 pA in left and right, respectively, of *a-c*. Current injections start at $t = 0$ in each record. Spikes recorded before (*a*) and during (*b*) application of 30 μ M SKF-38393, and during (*c*) subsequent application of a mixture of 30 μ M SKF-38393 plus 100 μ M Rp-5,6-DCI-cBIMPS. The response to the larger current injection in (*b*) shows a lower instantaneous spike frequency than in *a* and *c*; note also that spiking stops around 150 msec after the beginning of the current injection, as in Figure 27.11. *d*, plot of instantaneous spike frequency calculated from the first pair of spikes activated by individual depolarizations. Bars plot ± 1 S.E.M. *e*, plot of lead spike in recording in all three solutions, at fast sweep speed. From Vaquero et al. (2001). Copyright 2001 by the Society for Neuroscience.

Marc, 1995; Nguyen-Legros, 1988; Oyster et al., 1985; Peichl, 1991; Tauchi et al., 1990; Witkovsky and Deary, 1991; Witkovsky and Schütte, 1991). These processes arise from one, two, or possibly three morphological types of cell (namely, different amacrine cells, or amacrine and interplexiform cells; see Hokoç and Mariani, 1988; Kolb et al., 1990; Oyster et al., 1985; Tauchi et al., 1990), and position dopaminergic cells to be controlled by at least two different kinds of synaptic input. One is a direct excitatory input from ON-center bipolar cells (Boelen et al., 1998; Dong and McReynolds, 1992; Pollard and Eldred, 1990; Watt and Glazebrook, 1993; Yazulla and Zucker, 1988); the other allows dopaminergic processes to depolarize by disinhibition, when inhibitory input from GABAergic amacrine cells is reduced by hyperpolarizing input from OFF-center bipolar cells (Critz and Marc, 1992; Gustincich et al., 1997; Kamp and Morgan, 1980; Marshak, 2001; Piccolino et al., 1984).

Consistent with the net effect of these circuits, release studies have shown that dopamine release is augmented by light rather than by darkness (e.g., Kramer, 1971). Unfortunately, the rate at which ganglion cell activity can be

modulated by these circuits has not been measured. Although this should depend to some degree on how quickly extracellular dopamine concentration changes when dopamine release starts and stops, the rates of these changes are not yet known. Some of this could be rapid, given the amacrine and interplexiform cell processes that face synaptic vesicle clusters at ganglion cell dendrites (Pollard and Eldred, 1990; Watt and Glazebrook, 1993; Yazulla and Zucker, 1988), and the dendritic processes that wander down to the ganglion cell layer and even the optic fiber layer (Brunken et al., 1986; Guimarães and Hokoç, 1997; Kalloianis and Marc, 1990; Yazulla and Zucker, 1988). On the other hand, dopamine receptors have not yet been localized in ganglion cells at release sites of either dopaminergic amacrine or interplexiform cells. Moreover, a number of studies have reported not finding synapses from dopaminergic processes onto ganglion cells (Gustincich et al., 1997; Hokoç and Mariani, 1987, 1988; Kolb et al., 1990; Pourcho, 1982), even though dopamine receptors have been found in ganglion cells of some of these species (Nguyen-Legros et al., 1997; Tran and Dickman 1992; Verucki and Wässle, 1996). Unless the synapses are scarce enough to have been missed, one might imagine that dopamine reaches these ganglion cells by the paracrine type of transmission that was inferred originally from dopamine sensitivities of horizontal cells, photoreceptors, and pigmented epithelium (Deary and Burnside, 1989; Piccolino et al., 1984, 1987; Pierce and Besharse, 1985).

DOPAMINE “TONE”? It is not known if dopamine modulates ganglion cell light responses in all of the species referred to above, especially by modulating ganglion cell excitability as described above. However, dopamine responses have been studied in fish, reptilian, and mammalian ganglion cells, and at least two effects of dopamine on light responses resemble the effects of dopamine on spiking discussed above and effects of background light on responses to light flashes.

The first of these is to reduce instantaneous and sustained spike frequency. The earliest studies showed that dopamine reduced spike firing in cat ganglion cells, regardless of whether the dopamine was injected intravenously or iontophoretically applied (Straschill and Perwein, 1969; Thier and Alder, 1984). These studies also showed that dopamine inhibited spikes, regardless of whether they were elicited by receptive field centers or surrounds—for example, by illuminating ON-cell centers, darkening ON-cell surrounds, or illuminating OFF-cell surrounds (Straschill and Perwein, 1969; Thier and Alder, 1984); even spontaneous spike firing rates were reduced (Thier and Alder, 1984). When these effects were measured at different light intensities, dopamine was found to produce, in rabbit ON-center and OFF-center ganglion cells, a parallel and rightward shift of semi-

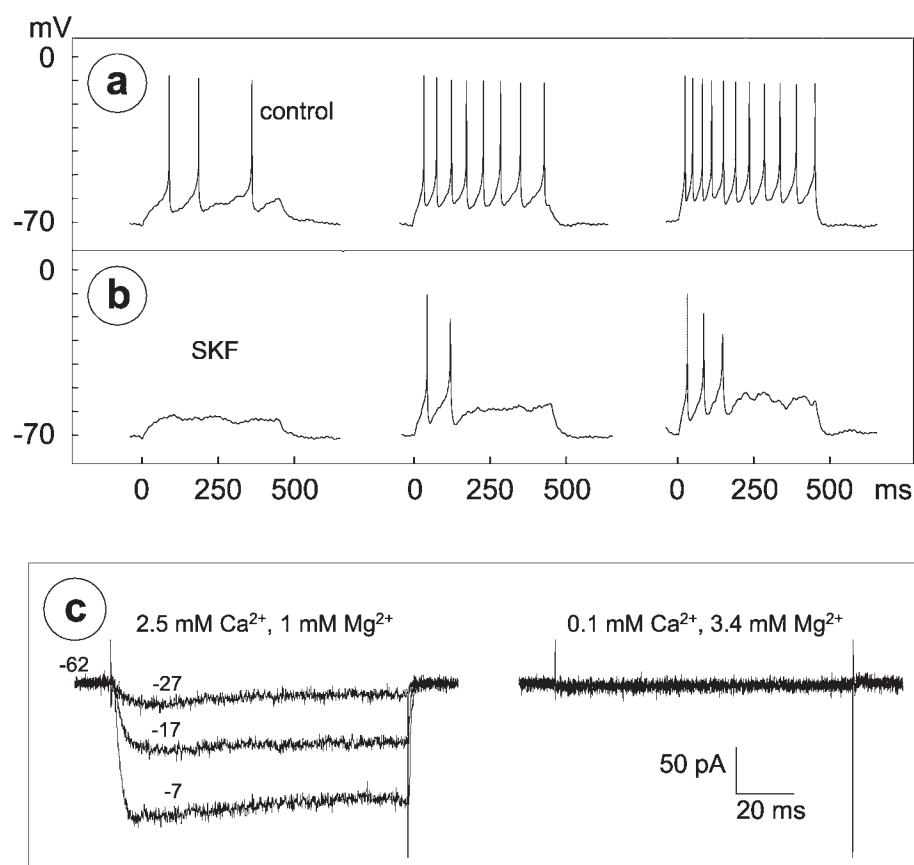

FIGURE 27.11. Intracellular recording of membrane potential of a ganglion cell dissociated from goldfish retina. Spikes are elicited by 450-msec, constant-current injections of 7, 11, and 15 pA in left, middle, and right of *a* and *b*. Current injections start at $t = 0$ in each record. Spikes recorded in a Ringer's solution containing 0.1 mM Ca²⁺ and 2.4 mM Mg²⁺, before (*a*) and during (*b*) application of 30 μ M SKF-38393. Note that, in SKF-38393, cell stops spiking around 150 to 200 msec after beginning of the current injections, as in Figure 27.10. *c*, lowering Ca²⁺ (and raising Mg²⁺) blocks whole-cell Ca²⁺ current that normally

activates at voltages traversed during spikes. Traces recorded in voltage-clamp mode, from a single cell (different from that in *a* and *b*) in control Ringer that contained 2.5 mM Ca²⁺ and 1 mM Mg²⁺ (*left*), and in test solution that contained 0.1 mM Ca²⁺ and 3.4 mM Mg²⁺ (*right*). As indicated by numbers next to traces, holding potential was -62 mV, and test potentials were -27, -17, and -7 mV. Compositions of Ringer's and pipette-filling solutions blocked voltage-gated Na⁺ and K⁺ currents. Adapted from Vaquero et al. (2001). Copyright 2001 by the Society for Neuroscience.

logarithmic plots of spike frequency against light intensity (so-called "R-log I curves"; Fig. 27.12; also see p. 846 of Jensen and Daw, 1986). These shifts, being parallel and rightward, resemble those produced by dopamine on spike frequencies elicited by current injections into goldfish ganglion cells (Vaquero et al., 2001), and by uniform background illumination on R-log I curves recorded from ganglion cells in cat (Sakmann and Creutzfeldt, 1969), mudpuppy (Thibos and Werblin, 1978; Werblin and Copenhagen, 1974), and rat (Green and Powers, 1982).

This does not imply that dopamine accounts for the position of R-log I curves measured over a wide range of background intensities. As yet, there is no way to know how much dopaminergic inhibition of ganglion cells contributes to adaptation, because the dependence of intraretinal dopamine concentration on light intensity, and the depen-

dence of both bipolar and ganglion cell light responses on dopamine concentration, remain to be determined. The parallel right-shift of R-log I curves that is produced, however, indicates that dopamine can reduce the light sensitivity of ganglion cells without changing the width of their dynamic range (e.g., Jensen and Daw, 1986)—in other words, dopamine can change σ in the Michaelis equation, without changing n or R_{\max} .

A second effect of dopamine is to truncate repetitive spiking. Dopamine (1) eliminates sustained spiking in dark-adapted OFF-center cells at the offset of central illumination (leaving a transient response only), (2) accelerates the decay of this OFF-response even after it becomes somewhat transient due to light adaptation (see below), and (3) accelerates the decay of spiking elicited in ON-center cells by the onset of central illumination (Fig. 27.13; Thier and Alder,

FIGURE 27.12. Poststimulus time histograms of an OFF-center ganglion cell in a rabbit eyecup. Stimulus was a 3-mm square of light at 1.6 log lux. Background illumination was approximately 1.4 log lux. Spike frequencies recorded in this cell at the offset (left) and

onset (right) of various stimulus intensities, in the absence (filled circles) and presence (open circles) of 65 μ M dopamine. (From Jensen and Daw (1986), with permission. Copyright 1986 by Elsevier Science.)

OFF BRISK-TRANSIENT (Y)

FIGURE 27.13. Peristimulus time histograms of an OFF-center ganglion cell in an in situ cat retina. Top row shows response to 7 cd/m² in presence of 3 cd/m² background illumination. Lower row shows response to 0.02 cd/m² in presence of 0.01 cd/m² background illumination. In each row, light responses were

recorded before (control), during (dopamine), and after (recovery) ionophoretic application of dopamine. Each trace shows 1024 msec of recording, with the stimulus light on (during the upward-step below each recording) for the first 512 msec. (From Thier and Alder (1984), with permission. Copyright 1984 by Elsevier Science.)

1984; see also Ames and Pollen, 1969). This change in spiking pattern emphasizes the transient component of ganglion cell light responses, resembles the effects of light adaptation on ganglion cell responses cited above (e.g., Yoon, 1972), and parallels the decrease in photoreceptor integration time that results from light adaptation (Baylor and Hodgkin, 1974).

The filtering of ganglion cell spiking by dopamine is also of interest because it might explain, to some extent, the shape of light responses that have been recorded after suppressing responses to the fast-acting inhibitory transmitters of the retina, GABA and glycine. The most notable example is that Müller and colleagues (1992) and Frumkes and colleagues (1995) found that GABA and glycine receptor blockers do not transform transient light responses of ganglion cells into sustained responses in well light-adapted cat retinas, whereas Caldwell and Daw (1978) found that this did occur at lower background light intensities. Using an entirely different approach, mouse ganglion cell light responses were found to be prolonged, but still transient, after photoablation of displaced amacrine cells that are likely to be GABAergic (Nirenberg and Meister, 1997). Similarly, in tiger salamander retina, various combinations of bicuculline, CGP35348, picrotoxin, and strychnine do not transform transient ganglion cell light responses into sustained ones, at concentrations that block the GABA_A, GABA_B, GABA_C, and glycine receptors in this species (Bieda and Copenhagen, 2000). And most recently, the recordings of Flores-Herr and colleagues (2001) have shown that rabbit ganglion cells spike more, but still transiently, after direct, hyperpolarizing, GABAergic and glycinergic inputs to these cells were reversed by raising the intracellular Cl⁻ concentration with whole-cell patch electrodes.

To better understand these spiking patterns, light-evoked excitatory postsynaptic current and spikes will have to be recorded under the same conditions, and whether transience arises presynaptically or postsynaptically will have to be checked (e.g., Awatramani and Slaughter, 2000; DeVries, 2000; Freed, 2000b; Hare and Owen, 1995; Heidelberger and Matthews, 1994; Lukasiewicz et al., 1995; Shiells and Falk, 1985). In any event, at least some of the results cited here suggest that dopamine and inhibitory amino acids can both truncate the responses of individual ganglion cells to light flashes. This raises a number of questions. Functionally, the most important would be what purpose this dual inhibition might serve. One clue may be that inhibition by dopamine takes several seconds to develop (Liu and Lasater, 1994b; Straschill and Perwein, 1969; Thier and Alder, 1984; Vaquero et al., 2001), whereas GABA can inhibit ganglion cells more quickly. These differences (and their corresponding recovery rates) suggest that fluctuations in GABA and dopamine release could drive “brisk fluctuating” GABA responses, but only “sluggish sustained” dopamine res-

ponses. Fluctuations in light intensity around a mean value may then produce fluctuating GABA responses superimposed over a relatively constant level of dopamine response. Examining this possibility could be facilitated by the availability of specific dopamine receptor antagonist. However, a number of commonly used agents have been found to produce effects unrelated to dopamine receptors, including changes in ganglion cell membrane potential and voltage-gated currents (Akamine et al., 2002; Guenther et al., 1994; Ito et al., 1997; Jensen, 1992).

Conclusion

During the first few years that patch-clamp methods were used to identify ion conductances in ganglion cells, discoveries of conductances and their voltage sensitivities were welcome news. Now, 15 years later, we want to know even more about ion conductances in ganglion cells, particularly as we find out how these conductances are controlled, which species and cells they reside in, and the conditions under which they might operate. One could argue that major progress along three fronts has been made. First, the number of ion conductances in ganglion cells is unlikely to double any time soon. Second, it appears that the susceptibility of these conductances to regulation by transmitters, extracellular modulators, and cytoplasmic messenger systems will be more the rule than the exception. Third, it now seems more than likely that some morphological types of ganglion cells use different conductances to generate spikes, at least under certain conditions. At the same time, we clearly have no complete “parts list” yet for any ganglion cell, to the extent that its excitability under various conditions can be accounted for in measured biophysical terms. Essentially, no ganglion cell has yet been “disassembled” carefully and thoroughly enough to know how to “assemble” one.

In parallel with this line of study, quantitative comparisons of spikes that ganglion cells generate with the inputs that elicit these spikes, and modeling of the statistical properties of these spikes has progressed to the point that the timing and variability of spike occurrences under certain lighting conditions can be predicted with remarkable accuracy. The model that can make these predictions (Keat et al., 2001) has few variables in it. In fact, the processes this model describes are so few that one would like to think that the properties of the channels underlying the generator and feedback voltages in these models must already have been found. If not, how then are we going to find these? The results reviewed in this chapter give at least some reasons to believe that these properties will be best sought under the conditions that the model applies to, and will be best measured with methods that do not disrupt the intracellular milieu that those conditions create. Fortunately, some of the methods for doing so have been worked out (perforated-

patch recording, different types of amplifiers, and various retinal preparations).

To construct mechanistic descriptions of excitability, maximum whole-cell ion conductances, the dependence of current amplitudes and kinetics on voltage, transmitters, modulators, and second messenger systems, the stationarity and variability of these dependencies, and the dependence of cytoplasmic messenger concentrations on various stimulus conditions, will have to be measured. Without knowing these, it will be difficult to know what component of spike generating models can be experimentally manipulated to test the uniqueness of fits to data and the variety of cells whose behaviors these models might predict. Also, as much as it now seems that spike generation will vary with the conditions it is measured under, one would like to know how much these changes actually amount to, and how well the underlying conductances have been characterized to understand and account for these changes.

Unfortunately, those interested in how ganglion cells spike under various conditions face a mountain of direct and indirect effects to unravel and resolve. For example, a large number of modulatory neurochemicals have been identified in the retina (see Chapters 20 and 22). How do these affect ganglion cell function? Components of several signaling cascades have been localized to ganglion cells, including protein kinase C, calcium/calmodulin-dependent protein kinases, and arachidonic acid. What controls these, and what do they do? More than one ion channel system is affected by some cytoplasmic messengers (Liu and Lasater, 1994b; Vaquero et al., 2001; also see Chapter 23) Are these effects synergistic, and if not, which effects dominate?

How multiple and flexible spike generating mechanisms in ganglion cells contribute to the transfer of information remains to be evaluated. At the level of retinal organization, one could imagine a number of possibilities. For example, modulation of ganglion cell excitability by mechanisms that are purely response dependent could limit the effect of adaptation to local, rather than global, maps. In the horizontal plane of the retina, this could form adaptation pools that are no larger than summation pools. In the vertical axis of the retina, this would enable the retina to adapt ganglion cells without necessarily altering photoreceptor or interneuron light responses. Modulation of ganglion cell excitability by mechanisms that are input dependent could allow ganglion cells to adapt under any conditions that drive the modulatory input (see Vaquero et al., 2001). One difference between this and response-dependent modulation is that tonically released chemical modulators could alter ganglion cell responses with less, if any, dependence on ganglion cell response magnitude and duration. Adaptation could still be spatially discrete if the cell that releases the modulator in question has a relatively small arbor (Brown and Masland, 2001; Kalloniatis and Marc, 1990; Smirnakis et al., 1997) or

if this cell has an inhibitory surround (Ammermüller and Kolb, 1995). By placing receptors for different modulators on single cells, and releasing these modulators with different stimuli, single ganglion cells could change their spike output under a variety of lighting conditions. By placing receptors for a modulator on some cells but not others, different ganglion cells could transform identical synaptic inputs into different spike outputs. Lastly, differences in spike output could obviously result, with or without modulatory inputs, from differences in the types of ion channels that ganglion cells express.

By placing these differences and modulatory mechanisms in the output neurons of the retina, ganglion cells seem not only anatomically positioned, but also electrophysiologically equipped to regulate and condition information flow from the retina to the rest of the visual system. By analogy to the notion that retinal ganglion cell mosaics help to “tile” visual space (Wässle and Boycott, 1991), intrinsic functional differences among ganglion cells, and adaptive mechanisms within ganglion cells, could be parts of strategies that “tile” parameter spaces.

28 Direction Selectivity in Retinal Ganglion Cells

RICHARD H. MASLAND

DIRECTION SELECTIVITY by retinal ganglion cells—the ability of some cells to report the direction of stimulus movement—was described in classic experiments by Barlow and Levick (Barlow et al., 1964; Barlow and Levick, 1965) more than 35 years ago. Despite much theory and many experiments, the mechanism remains unknown. Indeed, it can be argued, with some embarrassment, that small progress has been made since Barlow and Levick's classic studies. Those studies and subsequent ones have recently been the subject of a careful review by four experienced students of direction selectivity, including its codiscoverer (Vaney et al., 1999). Here I will: (1) outline the cardinal features of direction selectivity—that is, those experimental findings that seem universally accepted; (2) discuss some of the requirements for a mechanistic explanation of it; and (3) comment on certain controversies that have sprung up in the past few years.

Retinal direction selectivity appears deceptively simple. Perhaps for that reason, even sophisticated neurobiologists have sometimes offered theories of its mechanism that could have been seen with a few minutes' careful thought to be unworkable. For that reason, it is important to begin with a statement of the fundamental facts.

Fundamental features of direction selectivity in mammalian retinas

Direction selectivity has been most studied in the retina of the rabbit; work in other species will be noted where appropriate. The behavior of an idealized ON-OFF direction-selective (DS) cell (a separate ON type exists but will not be considered here) is shown in Figure 28.1. The cells can respond to a 50- μ m displacement of a spot of light 50 μ m in diameter. The displacement can happen anywhere within the receptive field, with the preferred direction remaining the same. The cells have the same directional preference for movement of a light spot or a dark spot. Similarly, the cells have the same directional preference for a light edge or a dark edge. If the receptive field is mapped with a flashing spot, ON and OFF responses are encountered at all locations.

These observations eliminate a trivial form of direction selectivity, in which an excitatory zone is flanked by an

inhibitory zone (Fig. 28.1D). In principle, a stimulus moving first across the inhibitory zone and later across the excitatory zone could, with the right timing, generate a null response as inhibition collides with excitation. A stimulus moving in the opposite direction, from the excitatory side to the inhibitory side, would encounter the excitatory zone first and create a positive response. This cannot be the mechanism, first because ON-OFF responses are encountered everywhere, and second because the directional preference is the same for a light or a dark edge (this is a quick diagnostic test for a putatively DS ganglion cell encountered during recordings). Instead, some sort of local subunit is reduplicated throughout the receptive field.

Nothing in the anatomical structure of the ON-OFF DS cell predicts direction selectivity (Amthor et al., 1984; Oyster et al., 1993; Yang and Masland, 1994). A series of ON-OFF DS cells injected after recording are shown in Figure 28.2. There is no correlation between the preferred direction and any feature of the dendritic arbor that has thus far been discerned.

However, one feature of the DS cell's response was explained by the cell's structure: its independence of the sign of contrast. The DS ganglion cell has a bistratified dendritic arbor (Fig. 28.3). One arbor lies within the ON zone in the inner plexiform layer and one arbor in the OFF zone. The ON arbor can mediate direction-selective responses to a light edge; the OFF arbor to a dark edge. The relative independence of these two mechanisms was demonstrated by Kittila and Massey (1995), who eliminated the ON input by blocking the responses of ON bipolar cells pharmacologically. With ON responses blocked, the DS ganglion cell remained direction selective, even though it could respond only to negative contrasts.

A major event in direction selectivity is feedforward inhibition

A series of important experiments on the mechanism of direction selectivity was carried out by Daw and his colleagues (Ariel and Daw, 1982a, 1982b; Caldwell et al., 1978; Wyatt and Daw, 1975). They recorded from ON-OFF DS cells *in vivo*, using electrodes that penetrated the globe, and

FIGURE 28.1. Response properties of the ON-OFF direction selective neuron in the retina. *A* and *B* are schematic, *C* is the classic illustration of Barlow and Levick (1965). The receptive field is indicated by a dashed line. *A*, The cell responds selectively to movement of a small spot from left to right. The directional preference is maintained for small areas within the receptive field. *B*, Direction-selective cells respond to either sign of contrast.

applied drugs to the retina by infusing them into the ophthalmic artery.

Their first critical observation was that a small moving stimulus that sweeps across the receptive field generates an asymmetrical wave of inhibition. Their result is schematized in Figure 28.4. Note that the cloud of inhibition does not occupy a fixed position, but moves around the receptive field, maintaining a constant position relative to the moving stimulus. When the stimulus moves in the null direction, the cloud of inhibition precedes the arrival of the stimulus in space. When the stimulus moves in the preferred direction, the cloud of inhibition trails the stimulus.

The importance of this inhibition was confirmed by the demonstration that retinal direction selectivity is entirely abolished by the GABA receptor antagonist picrotoxin

C, When the receptive field of an ON-OFF DS cell is mapped with a flashing spot, ON and OFF responses are encountered everywhere within the receptive field. This requires that some sort of local subunit be reduplicated within the field. In other words, the trivial mechanism shown in *D*, in which ON and OFF zones are segregated, cannot explain the behavior of the DS neuron.

(Caldwell et al., 1978). Under control conditions, the excitatory center of the receptive field is only slightly larger than the dendritic arbor of the DS ganglion cell (Yang and Masland, 1994). In the presence of picrotoxin, two things happen: (1) the receptive field almost doubles in size, and (2) all traces of direction selectivity are abolished. From cell to cell there is some biological variation, such that the picrotoxin-influenced receptive field may be slightly asymmetrical, but there is no consistency to this result.

It is also possible to show weak, feedforward excitation (excitation that spreads ahead of the moving stimulus) in the preferred direction (Amthor et al., 1996). However, this is also seen in the null direction as well when the masking inhibition is pharmacologically blocked (Chiao and Masland, 2002).

FIGURE 28.2. ON-OFF DS cells injected after recording. An arrow indicates the preferred direction for each cell (Yang and Masland, 1994). Thus far, no one has been able to find any correlation between a morphological feature and the preferred direction. Scale bar, 100 μm .

General requirements for direction selectivity

Barlow and Levick pointed out that two things are required for direction selectivity. There must be, somewhere in the system, a physical asymmetry such that inhibition (or in principle, excitation) is laterally displaced relative to the stimulus. As will be discussed later, this is usually interpreted as the process (axon or dendrite) of a neuron, but that is not necessarily so: one can imagine laterally displaced receptors, laterally displaced waves of intracellular calcium, or other molecular mechanisms that would achieve the same result. Nonetheless, something, somewhere, undergoes a lateral displacement in direction selectivity. The second element that is required is the time delay. The model now commonly termed the Barlow-Levick model invokes the process of a laterally directed inhibition. Some possible arrangements are shown in Figure 28.5.

In its simplest form (Fig. 28.5, *top panel*) such a mechanism, taken at face value, cannot work. A mechanism of direction selectivity must not only prevent responses during movement in the null direction, but *it must also permit responses in the preferred direction*. In the drawing, there is no difference between the total amount of inhibition that the ganglion cell receives in the null direction or the preferred direction. Something else must be postulated.

One such “something else” might be that the inhibition occurs presynaptic to the ganglion cell, rather than directly on it (*middle panel*). Another was imagined very early in the study of visual motion, from studies by Reichardt of insect behavior. From first principles, Reichardt and Hassenstein (Reichardt, 1961) proposed a model that outlined the components necessary for an elementary motion detector. It is in many ways similar to the model proposed by Barlow and Levick, in which a lateral displacement and a time delay are

FIGURE 28.3. How the ON-OFF DS cell can respond to both light edges and dark edges. The ON-OFF DS cell is a bistratified neuron. One arbor is stratified within the ON sublayer of the inner plexiform layer and the other within the OFF sublayer. The ON arbor subserves responses to light edges; the OFF arbor to dark edges. Because the retina's ON and OFF pathways are created at the first retinal synapse (between photoreceptors and bipolar cells), this implies that the fundamental mechanism of the directional discrimination is reduplicated for the ON and OFF pathways.

FIGURE 28.4. A moving "cloud" of inhibition precedes a stimulus moving in the null direction. The illustration shows the prediction made from the results of Wyatt and Daw (1975), in which the receptive field was probed with a moving stimulus and a flashed test probe. A heart-shaped contour of inhibition was observed.

required. However, the elementary motion detector was taken to the level of a formal model and had an additional requirement: some nonlinearity in the interaction between the presynaptic and postsynaptic motion-detecting elements (Fig. 28.6). This overcomes the difficulty described in the previous paragraph; namely, that a cell receiving input from many small motion-detecting elements receives the same amount of excitation and inhibition, no matter what the direction of motion, in the absence of another postulated mechanism. The mechanism postulated in the Reichardt model is a multiplicative step between the feedforward information and the straight-through information. There is a time delay, such that the feedforward information from point A arrives at the integrator at the same time as

FIGURE 28.5. Several different ways in which a laterally displaced inhibition could be arranged. The top panel shows a "post-synaptic model" in which an inhibitory amacrine cell makes an input onto the ganglion cell that is displaced toward the null direction. As drawn, such a model will probably not work. If the ganglion cell is isopotential (or is any form of simple, linear, integrate-and-fire neuron), the cell will be prevented from responding when the stimulus moves in the null direction, but also will be prevented from responding when the stimulus moves in the preferred direction. Even though the inhibition trails the stimulus, it will be detected by the ganglion cell. As has been pointed out by many, some other nonlinearity is required. The middle panel shows a model in which the inhibition is presynaptic. In this case, the amacrine cell inhibits the output of the bipolar cells (only some of the hypothetical synapses on bipolar cells are shown). This is a "presynaptic model," in which the output of the bipolar cells is direction selective. The two types of model are not mutually exclusive, and the bottom panel shows a case in which both mechanisms operate.

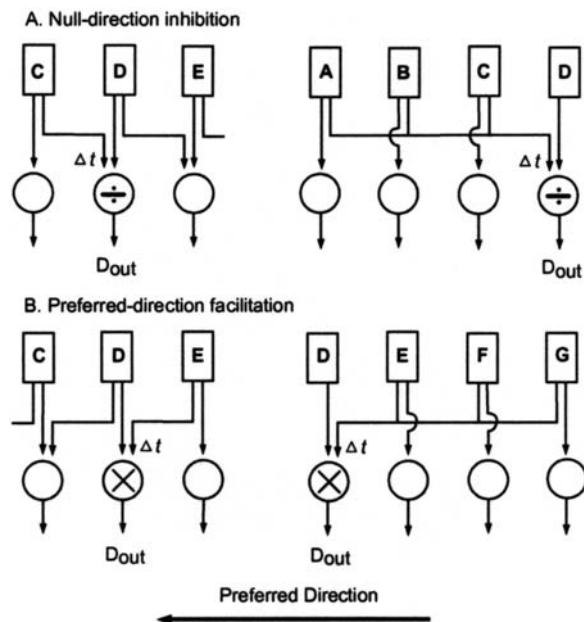

FIGURE 28.6. Schematic illustrations of the spatial asymmetries and nonlinear interactions that could create direction selectivity in retinal ganglion cells. For historical reasons, the inhibitory model is sometimes termed the Barlow-Levick model and the excitatory model the Reichardt model, but they are similar in many regards. The illustration also makes the point that single or multiple cells could participate in the asymmetrical inputs. (From Vancy et al., 1999).

straight-through information from point B. If these merely sum, there will be no difference between the preferred direction and the null direction. However, if they multiply, an asymmetry is created such that the system's output is greater in the preferred direction than the null direction.

The nonlinearity could just as well be divisive. It was later shown that for fly vision a multiplicative step followed by a subtractive step yields the best prediction of fly behavior (Borst and Egelhaaf, 1990). These models offer little in the way of neural mechanism. Instead, they are guideposts and the task, both in flies and in rabbits, is to learn whether and how they are implemented.

Presynaptic versus postsynaptic computation of direction selectivity

A controversy alluded to already (see Fig. 28.5) concerns the locus of the computation of direction selectivity. By this is meant whether the synaptic interactions that create direction selectivity occur on the DS ganglion cell itself or among the neurons afferent to the DS ganglion cell. In the second case, the input to the DS ganglion cell would already be direction selective.

Taylor and colleagues (2000) concluded that the first element to be fully direction selective in the rabbit retina is

the DS ganglion cell (this is what is usually meant by the somewhat imprecise phrase the “site of the DS computation”). They made whole-cell patch recordings from DS ganglion cells and found two kinds of evidence for a postsynaptic locus. First, holding the membrane potential at -30 mV or -70 mV allowed an isolation of excitation and inhibition on the ganglion cell. At -70 mV movement of a stimulus in the preferred direction caused a large depolarization; in the null direction it also caused a depolarization, but a smaller one. When the cell was clamped at -30 mV , the null direction depolarization was converted to a hyperpolarization. This repeats an earlier observation by Marchiafava (1979) in turtle retina. A parsimonious interpretation is that stimulus movement in the null direction causes the ganglion cell to receive a laterally displaced input that opens chloride channels (shunting inhibition, known to result from GABA_A receptors).

In confirmation of this interpretation, Taylor and colleagues carried out a second type of experiment, in which the intracellular concentration of chloride was raised by recording with a patch pipette containing 150 mM of chloride. As chloride diffused from the electrode into the cell, the driving force on chloride was reduced. In that case, shunting inhibition would have become less effective; in fact, the high chloride electrode very much lessened the ganglion cell's direction selectivity. Taylor and colleagues concluded that the asymmetry responsible for direction selectivity is a shunting inhibition of the dendrites of the DS ganglion cell.

In contrast, Borg-Graham argued, from experiments on turtle retinas, that the directional decision is made presynaptically—that the first direction-selective element lies somewhere earlier in the chain of synapses leading to the ganglion cell, so that the excitatory input to the DS ganglion cell is already direction selective (Borg-Graham, 2001). This conclusion was derived from modeling of experiments using patch recording. The presynaptic and postsynaptic models make different predictions for the excitatory and inhibitory synaptic conductance inputs onto the DS ganglion cells during traverse of the receptive field by a stimulus. They were estimated from the modulation of the ganglion cell's input conductance during the visual response and the apparent reversal potential of the evoked inputs. For example, if the computation is postsynaptic, there must be a temporal offset between excitation and inhibition of the ganglion cell. The finding was that the peak and average of the excitatory input was greater for responses generated by stimuli moving in the preferred direction. If correct, this is direct evidence for a presynaptic site of the directional discrimination.

At the moment, this conflict remains unresolved. Given the difficulties of these experiments, one possibility is that both presynaptic and postsynaptic mechanisms operate. The critical biological measurements are difficult ones. Retinal ganglion cells have small (20 to $30\text{ }\mu\text{m}$) somas but large

dendritic arbors. Retinal ganglion cells are not, like billiard balls on a table, a naked target. Instead, they are enveloped in the cytoplasm of the Müller glia and are protected on the surface by the inner limiting membrane, a tough extracellular proteinaceous matrix. The inner limiting membrane must either be penetrated or removed. An advance in this type of recording was the discovery that the inner limiting membrane can be physically peeled away from the ganglion cells, yielding access for patch or sharp electrodes (Peters and Masland, 1996; Taylor and Wässle, 1995). Even so, these cells are much more difficult to access than are, say, Purkinje or hippocampal neurons in a brain slice.

The second major difficulty is that the dendrites of the DS cells are not isopotential. They range up to approximately 800 μm in diameter and the diameters of their dendrites are far from uniform: the thinnest dendrites, approximately 0.3 μm in diameter, can exit directly from major dendrites that have diameters up to 1 μm (He et al., 1999). This creates many electrotonic complexities (indeed, many opportunities for interesting computations) but complicates the analysis of the somatic responses and raises the suggestion of nonlinearities that are invisible to an electrode placed at the soma. Among many other assumptions are that there is a single type of excitatory and a single inhibitory conductance, that the amount of electrotonic isolation is constant under all stimulus conditions; and that the current voltage relations are linear. Both groups of experimenters in this controversy are pushing the limits of current methodologies.

Starburst amacrine cells have features that could contribute to direction selectivity

From the earliest times, likely candidates for the laterally displaced element that creates direction selectivity were horizontal or amacrine cells. Amacrine cells quickly took the ascendancy because of their greater diversity. The original and still the leading candidate was the cholinergic, “starburst” amacrine cell. The first evidence came from electrophysiological experiments, which showed that the DS retinal ganglion cell responds very strongly to acetylcholine, is excited by anticholinesterase, and has its response to light depressed by cholinergic antagonists (Kittalia and Massey, 1997; Masland and Ames, 1976). The cells responded strongly to acetylcholine even when an isolated retina was incubated in medium containing high magnesium and low calcium, conditions that prevent synaptic transmission; this indicated that acetylcholine receptors were located directly on the ganglion cells, a finding subsequently confirmed by using antibodies against those receptors (Keyser et al., 2000). That the acetylcholine-releasing neuron was in fact an amacrine cell was shown directly by autoradiography of the acetylcholine-synthesizing neurons, which formed mirror

symmetrical populations located on either side of the inner plexiform layer and contained acetylcholine within two thin bands within the layer (Masland and Mills, 1979). Famiglietti (1983) then pointed out that a neuron adventitiously stained by the Golgi method stratified at the same level where bands of acetylcholine are present, and nicknamed this neuron the “starburst cell.” Definitive proof of the identity between the acetylcholine-synthesizing cells and the starburst cell (and neurofibrillar-stained cells observed by an independent method; Vaney et al., 1981) came when the starburst cells could be injected using fluorescent staining with DAPI as an intermediate step for targeting (Hayden et al., 1980; Masland et al., 1984a; Tauchi and Masland, 1984; Vaney, 1984).

The first suggestion that starburst cells were involved in direction selectivity was by Masland and colleagues (1984b), on the basis that (1) DS ganglion cells receive a strong cholinergic input, (2) the starburst cell is the only cholinergic neuron known to exist in the retina, and (3) a role in detecting motion would rationalize the apparent redundancy of the overlapping plexuses of starburst dendrites. They proposed that “the dense plexus of cholinergic dendrites and the transient nature of acetylcholine release combine to create the local subunit that enables detection of motion within regions smaller than the ganglion cells’ receptive fields,” but did not suggest a specific mechanism by which the directional discrimination might occur.

Are starburst cells the mechanism of motion discrimination?

Subsequent studies at both the light and electronmicroscopic levels have confirmed an intimate relationship between dendrites of the starburst cells and those of the DS ganglion cells (Famiglietti, 1992; Vaney et al., 1989). An important observation was that the synaptic inputs and outputs of the starburst dendrites are anisotropic (Famiglietti, 1991). The dendrites receive synaptic inputs along their whole length but make outputs primarily along the dendrites’ distal third (Fig. 28.7). This creates a directional polarization, such that, on average, inputs to the cell will be propagated centrifugally, from the center of the cell toward the ends of the dendrites.

This functional polarization of the dendrites represents a potential source for the lateral displacement postulated in all theories of direction selectivity. That it creates a local direction selectivity has recently been elegantly confirmed in experiments using calcium imaging and two-photon microscopy (Euler et al., 2002), show that the starburst cells have large calcium influxes at the distal release sites of their dendrites in response to centrifugal motion but much less to centripetal motion.

From the anatomic evidence, Vaney (1991) had seized upon this asymmetry to suggest a mechanism of direction

FIGURE 28.7. Synaptic asymmetries in the starburst cell can create an asymmetrical input to DS ganglion cells. At the top is shown the pattern of synaptic input and output on the dendrites of the starburst amacrine cell. Inputs from bipolar cells to the starburst cell occur throughout the length of the dendrites, but synaptic outputs are restricted to the distal third. This results in a net polarization of activity along the dendrites; on average, activity will propagate centrifugally, toward the distal dendrites. If the starburst cell is selectively connected to a DS cell, this asymmetry can create direction selectivity in the ganglion cell. In the illustration shown, the ganglion cell would respond to stimuli moving toward the right. The other, “empty” dendrites of the starburst cell would make outputs to other DS ganglion cells, those with preferred directions upward, downward, or to the left in the diagram. (From He and Masland, 1997).

selectivity. In this model the starburst cells are selectively connected to individual DS ganglion cells. On the upstream (preferred) side, they selectively excite the ganglion cell during movements in the preferred direction. This accords with the polarized nature of their dendritic activity, which tends to transmit signals from central to peripheral areas within the starburst cell’s arbor. This concept has the great appeal that it accounts for the overlap of the starburst cells. In the postulated arrangement (Fig. 28.7), only a fraction of the starburst cell’s dendrites are occupied with one DS cell. What happens to the starburst cell’s other, “empty” dendrites? They contact DS ganglion cells with other preferred directions. In other words, a single population of starburst amacrine cells can provide a directionally biased output to direction selective ganglion cells of several preferred directions. A similar model was formally stated by Borg-Graham and Grzywacz (1992) and was accompanied by modeling

showing many of the premises of the theory to be mathematically plausible.

The simplicity and elegance of this proposed arrangement make it very attractive. However, certain conflicts existed, most notably that under most conditions cholinergic antagonists fail to eliminate direction selectivity (Ariel and Daw, 1982a; He and Masland, 1997; Kittila and Massey, 1997; Masland and Ames, 1976). Those same antagonists (d-tubocurarine, dihydro- β -erythroidine, or mecamylamine) could be shown to prevent acetylcholine’s action on the retina’s acetylcholine receptors; this was done by applying large test doses of acetylcholine, which in the presence of the antagonist could be shown to produce no response from the DS ganglion cell. The antagonists thus are effective at the synapses in question but fail to prevent direction selectivity. This is not conclusive evidence, however, because the starburst cells are unusual in that they contain and release both acetylcholine and GABA (Brecha et al., 1988; O’Malley et al., 1992; Vaney and Young, 1988). The model depicted in Figure 28.7 could be either excitatory or inhibitory (or both, i.e., push-pull).

In an attempt to resolve the issue, He and Masland (1997) used laser microablation of the starburst cells as a further test. They identified starburst cells in isolated retinas by staining with DAPI, recorded the responses of DS ganglion cells, and then laser-microablated a patch of starburst cells on either the preferred side, the null side, or both. The fundamental result was that ablating starburst cells did not eliminate direction selectivity. In the preferred direction, where a vigorous response is normally observed, ablating starburst cells decreased the response to about the level expected from a pharmacological blockade of acetylcholine, but direction selectivity was retained. He and Masland reported a second experiment in which the effect of curare was tested in the presence of picrotoxin. As noted earlier, picrotoxin blocks GABA_A receptors and entirely eliminates direction selectivity. In the presence of picrotoxin, the application of curare caused a *symmetrical* decrease in the magnitude of the response of the cell to movements in any direction. This suggests that the cholinergic input to the DS ganglion cell is isotropic. These two experiments argue that the starburst cells carry out feedforward excitation of the DS cells, but from all sides; they make the ganglion cells motion sensitive but not direction selective (Fig. 28.8). (This amounts to a bidirectional Reichardt correlator.) This would imply that the asymmetrical connectivity postulated by the starburst theory does not exist.

A few years later, this result was contradicted by a different type of experiment, this time carried out in the retina of the mouse. Yoshida colleagues. (2001) immunolesioned the starburst cells in the mouse retinas. This was done by first creating a transgenic mouse in which the promoter for choline acetyltransferase was used to drive the human interleukin-2

FIGURE 28.8. Another view of the polarized output of the starburst amacrine cell, together with the classic illustration by Reichardt (1961) of a motion detector in insects. The polarization of the starburst cell's inputs and outputs (Fig. 28.7) will cause its synaptic output to be laterally displaced across the retina. When a moving stimulus (*gray rectangle*) traverses the retina, this can create feedforward excitation or inhibition.

receptor α -subunit (hiL-2R α). The foreign receptor was thus expressed in the starburst cells. An immunotoxin conjugated to a monoclonal antibody against hiL-2R α was injected into the vitreous. On binding to the receptor, it was internalized and killed the starburst cells. That the starburst cells were in fact absent could be verified by staining against choline acetyltransferase. After lesioning, these mice contained no DS retinal ganglion cells when studied electrophysiologically. Furthermore, optokinetic responses were depressed. This result would imply that in the mouse the starburst amacrine cells are critical for direction selectivity.

Which of these conclusions is correct? Both experiments have their weak points. It has been suggested that laser ablation of the starburst cells allowed the starburst dendrites to reseal, so that they continued to function in the absence of their cell bodies. This seems extremely unlikely. The laser photocoagulated the cell body and it could be demonstrated that the cell body was permanently (>8 h) accessible to extracellular dyes. Such an explanation would require that not one but all the dendrites reseal, and stay resealed for up to 8 hours. This does not happen in cultured cells and there is no reason to think it would happen in the intact tissue. Furthermore, ablating starburst cells on the preferred side had the expected effect—it depressed the response by about the same amount as did curare. It would be strange for the dendrites to reseal if the starburst cell is located on the preferred side but not when the starburst cell is located on the null side.

If the laser experiment contains an error, the more likely possibility is that it is due to the great redundancy of the starburst plexus. Because hitting a dendrite of a ganglion cell with the laser beam killed that ganglion cell (another reason for not believing in dendritic resealing), only a relatively small patch of starburst cells, outside but overlapping the DS ganglion cell, could be targeted. If a few missed cells were enough to sustain direction selectivity, the experiment would be invalid. Another ambiguity, discovered after the original experiments were carried out, is that there is cross-talk between the ON and OFF arbors of the ON-OFF DS cell. A method was devised that revealed the virtually complete population of amacrine cells (MacNeil et al., 1999; MacNeil and Masland, 1998). Surprisingly, it turned out that roughly half of all amacrine cells violate the ON and OFF borders within the inner plexiform layer. In the case of the ON-OFF DS cell, it can be directly demonstrated that OFF inhibition prevents ON excitation—a crossing of the ON-OFF border (Stasheff and Masland, 2002). Because for practical reasons the laser experiments could only target the ON starburst cells, some kind of cross-talk could have sustained direction selectivity.

The immunolesion experiments run different risks. One is collateral damage, notably the well-established bystander effect, in which a cell that is specifically targeted by a toxin kills its neighbors when it dies (this is presumably due to the release of proteases). Yoshida and colleagues (2001) had little way to know if additional amacrine cells were damaged, because specific stains for most amacrine cells are not available. A second difficulty is that immunolesioning takes a substantial amount of time, and this precludes recording from the same DS cell before and after the lesion. Thus, it was necessary to assume that all ON-OFF ganglion cells encountered in the immunolesioned animals would have been DS cells before the lesion.

Finally, it is not certain that direction selectivity in the mouse and the rabbit are computed in the same way. There

FIGURE 28.9. How a symmetrical amacrine cell could create an asymmetrical output onto a ganglion cell. The postulate is that synapses between the hypothetical amacrine cell and the ganglion cell are polarized, such that they occur only on one side of the dendritic arbor of the amacrine cell. If the amacrine cell is inhibitory and the interaction is divisive, this will create a null direction. The amacrine cell shown is a generic one, not intended to represent any known cell. From Jeon et al. (2002).

is no obvious morphological homolog of the rabbit's ON-OFF DS cell in the mouse (Sun et al., 2002). Direction selectivity has been reinvented many times in different species and different parts of the nervous system, and it is possible (though an inelegant explanation) that there is a species difference.

In conclusion, it seems certain that the starburst cells are involved in a major way in the computation of direction selectivity in the rabbit retina. Whether or not the starburst cells, by themselves, achieve the computation remains unclear. Certainly all of the available information— anatomy, electrophysiology, laser lesion, and immunole- sion—indicates that the starburst cells are important for direction selectivity. Whether they are solely responsible for the directional discrimination or merely contributors remains to be learned.

Alternative anatomies: where does the asymmetry occur?

In the most general case, direction selectivity is understood: A Reichardt-type correlator, with or without bells and whis-

tles, will generate direction selectivity in a neural circuit. The question remains how direction selectivity is biologically implemented. What would constitute proof of a theory of direction selectivity? A commonly held view is that the ultimate understanding will require that we locate the physical basis of the functional asymmetry long recognized as the central requirement of direction selectivity.

The asymmetry is commonly drawn as shown in Figures 28.5 and 28.6, which are suggestive of a neuron with a dendritic or axonal arbor polarized along the preferred-null axis. As noted earlier, other types of asymmetry are possible, including those localized on a molecular scale, but a neuronal asymmetry seems the more likely because of the larger scale (~50 to 100 μm) of the local subunit observed in physiological experiments. What might the asymmetry be? Among the collection of 29 different types of amacrine cells in the rabbit (MacNeil et al., 1999; MacNeil and Masland, 1998), there is no neuron that immediately suggests itself as possessing the kind of physical asymmetry shown in Figures 28.5 and 28.6. In other words, it seems unlikely that we will some day stumble on a neuron that points, arrow-like, up or down the preferred-null axis.

However, it is not necessary that a neuron be spatially biased in gross physical structure to create the preferred-null asymmetry. The specific case of a starburst cell, which is a radially symmetrical neuron that could nonetheless create direction selectivity, has been discussed above. It is important to note, however, that two different elements are confounded in the starburst model. One is the proximal-to-distal asymmetry in the conduction of electrical activity along the starburst cell's dendrites. The second is the postulate that starburst cells are selectively connected to the DS ganglion cell, such that only dendrites aligned along the preferred-null axis are connected to a specific DS cell (the other starburst dendrites are connected to other DS cells, with different preferred directions).

It is not necessary that an amacrine cell have the proximal to distal asymmetry possessed by the starburst cells for that hypothetical amacrine cell to create direction selectivity. Direction selectivity could be created by postulate two alone. How that could happen is illustrated in Figure 28.9. The drawing shows a DS ganglion cell receiving input from a mosaic of hypothetical inhibitory amacrine cells. The key postulate is only that connection between the inhibitory amacrine and the DS cell be asymmetrical, such that only at the “downstream” side of the amacrine cell's arbor does it synapse on the DS ganglion cell. As postulated by Vaney for the starburst cell, the other dendrites of the amacrine cell would be connected to DS cells with different preferred directions. The illustration is drawn as though the inhibition falls directly on the dendrites of the DS ganglion cell. However, it could just as well fall on a neuron afferent to the ganglion cell; for example, it could represent presynaptic inhibition of the release of glutamate by bipolar cells onto the DS cell or a more complicated circuitry involving several neurons.

The point here is to clearly separate the two different assumptions—asymmetrical dendritic conduction and anisotropic connectivity—that are included in the starburst hypothesis. The reason that this seems worthwhile is that postulate two, shown in Figure 28.9, would allow almost any narrow or medium-field amacrine cell to be the amacrine cell that creates the inhibitory asymmetry that finally results in direction selectivity.

Intradendritic microcircuitry within the inner plexiform layer

In their classic studies of the synaptology of the inner plexiform layer, Dowling and Boycott (1966) described a number of local synaptic interrelations. These include the familiar dyad synapse, in which a bipolar cell synapses on adjacent processes of an amacrine cell and a ganglion cell, with the amacrine cell immediately feeding back onto the bipolar cell. But synapses between amacrine cells and synapses of

FIGURE 28.10. Local interactions among the dendrites of cone bipolar cells, amacrine cells, and a DS ganglion cell. The ganglion cell was identified by recording; the preferred direction was established, and the cell was injected with HRP for electron microscopic analysis by serial sectioning. Note the complexity of the synaptic interactions, especially the local chains of synapses that can occur over very short distances, here less than 1 μm for the whole illustration. For example, amacrine cell 4 (A4) synapses on cone bipolar 2 (CB2), which then synapses on A2, which then synapses on a dendrite of the DS ganglion cell. The illustration is taken from Dacheux et al., 2003.

amacrine cells on bipolar cells away from the dyads were also observed, and these arrangements sometimes take complex and baroque forms, an example of which is the observation of chains of synapses among several (3 to 4) amacrine cells (Marc and Liu, 2000).

Recently, Dacheux and colleagues have been carrying out a study of the synapses afferent to an ON-OFF DS ganglion cell using serial section electron microscopy (Dacheux et al., 2003). The cell was recorded; its preferred direction was noted; it was then injected with HRP and processed for electron microscopy. A number of synaptic regularities were observed. Their interpretation will doubtless take some time and may require further serial sectioning to identify the cells of origin of the processes. Even at this stage, though, it is plain that major complexities exist on the synaptic scale of local microcircuitry.

A summary diagram of one such arrangement is shown in Figure 28.10. The preferred and null directions are indicated, as are the dendrite of a DS ganglion cell, two axon terminals of cone bipolars, and several amacrine cells. Note the chain of synapses in which A3 synapses on A2, and A2, which receives an additional input from a cone bipolar axon terminal, then synapses on the dendrite of the DS ganglion cell. Such chain synapses were very common, sometimes

directly involving the dendrite of the DS ganglion cell, and sometimes among the fascicle of processes that surround it. Many of the surrounding processes appear to belong to starburst amacrine cells, which are known to cofasciculate with the dendrites of the DS ganglion cells. However, there are also processes in these fascicles of unknown origin. Figure 28.10 reminds us that another level of neuronal interrelationship exists, on a spatial scale an order of magnitude smaller than the one usually discussed.

Acknowledgments

I thank Steven Stasheff and Chuan-Chin Chiao for comments on the manuscript, Rebecca Rockhill for making the figures, and Lyle Graham for discussions of the symmetry requirement (Fig. 28.9). RHM is a Senior Investigator of Research to Prevent Blindness.

29 Spatial Regularity among Retinal Neurons

JEREMY E. COOK

Patterns and Tiles

In this chapter, we “zoom out” from the study of individual retinal neurons and circuits to a consideration of how these individuals are organized across the retinal surface. In particular, we focus on an almost universal tendency for these neurons to lie in regular patterns. Although regularity can be a consequence of uniform size and tight packing, it also occurs among neurons that are widely spaced. In either case, it fulfills a behavioral requirement that each class of functional circuits should sample the visual scene systematically and completely, so that vital features (such as prey and predators) do not go undetected.

Regular arrays of retinal neurons often extend dendrites in a competitive, territorial manner that minimizes the overlap of their dendritic fields and causes them to tessellate, “tiling” the retina like the individual pieces (Latin: *tesserae*) of a ceramic mosaic. By convention, regular arrays of neuronal somata are often called *neuronal mosaics* even if precise dendritic tiling has not been shown directly, and the term *mosaic* is used in this sense throughout the chapter. It is important to be aware that geneticists and developmental biologists exploit the analogy of the tiled mosaic in another way, using it to describe mixtures or clusters of cells with distinct histories or genotypes and emphasizing the potential for abrupt contrasts at the boundaries of adjacent tesserae; these two senses of *mosaic* may confront each other uneasily in studies of retinal developmental genetics.

Neuronal mosaics are informative in many different ways. The following sections briefly review their implications for the function of the mature retina and the elucidation of its many neuronal types, consider what they can tell us about retinal development and evolution, summarize the methods used for their quantitation, and look ahead to questions that remain.

Retinal mosaics and visual function

The retina is organized in a way that allows each part of the image to be analyzed by many local circuits, working in parallel to assess different aspects of brightness, contrast, color, and movement. These analyses demand different degrees of spatial resolution, so neurons with different functions are repeated across the retina at different intervals. Neurons that

report fine detail are always small and closely spaced, whereas neurons that report movement or the widespread changes in luminosity that may herald a predator are often large and broadly spaced. In general, the spacings of overlapping circuits with distinct functions vary independently, and their mosaics are also spatially independent, so the retina as a whole cannot be accurately described as modular even though there are modular aspects to its function and to its development (Reichenbach and Robinson, 1995; Rockhill et al., 2000). In this respect the retina resembles the visual cortex, where functional maps are also overlaid in a flexible way that is repetitive but not strictly modular (Swindale, 1998).

The significance of the density and geometry of the sampling array is discussed in detail in Chapter 50. Here, we note only that the considerable contrasts of interval and scale between the functional types are made more extreme by regional variations in species that have a visual streak, area centralis, macula, or fovea. Neurons may conserve their branching patterns during retinal growth, but they cannot grow uniformly in all dimensions (allometrically) because growth that maintained a linear scaling relationship between dendritic diameter and length would change their physiological properties (Bloomfield and Hitchcock, 1991). Thus, functionally homologous neurons may look very different in different regions of the same eye and in eyes of differing size even before genuine interspecies variation is taken into account (Fig. 29.1).

Given this complex, multiparametric relationship between neuronal spacing and visual function, there are two distinct ways in which studying the spatial regularities of neurons can help us understand how the retina does its job. One is by helping us to decide how much spatial resolution a particular analytical function demands in a particular retinal region of a particular species at a particular stage in its growth. Simple cell counts can give us partial answers to such questions, but neuronal arrays give higher resolutions when they are regular than when they are not, and some techniques for measuring spatial regularity have the potential to provide more accurate density estimates than simple counting alone. The other, and perhaps more interesting, way is by helping us to draw up a catalogue of the different neuronal types in the retina and their functional roles, which is the subject of the next section.

FIGURE 29.1. Variation of mosaic spacing and scale across species. The graph shows how the spacing of the alpha-a ganglion cell mosaic varies with eye size (represented as retinal radius) in eight species of teleost fish, four of them at more than one stage of growth. The small alpha-a cell is from an adult zebrafish *Danio rerio* (marked *Dr* on the graph); the large one is from the sculpin *Bero elegans* (*Be*), to the same scale. Bar = 100 μm . What retinal mosaics tell us about neuronal types

It is hard to discover anything interesting by pooling data from heterogeneous neuronal populations, so a thoughtful neuroscientist must put a high value on understanding the diversity of functionally distinct neuronal types in the system under scrutiny. In the retina, mosaics have contributed greatly to this, not only practically, but also by helping to clarify the very concept of a neuronal type. This is a surprisingly slippery concept to grasp. At one extreme, neurons vary in so many details that (as with snowflakes) one can

argue that no two individuals are ever identical. At the other extreme, the retina is viewed simplistically by some as containing only five basic kinds of neuron (photoreceptors, horizontal cells, bipolar cells, amacrine/interplexiform cells, and ganglion cells). The term *class* can usefully be applied to these most basic divisions; however, within each class, neurons can be further divided into subclasses, types, subtypes, or variants, although there is no consensus yet on the terminology for such a hierarchy (Cook, 1998). Vaney and Hughes (1990) estimated that there could be as many as 70 functionally distinct neuronal types in a given retina, and subsequent studies have already confirmed an inventory of about 55 morphologically distinct neuronal types in mammals (Masland, 2001).

BETWEEN-TYPE AND WITHIN-TYPE VARIATION In attempting to get a grip on neuronal diversity, it is vital to find ways of distinguishing between two radically different forms of variation that neurons—indeed all cells in complex organisms—display. One is the categorical, hierarchical kind that is assumed to underlie cell-fate decisions during development, where transcriptional mechanisms force cells to choose between predefined pathways and positive feedback loops drive those choices to completion. Rowe and Stone (1980) described this, the kind of variation that distinguishes a cone from a ganglion cell or a red-sensitive cone from a blue-sensitive cone, as “between-type” variation. The other kind is the continuous variation of size, shape, and functional properties that we see in the phenotypes of all living things, which Rowe and Stone (1980) termed “within-type” variation. Much of this may be stochastic and inherently unpredictable, but some is correlated with external factors that have predictive power. A classic example is the correlation between the sizes of alpha and beta ganglion cells and their retinal eccentricities in the cat, which first allowed Boycott and Wässle (1974) to distinguish the two populations even though the largest (most peripheral) beta cells overlap in size with the smallest (most central) alpha cells.

In these terms, the task of identifying neuronal types equates to the task of working out which aspects of neuronal diversity are between-type variation and which are within-type variation. At first sight, this redefinition may seem unhelpful, even pedantic, because at the level of individual neurons a distinction may simply not be available. When we measure a character such as cell size across a mixed population, we often find that the overall distribution is unimodal even though the averages for the component types may be distinct. Unless a major source of within-type variation can be factored out (as for the cat ganglion cells just described), it is impossible to assign an individual neuron to a type on this basis, even provisionally. Rodieck and Brening (1983) argued that the problem could be tackled only by examin-

ing many variables at once. In their view, variables of shape, stratification, receptive field, conduction velocity, transmitter content, projection target, and so forth should be viewed as defining a multidimensional virtual space within which every objectively defined neuronal type (natural type) would be represented as a discrete cluster of points, separable in at least one dimension from every other cluster. Their argument was helpful in clarifying the problem, and their approach to solving it remains the ideal approach, but it is so labor intensive that practical applications are rare (for an exception, see Kock et al., 1989).

This is where mosaics show their value. The more we can discover about the within-type variation in a population of neurons, the easier it becomes to isolate between-type differences. The discovery of a regular array of neurons with complete retinal coverage gives us access to a presumptive “natural” type laid out for inspection (Fig. 29.2A). Presented with such an array, we can hypothesize that the variation we see among its members is within-type variation. Then, by noting which features show the most within-type variation over the population, we can avoid relying on these features when attempting to assign individual neurons to specific types.

MOSAICS AS GUIDES TO WITHIN-TYPE VARIATION The first observations of mosaics were made serendipitously, when particular populations drew attention to themselves by having an unusual reaction to staining and/or being in an unusual retinal plane (Stell and Witkovsky, 1973; Wässle and Riemann, 1978). Observers had little difficulty in deciding which neurons belonged to the mosaics they described because the property that drew their attention, often combined with clear evidence of dendritic tessellation, left the issue in no doubt. The concept of a natural type was implicit in the very existence of such a mosaic.

Studies of these self-evident mosaics have led to some valuable and durable conclusions. One, as we have seen, is that absolute soma size is poorly correlated with neuronal type. A second is that patterns of *dendritic* stratification tend to be strongly conserved within a mosaic-forming neuronal type, to the extent that otherwise similar neurons with distinct stratification patterns almost always form spatially independent mosaics (Cook, 1998). A third conclusion, refuting earlier assumptions, is that *somatic* stratification is only weakly correlated with neuronal type. Individual cells sometimes have their somata “misplaced” into the wrong layer even though they meet other criteria for membership of a type and their dendrites tessellate with those of their neighbors (Fig. 29.2B). These “misplaced” cells can even include cells that belong to so-called displaced types but are not actually displaced (amacrine cells: Wässle et al., 1987; ganglion cells: Cook and Noden, 1998). Indeed, in some cases there is no right or wrong layer for the somata of a

FIGURE 29.2. Sporadic variation within a mosaic-forming neuronal type. These A-type horizontal cells in a cat retina have been immunostained for calbindin. Most of them (A) lie at the border of the outer plexiform and inner nuclear layers, but others (B) are misplaced into the ganglion cell layer, where in different circumstances they could be mistaken for biplexiform ganglion cells. Bar = 100 μ m. For further details, see Wässle et al. (2000). Unpublished photographs reproduced by kind permission of Prof. Heinz Wässle.

mosaic-forming population, and they appear to be arbitrarily distributed in depth (Fig. 29.3). These conclusions exposed serious flaws in traditional morphological classification schemes for retinal neurons.

A further interesting conclusion was reached by blending in some later observations. Chalupa and his colleagues (White and Chalupa, 1991) found that the alpha ganglion cell mosaics of the cat (both outer and inner stratified) contained a subset of cells with somatostatin-like immunoreactivity, confined largely to the inferior (ventral) half of the retina and absent from the region where the density of alpha cells peaks. It has been widely assumed that a neuron's expression of neurotransmitter or neuromodulator genes directly reflects its function, with the result that transmitter

FIGURE 29.3. Continuous variation within a mosaic-forming neuronal type. Two partially overlapping, alpha-a (outer-stratified) ganglion cells from the cichlid fish *Oreochromis spilurus* are seen in profile below; one with its soma in the ganglion cell layer (GCL) and one with its soma in the inner nuclear layer (INL). The complete mosaic is shown above, with iconic symbols representing different degrees of soma displacement. The somatic part of each symbol marks the actual location. The mosaic is highly regular but the distribution of soma depths is arbitrary and sporadic. Bar = 1 mm for retina; 100 μ m for cell profiles. I, D, N, and V show the temporal, dorsal, nasal, and ventral poles of the retina. For further details, see Cook and Becker (1991). © 1991 Wiley-Liss, Inc. Reprinted by permission.

content has often been used as the basis for an arbitrary classification. However, in these studies of a uniform population, the archetypal mosaic of the mammalian inner retina, this neurochemical marker picked out some individuals and not others. Although highly reproducible anomalies are known to occur within some natural types (Masland et al., 1993), and there may be scope for genuine functional differences among mosaic members (Cook, 1998), this example demonstrates that neurochemical phenotypes are no more intrinsically reliable than morphological phenotypes as guides to neuronal taxonomy. It has long been understood in fields outside neuroscience that gene expression can sometimes be nonfunctional; that eukaryotic cells must often tolerate uncontrolled expression because of constraints imposed by combinatorial gene regulation. Bowers (1994) has summarized the evidence for neuroscientists, and all authors (and reviewers) of papers in which neurochemical observations

are taken as evidence of neuronal types should read that summary.

EXPOSING HIDDEN MOSAICS AND TYPES In the outer retina, I have already noted that the high regularity of neuronal mosaics may sometimes allow the identity of a neuron to be confirmed directly by its position. In the less regular world of the inner retina, there is no possibility of this direct approach, but mosaics can help with neuronal identification in less direct ways.

For example, in a preparation where most of the relevant neurons are visible, one can learn much about the type-specific characteristics of an unfamiliar mixed set of neurons merely by attempting to assign them to mosaics. The trick is to start by defining arbitrary cell-type criteria that are based on all the observable differences between neurons that make up clusters or clumps. Clustered neurons with overlapping dendrites are likely to belong to different mosaics, so any features that consistently distinguish between cluster members are prime candidates for between-type variation. These provisional cell-type criteria may need to be adjusted arbitrarily, by trial and error, until a regular, self-consistent set of mosaics emerges. However, their objectivity can then be established by testing the same criteria on new specimens. It was this iterative approach that made it possible to understand an atypical and confusing set of large retinal ganglion cell types in a tree frog (Shamim et al., 1999).

Even by such methods, not all functionally distinct types can be distinguished directly by shape or size. Direction-selective ganglion cells provide good examples of such types and of other ways to expose their hidden order. In the rabbit retina, bistratified ON-OFF direction-selective ganglion cells occur at a much higher spatial density than would seem necessary for uniform retinal coverage; they also appear to be randomly distributed. Their high coverage is explained by the fact that they actually comprise distinct functional types with different preferred directions of motion, overlaid as a polymosaic of overlapping arrays. Even when the distinct types are functionally identified and compared, they remain morphologically indistinguishable. In this case, the key to visualizing them is the intracellular injection of a tracer that passes through gap junctions, selectively coupling cells of the same type. Tracer-coupling shows that they do in fact form regular, independent, beautifully tessellated mosaics (Amthor and Oyster, 1995; Vaney, 1994a). This technique is also useful for revealing the detailed mosaic organization of types that are already morphologically distinguishable (Ammermüller et al., 1993) and for revealing gap-junctional connections between the separate mosaics of different neuronal types (review: Mills, 1999; Vaney, 1994b; Xin and Bloomfield, 1997).

A separate category of direction-selective ganglion cells, again comprising distinct types with different preferred

directions of motion, projects to the accessory optic system. As before, these cells appear almost random in their arrangement when taken together. However, spatial correlogram analysis has been applied to distribution data from a frog, a reptile, a bird, and a mammal to show that these evolutionarily conserved cells possess exactly the kind of cryptic order that is predicted for a polymosaic of overlaid arrays (Cook and Podugolnikova, 2001). Because these apparent exceptions have both turned out to prove the rule, it seems likely that all neurons that integrate signals across their dendritic fields (rather than processing them only locally within the dendrites) may form regular mosaics (DeVries and Baylor, 1997; Rockhill et al., 2000). This being so, the combination of high coverage with low apparent regularity should always trigger a search for hidden mosaics and multiple functional types.

What retinal mosaics tell us about development

Studies of spatial regularity have provided many insights into retinal development. However, our present state of knowledge, accumulated piecemeal from studies of several model systems, fails to point to a unifying mechanism that could underlie all mosaic patterns. On the contrary, there seem to be three separate ways in which mosaics can be established in the retina, with evidence that they may act in combination, in different developmental contexts.

INDUCTIVE INTERACTIONS AND MOLECULAR MARKERS The interlaced and often highly regular mosaics of retinal photoreceptors are obvious targets for developmental studies. In fish in particular, the cone mosaic is often geometrically exact and consists of regularly repeated modules (Engström, 1963), which has led to speculative comparisons with the near-crystalline patterning of the compound eyes of insects. In the eye of a fly, cell fate is known to be determined by a cascade of inductive interactions, mostly between immediate neighbors. The first photoreceptors of the fly (R8 cells) are formed by a multistep process of lateral inhibition within an initially featureless bed of dividing cells and act as reference points for the construction of each ommatidial facet of the eye. This process spreads across the eye in a visible traveling wave, the morphogenetic furrow, which marks a progression of inductive and responsive competence in which the signaling protein Hedgehog plays an important self-regulating role and each cohort of differentiating cells acts as a spatial template for the next (for a summary of the molecular interactions, see Baonza et al., 2001). A traveling wave may be needed to allow a globally coherent pattern to emerge from interactions that involve only immediate neighbors; indeed, when different eye regions in a mutant fly start the process independently, pattern coherence is lost (Heberlein and Moses, 1995).

In the retinas of vertebrates, built to an entirely different structural plan, there is no known equivalent to the morphogenetic furrow. Nevertheless, some of the primary inductive mechanisms are known to have been conserved, and a self-regulating traveling wave of expression of the orthologous gene *Sonic hedgehog* has recently been shown to sweep through the zebrafish retina in the first differentiated neurons, the retinal ganglion cells (Neumann and Nüsslein-Volhard, 2000).

In the fish retina, the earliest regular patterns that can be seen by conventional histology comprise either regular rows of morphologically identical single cones or alternating rows of double and single cones (Fig. 29.4), and in some species these rows are eventually transformed into a modular square mosaic (Engström, 1963; Shand et al., 1999). As morphological distinctions between the photoreceptor types are slow to develop, studies of their earliest relationships require them to be identified in another way, usually by their content of photopigment (opsin) mRNA. Raymond and colleagues have shown that the first opsin to be expressed in the embryonic eyecup of the goldfish is distributed in a predictable pattern, beginning at the nasal margin of the ventral fissure and spreading around the retina in a circular or spiral path. The cells producing this first opsin sometimes form regular rows at the leading edge of the wave (Raymond et al., 1995; Stenkamp et al., 1996). Further, in the zebrafish, an additional wave of *Sonic hedgehog* expression precedes this wave of photoreceptor differentiation and seems to be necessary for it (Stenkamp et al., 2000). The potential parallels with the fly's eye are clear, but it is not yet possible to say whether the fish has a direct equivalent to the fly's prepatterned array of R8 cells, defining modules in the cone mosaic. One reason is that this first opsin is actually found in rod photoreceptors, which are *not* regularly patterned in the adult retina and *not* required for the formation of a normal cone mosaic (Wan and Stenkamp, 2000). Another reason is that we still know very little about the long period of cone differentiation that precedes the expression of cone opsins and next to nothing about the initial spatial relationships of the cells that will develop into the different cone types over this long period (Cook and Chalupa, 2000). However, studies of retinal regeneration after physical wounding or chemical lesioning show that the densest regenerated populations, where opportunities for inductive interaction are greatest, are also typically the most orderly (Stenkamp et al., 2001), so we may speculate that local relationships are important.

Computer-modeling studies (Tohya et al., 1999) confirm that regular mosaics of four different cell types can emerge from cellular-automaton rules of differentiation that involve purely local interactions and are applied to initially random arrangements. Different rules converge on the same simple patterns, precisely matching those observed in real fish, and these rules operate most efficiently when they act at an

FIGURE 29.4. Quasi-crystalline cone lattice patterns in salmonid fish. Tangential sections through the cone ellipsoids show a typical square mosaic without corner cones (*A*) and a row mosaic (*B*). Where both forms coexist within one retina, the row pattern occupies younger, more peripheral regions. DC = double cone; S = single cone. Bar = 50 μ m for microphotographs. advancing wavefront (such as the fly's furrow or the marginal zone of a growing fish retina) rather than across a large area at once. Whether the biological interactions that underlie the formation of real cone mosaics will turn out to be anything like the assumptions of such models remains to be seen. However, the approach is adaptable: a more recent alternative model is able to create appropriate patterns based on the assumption that the cone mosaics arise by secondary cell rearrangements among predetermined cone types that differ in their adhesion properties (Mochizuki, 2002).

Mammals also have cone mosaics, and those of Old World monkeys such as the macaque have been studied intensively. However, tools for probing opsins are not as precise in mammals as in fish, and the individual cone mosaics are not as precise either (Engström, 1963; Roorda and Williams, 1999). Blue-sensitive cones, which comprise about 10% of the cone population and form regular mosaics in macaques and humans, are present in all mammalian orders (although not all species) but do not always form regular mosaics (see Chapter 50). Red- and green-sensitive cones are derived from an ancestral type that seems not to form a regular mosaic in any placental mammal (Ahnelt and

Kolb, 2000), and recent spectrophotometric studies show that they are intermingled in the human fovea as irregular clumps and clusters (Roorda and Williams, 1999). Other investigations into the origins of mammalian cone patterning were summarized by Cook and Chalupa (2000).

LATERAL MOVEMENTS OF DEVELOPING NEURONS A second way to generate a regular mosaic would be to create a random array of fate-determined neuroblasts and then move them to regularize the spacing of each distinct type. Rockhill and colleagues (2000) noted that such an approach might reduce the aliasing effects that would be expected if successive wavefronts of differentiation laid down overlapping patterns at different scales, and there is now convincing evidence that mosaic-forming neurons do move laterally within the retinal plane during development.

An ingenious method for demonstrating such movements relies on the random and irreversible inactivation of one of the two X-chromosomes in every cell of a female mammalian embryo. This property has been used to generate transgenic mouse embryos whose eyecups contain a pepper-and-salt distribution of multipotential precursor cells, half

FIGURE 29.5. Evidence for the tangential migration of developing neurons. In this wholemount retina from an adult chimeric mouse, the *dark patches* are columns of lacZ-active cells, derived from a transgenic embryonic stem cell that was injected into the blastocyst. Two individual lacZ-active horizontal cells (*arrows*) have migrated laterally from these columns. They are both immunopositive for calbindin, like the other, lacZ-inactive members of the horizontal cell mosaic. Bar = 50 μ m. For further details, see Reese et al. (1999). © 1999 European Neuroscience Association. Reprinted by permission.

with an active *lacZ* marker gene and half without (Reese et al., 1999). The *lacZ*-active cells go on to generate beta-galactosidase-positive, blue-reacting clones of retinal cells, whereas their neighbors form white, nonreacting clones. Within both white and blue clones, about 85% of all cells maintain strict radial alignment. However, cones, horizontal cells, ganglion cells, and at least one type of amacrine cell, which make up the remaining 15%, are commonly tangentially displaced into clonally unrelated columns (Fig. 29.5)—so commonly, indeed, that it would seem lateral movement is the universal rule. This displacement occurs late, in many cases after birth. Its extent is limited to some 10 or 20 soma diameters, but this could be enough to explain the emergence of mosaics (Reese et al., 1999). Similar evidence of cell dispersal in chick retinas had earlier been interpreted as arising from the migration of precursors, rather than differentiated neurons (Fekete et al., 1994). The same neuronal types were involved, however, and the same explanation now seems likely to apply (review: Reese and Galli-Resta, 2002).

This evidence that the neurons of all the major mosaic-forming classes move laterally during development does not, of course, prove that their movement establishes their mosaics. In many cases this further logical step is hard to take because there is no way to identify a future member of a particular mosaic until that mosaic is complete. However, the cholinergic amacrine cells of rodents bind antibodies to the transcription factor Islet-1 (Galli-Resta et al., 1997) and

FIGURE 29.6. Minimal-spacing rules as a basis for neuronal mosaic generation. The *dots* in these figures represent young cholinergic amacrine cells in a rat retina during the period of mosaic formation, and the *polygons* represent their Voronoi domains, constructed to include all points that are closer to that dot than to any other. The dots in *A* represent the locations of actual Islet-1-positive amacrine cells in a rectangular sampling region of the inner nuclear layer. The dots in *B* represent the result of a computer simulation in which points were positioned randomly by a probabilistic minimal spacing rule, with the minimal spacing set to $15 \pm 2 \mu$ m (mean \pm standard deviation). The distributions are indistinguishable, not only to the eye but also to Voronoi and Fast Fourier Transform analysis. For further details see Galli-Resta et al. (1997). © 1997 Society for Neuroscience. Reprinted by permission.

two cholinergic markers (Galli-Resta, 2000) while they are still migrating radially to form two independent mosaics in the inner nuclear layer and the ganglion cell layer. During their migration, they show no spatial order beyond a minimal spacing imposed by their occasional physical contact but by the time they reach the boundary between the inner nuclear layer and the ganglion cell layer, they show a more regular pattern with a minimal spacing several times the soma diameter. Remarkably, their regularity is then maintained throughout a period of 5 days, during which up to 30% more cells of the same type enter each array. To achieve this, existing cells must move sideways to accommodate the newcomers (Galli-Resta et al., 1997).

The mosaics that are seen in this situation can be simulated rather exactly (Fig. 29.6) by a simple computational model in which the only constraint on cell positioning is a probabilistic limit on the minimal spacing between cells (Ammermüller et al., 1993; Galli-Resta, 1998). When neuronal density is relatively high, as it is here (and also in the case of the blue-sensitive cones—but not the rods—of the ground squirrel retina: Galli-Resta et al., 1999), this simple minimal-spacing rule is sufficient to create a fairly regular mosaic. It seems that many, and perhaps all, retinal mosaics may reflect a simple rule of this kind. Whenever spatial autocorrelograms have been computed for inner-retinal neurons,

their dominant feature has always been a central area of low density that represents a zone around each cell from which others of the same type are excluded, and there has been no sign of longer-range order that might suggest a more complex patterning rule. In fact, of all the cell types so far studied in this way, only cones have shown evidence of long-range order (Cook and Noden, 1998; Curcio and Sloan, 1992), and modeling studies show that the particular type of order they possess can be created entirely by short-range interactions (Tohya et al., 1999).

In the case of cones, a minimal spacing is imposed by the requirements of efficient packing, because cone inner segments contact their neighbors directly. It is less clear what might determine the larger minimal spacings of horizontal cells and inner-retinal neurons during development: for example, the minimal spacing of rodent cholinergic amacrine cells is at least three times the soma diameter at this stage (Galli-Resta et al., 1997). A diffusible repulsive or inhibitory signal seems unlikely in this model because the exclusion radius around close pairs of such cells is no greater than that around single cells (Galli-Resta, 2000). An obvious alternative, that such cells might already be in direct contact with their neighbors through transient, fine filopodial processes, is considered below, in the context of dendritic development. Raven and Reese (2003) have shown that a normal complement of cones is not necessary for the formation of the horizontal cell mosaic in mice, so cone afferents do not appear to be required as mediators in the signaling process. Reese and Galli-Resta (2002) provide a more detailed review of many of these issues.

A mechanical, cytoskeleton-mediated basis for mosaic generation is suggested by recent evidence that the precision of some neuronal arrays is reversibly dependent on normal microtubule function (Galli-Resta et al., 2002). One interpretation of this finding is that regularity is directly determined by microtubule-mediated forces between the linked processes of neighboring neurons. However, microtubules have other vital roles, including cytoplasmic transport and the intracellular positioning of the nucleus, so further work is needed to understand this interesting effect.

It is worth noting, in this context, that less is known about the control of nuclear location within dividing or migrating neurons than about practically any other observable aspect of neuronal behavior. Even interkinetic perikaryal translocation in the radial dimension of the retina is poorly understood, despite having been reported more than 30 years ago (see Chapter 6, Development of the Vertebrate Retina). It is actually the position of the nucleus within the complex membranous envelope of a differentiated neuron that determines the regularity of the mosaic as normally measured (see Methods for Measuring Mosaics, below). At present we do not know when, by how much, or by what mechanism a nucleus might move tangentially *within* its neuron in response

to external signals, and we shall not be able to say that we fully understand mosaic development until we do.

EFFECTS OF NEURONAL DEATH ON MOSAIC DEVELOPMENT A third model of mosaic formation involves the selective death of neurons. This is unlikely to be a universal mechanism of mosaic formation because mosaics are a major feature of the retina in all vertebrate groups, whereas in anamniotes the death of differentiated retinal neurons is thought to be rare (Williams and Herrup, 1988). Even so, the massive and widespread increase in programmed cell death within the amniote (and particularly mammalian) radiation must at the very least have disrupted those mosaics that were previously formed by other mechanisms and may have stimulated the emergence of entirely new mosaic-forming mechanisms.

For example, the alpha and beta ganglion cell mosaics of the domestic cat (together forming half of the ganglion cell population) are highly regular in the adult, yet 80% of all ganglion cells die between embryonic day 28 and postnatal week 6 (Williams et al., 1986). How can these observations be reconciled? The most obvious possibility is that programmed cell death, even while it is tending to obliterate any preexisting regularity, might be actively selecting survivors that will form regular arrays. The limited evidence currently available is consistent with such a mechanism (Chalupa et al., 1998). Between postnatal day 12 and adulthood, the overall density of alpha cells in the central region falls by about 20%. Over the same period, the incidence of opposite-sign pairs among nearest-neighbor alpha cells rises from less than 60% (not much higher than when two random populations are overlaid) to about 90% (matching the adult level of regularity). It is not yet known how this rise in opposite-sign pairs is achieved, but postnatal intraocular injection of the sodium-channel blocker tetrodotoxin reduces the regularity of the adult alpha mosaics without increasing their density (Jeyarasasingam et al., 1998). This suggests that electrical activity affects the spatial selectivity of alpha cell death without controlling its extent. Computer simulations confirm that the death of 20% of the original cells could account for the observed increase in regularity, provided that neighbor-pairs of the same sign were selectively targeted and that one from each pair died. However, there are many questions about the role of cell death still to be answered, and it has been shown not to contribute to the regularity of the cholinergic amacrine arrays of the rat (Galli-Resta, 2000).

MOSAICS, COMPETITION, AND THE DEVELOPMENT OF DENDRITIC FIELDS Implicit in the concept of a mosaic is the property of dendritic tessellation, yet we know surprisingly little about how the sizes and shapes of individual dendritic trees are controlled (review: Scott and Luo, 2001). Most studies of dendritic growth have been directed toward ganglion cells. Their patterns of dendritic growth have been

shown to be determined competitively in many experiments involving the elimination of other ganglion cells; their dendritic rearrangement in such circumstances is disrupted by tetrodotoxin and therefore apparently depends on electrical activity (Deplano et al., 1999). However, only a few studies have directly addressed the question of whether dendritic competition is selective between members of a ganglion-cell type, as it must be if it has a role in mosaic formation (Weber et al., 1998). Such a role, while it needs to be confirmed, would be consistent with the observations that ganglion cell types with different receptive-field sizes establish similar levels of functional coverage (DeVries and Baylor, 1997), that coverage is constant across substantial intraretinal gradients of cell density (review: Weber et al., 1998), and that coverage tends to be maintained when cell density is altered by normal or abnormal eye growth (Finlay and Snow, 1998).

Although competitive *dendritic* growth alone cannot account for the regularity of *somatic* mosaics, a recent computational model (Eglen et al., 2000) has shown how cell-type-selective dendritic interactions might provide a controlling mechanism for the lateral migration of somata described above. In this model, differentiated neurons reposition themselves constantly to minimize the overlap between their dendrites. Under some constraints (fixed dendritic field sizes), their distributions have properties that converge with those created by minimal spacing rules, where regularity increases with density up to a packing limit. Under other constraints (adaptive dendritic field sizes), they resemble distributions that have been observed in older retinas, where regularity and density are independent of each other (Eglen et al., 2003).

Models based on dendritic interaction may not seem relevant to the earliest stages of mosaic formation, when neurons lack differentiated dendrites. However, similar interactions may be possible even between immature cells because some immediately postmigratory neurons—for instance, retinal ganglion cells in the chick (Nishimura et al., 1979)—are surrounded by a halo of fine protoplasmic processes that may reach out to more distant neighbors, as do the telodendria of immature S cones (Xiao and Hendrickson, 2000). Such processes also resemble the delicate, hard-to-visualize cytonemes of invertebrates (review: Bryant, 1999), which have been implicated in remote contact-mediated signaling functions. Indeed, they may not differ greatly from the motile filopodia that later cover the dendrites (review: Wong and Wong, 2001). Thus, paradoxically, a model such as that of Eglen and colleagues (2000) might be more relevant to the earliest stages of neuronal differentiation, when most neuronal processes are transient, motile, and unbranched, than to later stages, when a thicket of established dendritic branches must seriously constrain neuronal movement.

In vitro time-lapse imaging techniques have recently revealed much that is new and interesting about the short-term behavior of dendritic filopodia and growth cones and their molecular regulation by extrinsic factors such as neurotransmitters, as well as intrinsic factors such as small GTPases (Wong and Wong, 2001). However, the growth and remodeling of ganglion cell dendrites is a long-term process, not well suited to in vitro study, and the molecular bases of dendritic competition and the cell-type-specific recognition that must underlie it are not yet known, even in outline (Sernagor et al., 2001; see also Chapter 6).

In the fly *Drosophila*, a particular class of segmentally repeated sensory neurons (MD cells) shows type-specific tiling behavior that might more easily be studied directly, in living embryos. The dendritic interactions of MD cells are abnormal in several mutants, disrupting tiling behavior and normal competitive interactions across the midline. The defective gene in at least one of these mutants, *flamingo*, has mammalian homologs and codes for a protocadherin that would appear to be a good candidate for selective cell adhesion (Gao et al., 2000). If MD neurons are as good an experimental model for selective dendritic competition as the initial studies suggest, dendritic tessellation may yet join the large class of vertebrate developmental problems into which significant insights have been gained from invertebrate models.

What retinal mosaics tell us about evolution

We have seen how mosaics help us to develop objective neuronal classifications, which are essential for any useful comparisons between species. In addition, the spatial characteristics of each mosaic (its regularity, density, gradients, coverage) are phenotypic characters in their own right that can be used in identifying cross-species homologies. In these two ways, mosaics help us to understand how neuronal types are interrelated and ultimately how they evolved.

COMPARING NEURONAL TYPES ACROSS SPECIES The notion of a natural type among neurons is closely analogous to the notion of a species among organisms in its implications of self-similarity and isolation, whereas a neuronal class is analogous to a genus. It is disturbing, therefore, that our understanding of most neuronal types remains firmly rooted in an 18th century, Linnaean mode of thought that classifies cells only by morphological and functional similarity, whereas the rest of biology long ago embraced the Darwinian view that it is ancestry, not similarity, that acts as the key to unlock biological meaning. For a full understanding of any part of the brain, we need to see neuronal classifications not only as hypotheses about the boundaries of variation in neuronal structure and function in a single species, but also as hypotheses about the evolutionary relationships between

natural types in different species and the developmental programs that create them (Cook, 1998). Although comparative studies of cone mosaic patterns go back more than half a century (review: Engström, 1963), the scope for a broader evolutionary view can be illustrated by a few of many possible questions to which there are, as yet, no clear answers: Which of the recorded neuronal types in salamander, turtle, cat, and monkey retinas have common ancestors and so are homologous, rather than merely analogous? What developmental mechanisms control the emergence of a new, mosaic-forming, neuronal type and enable it to show self-recognition? Why do mammalian ganglion cell mosaics seem to come in inner- and outer-stratified pairs? The last of these alone is addressed here.

IS THE PAIRED MOSAIC A MAMMALIAN INVENTION? The dominance of mammalian alpha and beta cells in early studies of mosaics, starting with those that first showed the importance of dendritic stratification (review: Wässle and Boycott, 1991), has created a general impression that mosaic-forming neurons are typically organized into pairs of related subtypes that differ only in their stratification and in giving opposite-sign physiological responses to visual stimuli. In fact, such mosaic pairings seem to be unusual among vertebrates as a whole (Cook, 1998), and their predominance in mammals may reflect the emergence of novel, late-acting mechanisms of mosaic formation in response to neuronal death.

However, the paired, monostratified alpha and beta mosaics of the cat are known to be derived from multistratified precursor populations by dendritic remodeling (review: Chalupa et al., 1998). When the definitive adult inner- and outer-stratified mosaics of a pair are overlaid and compared, they show some degree of spatial interdependence (alpha cells: Jeyarasasingam et al., 1998; beta cells: Zhan and Troy, 2000), which is unusual among retinal mosaics in general, even those that are synaptically coupled (Galli-Resta et al., 2000; Rockhill et al., 2000). Thus, it is plausible that some of the order in these paired mosaics is created by a process that encourages neighboring multistratified cells to remodel their dendrites into opposite-sign pairs and that each complementary pair of mosaics may have evolved by the developmental remodeling of a single ancestral mosaic whose neurons remained bistratified or multistratified throughout life. For example, both of the mammalian alpha mosaics might be homologous to a single mosaic of prominently bistratified large ganglion cells (alpha-ab cells: Fig. 29.7) that occurs in fish, frogs, and reptiles (Cook, 1998). To test such hypotheses, we would need either to study the phenotypes of these cells in many more species, especially among reptiles and primitive mammals, or to hack directly into the transcriptional control code that defines each neuronal type and seek homologies at that level. The

FIGURE 29.7. A bistratified ganglion cell mosaic could be the ancestor of the mammalian alpha mosaics. The two strictly bistratified cells in *A* form part of a highly regular mosaic in a gekkonid lizard. Only their inner trees are shown in plan view here, but the cell on the left is also shown in profile view (*B*). All non-mammalian species studied so far have a single, prominent mosaic of large-bodied ganglion cells that are either bistratified or predominantly inner-stratified. It is likely that these have a mammalian homolog. As mammalian alpha cells are initially multistratified, they are obvious candidates for this role. Bar = 50 μ m. second method should be quicker, once the tools for it become available.

Methods for measuring mosaics

It is the limits of the dendritic field that determine a neuron's excitatory receptive field (see Chapter 26) so, ideally, the quantitation of mosaics would focus on dendrites. However, it is technically challenging to define the individual limits of a large array of partially overlapping dendrites, so mainstream methods of quantitation consider only soma location. The analysis can take several different forms, according to its aims. There is no space here for a detailed discussion of each approach but the references include such discussions.

METHODS BASED ON NEAREST-NEIGHBOR DISTANCE The aim may simply be to establish the objective reality of the mosaic, a step made necessary by the tendency of our own visual systems to perceive pattern in random distributions. The methods first adopted for this task were based on the statistical distribution of the distance from each neuron to its nearest neighbor of the same type (the nearest-neighbor distance, or NND; Wässle and Riemann, 1978). NND-based methods still underlie the most useful general tests of mosaic

significance, but care is needed in interpreting them because some tests overestimate the degree of regularity within a small, irregular or elongated sample (Cook, 1996). The most common, easiest, and most conservative test is based on the *conformity ratio* (mean NND/standard deviation). The sampling distribution of this ratio has now been tabulated for a wide range of sample sizes and shapes so that the significance of an observed value can be found by looking it up on a chart (Cook, 1996).

It is often useful to show that one mosaic is spatially (and so presumably functionally and developmentally) independent of another. Historically, NND methods have been used for this, too, the standard approach being to combine the two mosaics and attempt to show that the NND distribution of the combined set is close to that expected for a random population. This approach is seriously flawed, not only because its sensitivity depends on the orderliness of the individual mosaics and their relative spacings, but also because the sum of two mosaics depends on their spatial relationship within the sampling area (Cook, 1996). Spatial correlograms, discussed in the next section, offer a much more informative approach to issues of this kind.

METHODS BASED ON SPATIAL CORRELATION A powerful technique for the assessment of spatial order is the spatial correlogram, introduced into retinal studies by Rodieck (1991), which reveals coincidences and relationships in two-dimensional space. To create a spatial correlogram, each neuron in an array is placed, in turn, at a central reference point and the locations of all its neighbors are plotted around it. The accumulation of overlaid plots reveals overall trends in neighbor-relationships. *Autocorrelation* of a single array with itself explores its internal spatial relationships and can reveal local order, global order, and some aspects of array geometry, whereas *cross-correlation* of one array with another explores any spatial interactions between the two. Although the correlogram itself is primarily a tool for visualization, it can be used to derive a quantitative measure known as the density recovery profile, or *DRP* (Rodieck, 1991), which is basically a histogram of the mean neuronal density in a series of concentric rings around the correlogram's origin.

The autocorrelation-DRP of a large sample drawn from a random point distribution is completely flat. By contrast, autocorrelation-DRPs from individual neuronal mosaics are never flat, because each neuron is surrounded by a territory from which other neurons of the same type tend to be excluded. This exclusion leads to a central hole in the autocorrelation-DRP and a deep well in the *DRP*. The size of the neighbor-depleted region can be used to derive an objective measure of the minimal spacing within the array (the exclusion radius) and a measure of the regularity of the array (the packing factor; Rodieck, 1991). Autocorrelation-DRPs with

partial-depth wells may be seen when the sample contains a mixture of spatially independent neuronal types (Cook and Podugolnikova, 2001).

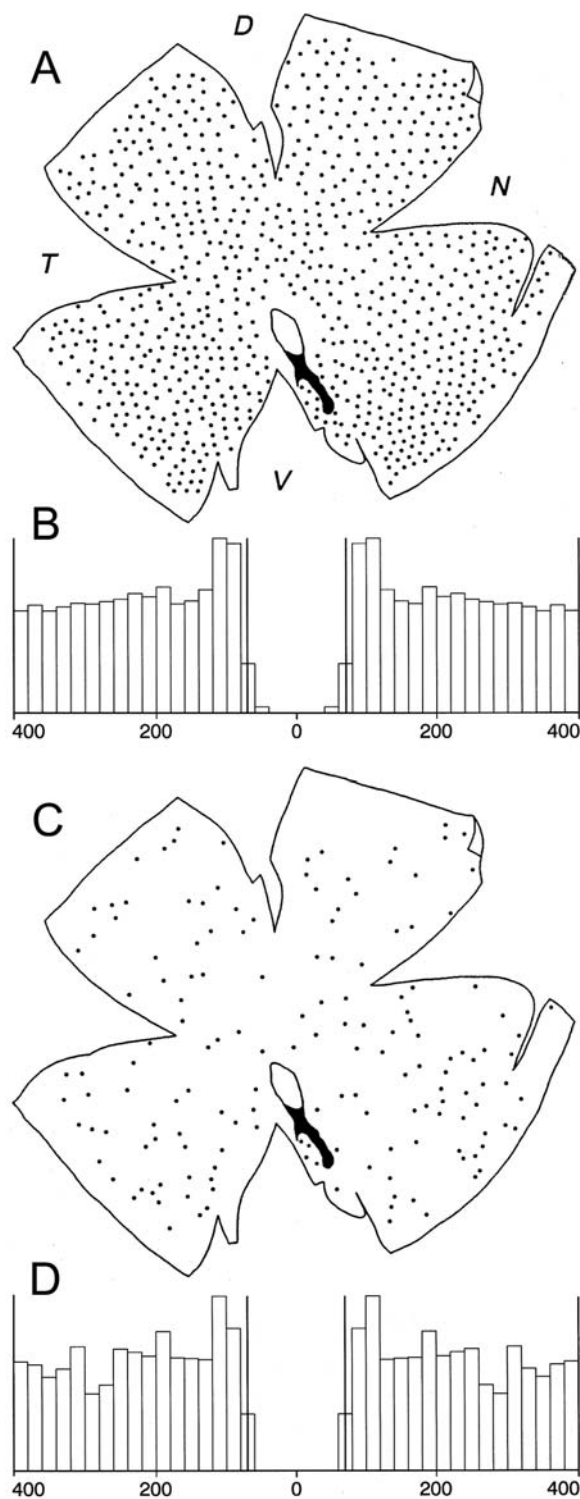

Cross-correlograms derived from two distinct mosaics normally yield essentially flat DRPs, demonstrating spatial independence, although short-range steric hindrance between costratifying neurons can cause minor central deviations. Where the cross-correlation-DRP shows a broad central well like that of an autocorrelation-DRP, the most likely explanation is that the two "mosaics" are actually subsets of a single mosaic.

A major merit of spatial correlograms is their robustness in the face of imperfect sampling procedures. Real neuronal mosaic samples vary in spacing across the sample area and contain gaps where individual neurons or clusters have failed to label or are damaged or obscured. Estimates of the exclusion radius are remarkably resistant to this kind of under-sampling, to the extent that the radius of a regular mosaic may be correctly estimated when as few as 20% of the neurons actually present in the sample area are included in the analysis (Fig. 29.8). In such a case, NND-based methods are virtually useless (Cook, 1996).

METHODS BASED ON VORONOI DOMAIN ANALYSIS A method that is growing in popularity is the analysis of Voronoi polygons, constructed around each cell in a mosaic so as to include all points that are closer to that cell than to any other (Ammermüller et al., 1993; Curcio and Sloan, 1992; see also Fig. 29.6). This approach is potentially more informative than NND analysis in that it allows additional aspects of mosaic geometry to be assessed (e.g., the distribution of the number of neighbors around each neuron) as well as the typical spacing. At present the extra data is of limited use because (as the method itself has been used to confirm) nothing more than the establishment of a certain minimal spacing between neurons may be needed to simulate all their observable properties (Galli-Resta et al., 1999). With a tightly packed, quasi-crystalline mosaic such as the human cone mosaic, however, estimates of domain orientation and neighbor number can be used to identify regional discontinuities within the mosaic (Curcio and Sloan, 1992). The method has been discussed in more detail by Zhan and Troy (2000).

There is a risk with this type of analysis that users will interpret the several different variables that can be computed from a single dataset as though they were statistically independent and thus overestimate their significance. The full utility of this approach will be reached only when there is consensus on a set of tests that can be applied without falling into this trap.

OTHER METHODS Other methods have appeared at various times in the literature, although their advantages have not

always been clear enough to lead to wider uptake. For example, Galli-Resta and colleagues (1997) used a fast Fourier transform method to confirm the close similarity between real mosaics of cholinergic amacrine cells and simulated mosaics created by a minimal-spacing rule, and their paper provides a useful set of direct comparisons between this and standard methods based on NND, spatial correlograms, and Voronoi analysis. Stenkamp and colleagues (2001) have recently used a form of quadrat analysis to assess clustering, as an alternative to the NND-based dispersion index (review: Cook, 1996), which is also capable of measuring the entire spectrum of order from regularity through randomness to clustering.

Looking ahead

The 1980s saw a revival of interest in structural and functional diversity within the retina and the birth (after a long but little-remarked gestation) of the important concept of a natural neuronal type. Concurrently, evidence was accumulating for spatial regularity as a common phenomenon among retinal neurons. In the 1990s, these ideas became more firmly coupled as mosaics were found in a wide range of species and used to address questions of functional diversity and cross-species homology. Recent work suggests that the focus in the next few years will be on exploring the mechanisms through which mosaics develop, whether at the level of cell-fate determination, cell migration, or cell death. What, then, are the big questions that remain?

For the molecular developmental neurobiologist, the key questions must be how neurons acquire their type-diversity and spatial patterning through the interplay of intercellular and intracellular signaling pathways, and how these properties are created and maintained by transcriptional control. These are questions that transcend the visual system and seem likely to be answered first for the spinal cord (review: Lee and Pfaff, 2001), but the diverse and well-defined neuronal mosaics of the retina offer an excellent model in which to test the generality of the answers.

FIGURE 29.8. The exclusion radius is insensitive to undersampling. The alpha-b (inner-stratified) mosaic of *Oreochromis spilurus* is highly regular (A) and has a well-defined minimal spacing, shown clearly by the well in the autocorrelation-DRP (B). This yields an exclusion radius (Rodieck, 1991) of 70 μm . When 80% of these cells are deleted at random, simulating an incompletely sampled mosaic in which only one cell in five is recorded, the mosaic (C) now appears irregular to the untutored eye. However, the autocorrelation-DRP, although “noisier,” is otherwise unchanged (D) and the calculated exclusion radius is still 70 μm . T, D, N, and V show the temporal, dorsal, nasal, and ventral poles of the retina. For further details see Cook (1996). © 1996 Cambridge University Press. Reprinted by permission.

At the cell-biological level, the primary spatial patterning issue must be the molecular mechanisms that are used by members of each mosaic-forming type to recognize each other reliably within a crowd of other types while migrating to appropriate positions, staking out territory, and tiling the retina with their dendritic trees. In this respect, the recent discovery of large families of molecules with the potential to mediate highly selective adhesion, attraction, and repulsion among neuronal processes (Wu and Maniatis, 1999; Yu and Bargmann, 2001) is highly encouraging, as are recent technical advances for studying living, growing neurons in their natural habitat (Lichtman and Fraser, 2001). An interesting secondary issue is the molecular control of type-specific dendritic branching patterns. Factors such as branch density, branch angle, and narrowness of stratification will strongly affect the density of interdendritic contacts at the boundaries of neighboring dendritic fields (Lohmann and Wong, 2001; see also Chapter 6) and so may be related to type-specific variations in coverage factor, precision of tessellation, and the contouring of physiological receptive fields. A third issue needing exploration is the two-edged relationship between spatial regularity and cell death discussed earlier; a fourth is the generality of spatial regularity among neurons elsewhere in the CNS, which has hardly yet been touched upon (Stevens, 1998).

Finally, the key issue for the evolutionary biologist must be to discover what these conspicuous and fascinating patterns can tell us about how retinal neurons have evolved. During which of the evolutionary transitions that shaped the major vertebrate lineages have mosaic-forming neurons (and thus, closing the circle, their transcriptional control systems) undergone duplication or “speciation” to create novel neuronal types with independent functions and tilings? What are the genetic and/or epigenetic mechanisms of adaptation that enable homologous neuronal types to vary their regularity and spacing in response to divergent visual demands in related taxa of a single lineage? Ahnelt and Kolb (2000) have begun to address these difficult questions with respect to mammalian cones, but only when they can be answered for all the major neuronal classes and vertebrate groups shall we be able to say that we understand the relationships between development, structure, and function in the retina.

IV ORGANIZATION OF VISUAL PATHWAYS

30 The M, P, and K Pathways of the Primate Visual System

EHUD KAPLAN

OVERVIEW

Why are neural streams worth studying?

To our mind's eye, the world appears as a combination of colors, sizes, movements, locations, and other attributes of the visual world. It is tempting to assume that every one of these attributes is handled by a separate neural population, which constitutes an information channel or stream. The observation that the visual system comprises several neuronal populations or streams suggests the possibility that each stream performs a distinct function in vision. We believe that understanding the link between the properties of the neurons in each stream and those visual functions should illuminate the computations that are performed by the visual system as it analyzes the visual world. Here I shall review the current state of our understanding of the three neuronal populations that together make up the output of the primate retina: the so-called M (magnocellular), P (parvocellular), and K (koniocellular) streams. A review is timely for several reasons: (1) Recent intracellular recordings in vitro have generated detailed information about the morphology and physiology of several types of retinal cells, including some cell types that had not been characterized before; (2) a significant new population of cells (the Koniocellular, or K cells) had been identified within the lateral geniculate nucleus (LGN), with distinctive patterns of projection into the visual cortex; (3) detailed microscopic analysis of retinal circuits has revealed new information about synaptic patterns of connections; and (4) more sophisticated stimulation techniques have shed some new light on the details of the organization and dynamics of the various neuronal populations that make up the early visual system of primates.

After a brief review of the relevant anatomical structures of the primate early visual system, I shall consider several aspects of the physiological characteristics of the three main neuronal streams and discuss their functional implications.

Cell types, visual streams, and parallel information processing

When one considers diverse neuronal populations within a neural entity such as the visual system, it is important to have a clear understanding of the taxonomical notion of *cell type*. In the primate visual system, the M, P, and K populations are thought to consist of three different types of neurons. The concept of a neuronal type, and its relationship to visual neuroscience, has been discussed extensively in the past (see, for example, Rodieck and Brening, 1983; Stone, 1983). Usually, one refers to a group of neurons that is distinct from other groups along one or more important dimensions, such as morphology, physiology, or connectivity. Even if along any one dimension the variations among cells form a continuous transition with a unimodal distribution (say, from small to large neurons, or from fast conducting to slow conducting), when the entire cell population is examined along *multiple dimensions*, one typically observes distinct clusters. This point is illustrated for two dimensions in Figure 30.1.

A seductive and widespread hypothesis is that different cell types serve distinct functions. If the various populations also have distinct patterns of connectivity, it is often assumed that we are looking at distinct neuronal streams or functional pathways, each devoted to the representation and analysis of a different aspect of the visual world, for which each stream is specialized. It is thought that the spatiotemporal distribution of light on the two-dimensional retinal surface is transformed by the visual system into a set of higher-order representations, or abstractions, of several aspects of the visual world, such as color, size, edge orientation, or movement. The notion of parallel representation suggests, in turn, that each neuronal type should probably cover the entire visual field, so as to avoid having regions in which one cannot see some important aspect of the world, such as blue or vertical edges or movement.

We do not know currently how many major attributes of the visual world are represented by the visual system, but it is probably safe to assume that the number is larger than 3, though probably less than 20. One might try to estimate the number of possible dimensions by considering how many neuronal types are represented at any point in the retina.

Such information is exceedingly difficult to obtain and is available in only a few cases, such as the elegant work of MacNeil and Masland (1998), who found 29 types of amacrine cells at every point in the rabbit retina. The relatively large number of visual dimensions suggests that each of the three major visual streams we are discussing here (M, P, and K) must deal with more than one attribute of the visual world. We hope to determine at least some of the functions of the various streams by comparisons of the respective properties along some of the dimensions mentioned above, and much of what is to follow will be taken up by that effort.

Anatomical vs. physiological classification

In discussing neuronal streams it is useful to keep in mind the distinction between labeling neurons according to (1) where they are or who they connect with, which is usually

FIGURE 30.1. Two cell populations might have a unimodal distribution along any one dimension, but when analyzed along more than one dimension (two in this example: size and response threshold), they form two distinct clusters.

qualitative and unambiguous; and (2) their physiological (or other) properties, which can vary in quantitative measures (e.g., conduction velocity, response time course, or chromatic opponency). The latter classification is often less certain and more controversial than the former.

Properties of the M, P, and K streams: a summary

Table 30.1 provides a concise overview of our current knowledge of the three major visual streams in the primate visual system: M, P, and K. The subsequent sections will elaborate on some of the entries in the table. We note that much more is known currently about the P and M populations than about the K population, which was discovered more recently, and which is much more difficult to study in isolation. There are several extensive reviews of the M/P pathways at various stages of the visual system (Kaplan et al., 1990; Lee, 1996; Merigan and Maunsell, 1993). Less is known about the K (koniocellular) pathway, but the reader is referred to Irvin et al. (1993), Hendry and Reid (2000), White et al. (2001), and Xu et al. (2001).

THE UNDERLYING ANATOMICAL CIRCUITRY

Retina

GENERAL SCHEME The primate retina follows the general scheme of other vertebrate retinas. After traversing the retina, light is transformed by the photoreceptors into electrical signals that are communicated to the bipolar cells, which relay the message to the ganglion cells, whose axons form the optic nerve. Two additional layers of cells, the horizontal cells and amacrine cells, form lateral connections

TABLE 30.1
Properties of the P, M, and K Pathways

Property	P	M	K
Clear spectral opponency/selectivity	Yes	No	Some (Blue-ON)
Luminance contrast gain	Low	High	High
Receptive field size	Small	Large	Large
Spatial resolution of individual neurons	Similar to M	Similar to P	Variable
Ganglion cells/mm ² (acuity of cell group)	Many (high)	Few (low)	?
Retinal source	Midretinal ganglion cells (RGCs)	Parasol retinal ganglion cells	Unknown (some from blue-ON bistratified RGCs)
LGN projection target	Parvocellular	Magnocellular	Intercalated (K)
V1 projection target	Layer 4C β	Layer 4C α	Layers 2-3, CO blobs
Cell size	Small	Large	Large/varied
Conduction velocity of axons	Low	High	Low/varied
Response to light steps	Tonic	Phasic (transient)	Phasic; some sluggish
Contrast sensitivity at scotopic luminance	Poor	Good	?
Linearity of spatial summation	Linear (X-like)	75% linear, 25% nonlinear (Y-like)	Linear (X-like?)
Fraction of LGN population	~80%	~10%	~10%

with elements of the three major layers, and these are believed to provide the basis for the antagonistic center-surround organization of receptive fields of retinal neurons (Kuffler, 1953; Werblin and Dowling, 1969). All told, the retina of Old World primates comprises approximately 80 cell types: 4 types of photoreceptors, 10 types of bipolar cells, 2 types of horizontal cells, 30 to 40 types of amacrine cells, and 20 types of ganglion cells (for extensive reviews, see Rodieck, 1988; Wässle and Boycott, 1991; Dacey, 2000).

GANGLION CELLS

Parasols and midgets. An early indication that the primate retina contains more than one homogeneous neural stream came from the anatomical studies of Polyak (1941), who described two major types of ganglion cells, distinguished by their morphology: midget and parasol cells. Later work has established that the midget cells of the central few degrees receive their input from bipolar cells that get their input from a single cone, establishing a “private line” from cone to ganglion cell (although each cone connects to one ON and one OFF bipolar cell). The parasol cells, by contrast, receive their inputs from several diffuse bipolar cells, which in turn sample from several cones. This basic anatomical difference results in a dramatic difference in physiological properties and, by inference, in visual function, as we shall discuss below.

Injections of tracers into the LGN have shown that the parasol cells project to the magnocellular layers of the LGN (the bottom 2 layers), whereas the midget ganglion cells innervate the upper 4 layers, the parvocellular layers (Leventhal et al., 1981; Perry et al., 1984). These anatomical destinations have given these two major visual streams their commonly used names, the M (magnocellular projecting) and P (parvocellular projecting). This nomenclature is a source of some unfortunate confusion, since anatomically we speak of *Parasol* (M) and *Midget* (P) retinal ganglion cells. However, the M and P labels have the advantage of being completely unambiguous, because the ganglion cells that project to the LGN synapse either in the parvocellular or in the magnocellular layers, with no overlap.

The segregation of pathways into P and M streams starts right at the very first visual synapse: the midget bipolar cells innervate the midget ganglion cells, the parasol cells are innervated by diffuse bipolar cells (Boycott and Wässle, 1991; Calkins and Sterling, 1999), and each point in the retina is covered by both cell types.

We note that both the M/P and parasol/midget nomenclatures are strictly anatomical and carry no explicit information about the physiological properties of the relevant populations. These properties will be discussed later.

Bistratified and other types. Another distinct morphological type has been added to the parasol and midget cell types with the inclusion of the bistratified ganglion cells, which make synaptic contacts at both the upper and lower sublaminae of the inner plexiform layer (Dacey, 2000; Dacey and Lee, 1994). Because we know that ON and OFF ganglion cells synapse separately in these sublaminae (Famiglietti and Kolb, 1976), the bistratified morphology predicts that the bistratified cells will show ON/OFF responses to light steps; a recent report by Dacey and Lee (1994) confirms that expectation. Backfilling experiments have shown that these ganglion cells project to the intercalated layers (the layers just underneath the major layers of the LGN, which are also called the interlaminar layers, or the koniocellular [K] layers). The cells in these regions had been shown to project to the cytochrome oxidase-rich regions of the upper layers of the primary visual cortex (CO “blobs”) (Diamond et al., 1985; Hendry and Yoshioka, 1994). The properties of other ganglion cells that project to the K layers of the LGN are not yet known. We also note that, although there is evidence that the M and P streams diverge already at the first synapse, between photoreceptor and bipolar cell (Calkins and Sterling, 1999), the situation regarding the K stream is still unknown.

Some typical examples of primate retinal ganglion cells are shown in Figure 30.2, together with their LGN projection targets.

TERMINOLOGY The terms *parasol*, P_α , M (or MC), *phasic*, and *broad-band* have all been used (somewhat loosely) in the literature to refer to the same population of neurons. Similarly, the terms *midget*, P_β , P (or PC), *tonic*, and *color opponent* have been used to refer to the other major type of ganglion cell. The term *midget system*, which is used by some authors, is somewhat more accurate, because it excludes other, quite different, cell types (Rodieck and Watanabe, 1993) that project to the parvocellular layers of the LGN. Koniocellular layers have been called S, interlaminar, intercalated, or K layers. Whatever terminology is used, it is important to keep in mind the distinction between strictly anatomical classification (parasol, P_α , and midget, P_β) and classifications that rely on the physiological properties of the cells (tonic, phasic, color-opponent).

TILING, SAMPLING DENSITY, AND SPATIAL RESOLUTION As mentioned above, each cell type should tile the retina completely, so the visual attribute for which the type is specialized will be represented everywhere in the visual field. In some cases, the tiling might be overlapping, with a coverage factor (the number of cells of a given type at each retinal point) >1 . Dacey (1993) has shown that the midget cells tile the retina with a coverage factor of approximately 1, leaving no holes, but with no overlap of dendritic fields. Similar

FIGURE 30.2. Examples of the morphology of some of the common ganglion cell types in the primate retina, together with their projection targets in the LGN, and some of their physiological properties (Dacey, 2000).

information for the parasol cells is available from looking at the areal density of the cells, rather from a detailed mapping analysis. This shows that the retinal coverage of the parasol cells is qualitatively similar to that of the midget cells: as their density changes, their dendritic field sizes vary by a similar factor. The lower density of parasol cells explains why the spatial resolution of the parasol (M) system is much lower than that of the P system. Although the spatial resolution of individual M cells is virtually identical to that of individual P cells (Blakemore and Vital-Durand, 1986; Crook et al., 1988) because of their higher sensitivity to luminance contrast (see below, Figure 30.5), their ability to faithfully represent spatial patterns is much poorer than that of the P system, with the difference being determined by the Nyquist limit of spatial sampling (which requires at least two samples along any direction for each cycle of spatial frequency in the stimulus). The similar spatial resolutions of individual M and P cells is clarified in Figure 30.3, which shows that despite

FIGURE 30.3. Large cells (M) can have spatial resolution (ability to respond to fine patterns) that is similar to that of small cells (P) if they are sensitive enough, even though their “cutoff frequencies” (the spatial frequency at which the horizontal and sloping asymptotes intersect) are quite different. The shape (Gaussian), radius and sensitivity of the detectors in this example are similar to those of M and P cells recorded in the laboratory.

the large receptive field center of M cells, their high-contrast gain gives them acuity that is like that of P cells. We note that the high acuity of individual M cells is especially remarkable in view of the fact that parasol cells have been shown to be electrically coupled (Dacey and Brace, 1992), and such coupling is bound to lower their spatial resolution, both individually and as a network.

RETINAL ECCENTRICITY The density of cones and rods varies steeply across the retina, and these gradients are reflected in the subsequent stages of retinal circuitry and function. Several important aspects are mentioned below.

Parasol/midget ratio. Early reports suggested that M cells were less well represented in and around the fovea, but later studies (Perry et al., 1984; Silveira and Perry, 1991) found the ratio of parasol and midget cells in the macaque retina to be uniform across the retina, reinforcing the view that these two streams form true neuronal types in the sense that was discussed above. This uniform coverage casts doubt on attempts to use selective stimulation of the M or P populations by restricting their stimuli to particular retinal eccentricity. However, in humans the situation might be different, because Dacey and Petersen (1992) reported indirect evidence, based on measurements of dendritic field size at two retinal eccentricities, that suggested that the P/M ratio in the central retina might be as high as 30/1.

Receptive field size. The diameter of receptive fields increases for both M and P cells as one moves away from the fovea, but, at any given retinal eccentricity, the diameters of M cells’ receptive fields are larger than those of P cells from the same retinal eccentricity (Croner and Kaplan, 1995). This trend reflects the underlying increase in the dendritic trees of ganglion cells as one moves from fovea to the retinal

periphery and has consequences for the physiological properties of the cells, primarily their contrast sensitivity and chromatic selectivity, but also their state of light adaptation.

Near the fovea the midset bipolar cells receive synaptic input from a single cone and deliver their output to a single midset ganglion cell. This produces a very narrow receptive field center. At retinal eccentricities beyond approximately 7 degrees, the bipolar cells start collecting input from an increasing number of cones, and the midset ganglion cell receives input from an increasing number of bipolar cells. The much larger collecting area of M cells (~6 to 8 times that of P cells; Croner and Kaplan, 1995) accounts for at least some of their relative superiority in luminance contrast gain. Data from the human retina suggests significantly larger areal ratios in the central retina (Dacey and Petersen, 1992).

The effect that receptive field size has on contrast sensitivity is discussed later in this chapter.

LGN

M, P, AND K POPULATIONS We shall now review briefly the LGN anatomy. A recent review can be found in Sherman and Guillery (1996). The primate LGN is comprised of 6 layers, arranged in 2 major divisions, and numbered from the bottom (1) to the top (6). The upper one contains 4 layers of smaller cells, the parvocellular layers; the lower one has 2 layers of larger cells, the magnocellular layers. Layers 6, 4, and 1 receive their input from the *contralateral* eye; layers 5, 3, and 2 are innervated by the *ipsilateral* eye. Intracellular staining of retinal ganglion cells projecting to the cat LGN by Bowling and Michael (1980) shows little violations of layer boundaries. Approximately 80% of the cells in the nucleus are in the parvocellular layers, and 10% are in the magnocellular layers.

More recently, Norton and Casagrande (1982, in the *galago*) and Hendry and Yoshioka (1994, in the macaque monkey), have shown that there is another distinct group of LGN neurons, which are immunoreactive for the alpha subunit of type II calmodulin-dependent protein kinase, and are located under each of the major six layers. These are the intercalated layers, or koniocellular (K) cells, which account for ~10% of the cells in the macaque LGN. They have been shown (Hendry and Yoshioka, 1994) to project directly to the CO-rich regions of the primary visual cortex ("blobs"; Carroll and Wong-Riley, 1984).

In addition to the primary "relay" cells, which receive their input from the retina, there is a small number of inhibitory GABAergic interneurons. The magnocellular layers have four times as many interneurons as the parvocellular layers (Hámori et al., 1983), but the functional significance of that difference is unknown. As is the case in other mammalian species, the primate LGN receives a

massive feedback input from the striate cortex, which has recently been reported to increase the gain of LGN neurons (Przybylski et al., 2000).

Primary visual cortex

CONNECTIONS The information from the LGN is fed primarily into layer 4 of the primary (striate) visual cortex, or V1. Magnocellular cells synapse in layer 4C α , and parvocellular cells synapse in 4C β . Collaterals of both are sent also to layer 6, the layer that, in turn, projects back to the LGN (Gilbert and Kelly, 1975). In addition, the koniocellular cells project into the CO-rich zones of the upper layers, the CO "blobs" (Hendry and Yoshioka, 1994).

From V1 the information is relayed to the rest of the visual system, and the pattern of M/P/K connectivity below and above V1 has given rise to the notion of parallel systems or streams, each handling some portion or aspect of the visual information. Thus the output from the CO blobs is relayed to specialized CO bands in V2, which are embedded among CO-poor pale bands (Livingstone and Hubel, 1984b, 1987). The overall connectivity of the three streams, from the retina through the LGN to the visual cortex, is shown schematically in Figure 30.4.

PHYSIOLOGICAL PROPERTIES

Response dynamics: tonic and phasic cells

The first physiological indication that the primate retina contains more than one functional type of ganglion cell came when Gouras (1968) reported that in response to light steps, some cells responded in a tonic, sustained fashion, whereas others responded phasically. This difference in dynamical properties has remained one of the clearest distinguishing characteristics of these two main cell types. Gouras recorded from the cells inside the eye, so the anatomical characteristics of them were unknown at the time, but subsequent studies have established that the phasic cells correspond to the parasol cells, which project to the magnocellular layers of the LGN, and the tonic cells correspond to midset ganglion cells projecting to the parvocellular layer.

Luminance contrast gain

Another major physiological difference between the M and P populations is the contrast gain (change in response for a unit change in contrast) for luminance patterns, which is high for M cells at low contrasts and low for P cells at all contrasts (Kaplan and Shapley, 1986). Contrast gain depends directly on the photon flux over the receptive field (Enroth-Cugell and Shapley, 1973). At all eccentricities, the flux collected by M cells is greater than that collected by

FIGURE 30.4. A simplified connectivity diagram of the M, P, and K pathways in the primate visual system. The magno-dominated dorsal (“where”) stream is marked in *dashed lines and bold italics*; the ventral (“what”) stream is indicated by *solid lines and faint stripes*.

FIGURE 30.5. The luminance contrast gain (slope of the response *vs.* contrast function) of M cells is much higher at low contrasts than that of P cells, but is similar at higher contrasts. The stimulus was a black and white grating, drifting at 4 Hz. All 36 retinal ganglion cells in this data set (28 P and 8 M) were recorded as S potentials in the LGN of the same macaque monkey. Contrast is defined as $C = 100 \cdot \frac{L_{\max} - L_{\min}}{L_{\max} + L_{\min}}$, where L is the luminance level. The response measure was the fundamental Fourier component of the average firing at each contrast (± 1 SEM). (from Kaplan and Shapley, 1986)

P cells, and that accounts for at least some of their superior contrast gain (Croner and Kaplan, 1995; Kaplan and Shapley, 1986; Shapley et al., 1981;). This is shown in Figure 30.5, which shows the average response versus luminance contrast for M and P cells in the retina of one macaque monkey. Kaplan and Shapley (1986) recorded the responses of retinal ganglion cells in the LGN in the form of S potentials, a small extracellular potential that is seen in the LGN each time a spike is fired by a retinal ganglion cell that innervates the LGN neuron near the recording electrode (Bishop, 1953; Kaplan and Shapley, 1984). This approach allows the correct identification of the recorded retinal cells as P or M, as opposed to intraretinal recordings *in vivo*, where one must rely on physiological characterization of the cells to determine their projection targets.

It is not yet certain whether the difference in receptive field size is sufficient to account for the different gains or whether some other process, such as antagonistic cone input, could lower the gain of P cells. It is also possible that some yet unknown process is responsible for the high gain of M cells at low contrast, and that process saturates as contrast exceeds ~15% to 20%, after which the gain of M cells is rather similar to that of P cells. It is possible, then, that the response of M cells is governed by two mechanisms, one for low and the other for high contrasts.

X/Y/W homology and linearity

HOMOLOGY Early studies of primate LGN neurons by Dreher et al. (1976) and Sherman et al. (1976) suggested a correspondence between the cells found in the upper (parvocellular) layers and the X type found in the cat retina (Enroth-Cugell and Robson, 1966). Similarly, cells found in the magnocellular layers were thought to correspond to the Y type of cat retinal ganglion cells. These studies focused on the time course of the responses (X/parvo = sustained, Y/magno = transient), rather than on the linearity of spatial summation, which was the criterion used originally by Enroth-Cugell and Robson to distinguish X from Y ganglion cells in the cat retina. When the original linearity test was applied by Kaplan and Shapley (1982), they reported that all the parvocellular neurons and 75% of the magnocellular cells were X-like, whereas 25% of the magnocellular neurons were Y-like.

Another study that investigated the issue of linearity of spatial summation (Sherman et al., 1984; Levitt et al., 2001) reported that the degree of nonlinearity among the magnocellular neurons was distributed unimodally, rather than bimodally as was found for cat retinal ganglion cells (Hochstein and Shapley, 1976). The cells at the tail of that unimodal distribution were probably the ones that Kaplan and Shapley labeled as “Y-like.” It is worth pointing out that Calkins and Sterling (personal communication) found that

approximately one-third of the parasol cells in their sample received much more amacrine input than the other two-thirds. Because amacrine cells are often nonlinear, this result suggests that these ganglion cells would show stronger nonlinearities, and thus would be classified as “Y-like.” Because of the similarities between the cat X/Y population and the monkey M population, Shapley and Perry (1986) have suggested that these be considered homologous, and that the P cell type was something that primates have developed for higher resolution and perhaps for color vision. Studies of the laminar organization and development of the cat LGN have provided data that support this view as well (Mitzdorf and Singer, 1977; Shatz, 1981, 1983). In addition, a comparative study of several mammalian retinæ by Peichl et al. (1987) showed that in all of them the alpha cells (the ones corresponding to the nonlinear Y-like cells in the cat retina) account for 1% to 4% of all retinal ganglion cells. If we were to accept one-fourth to one-third of the M ganglion cells as Y-like, the monkey will have the same fraction of Y-like ganglion cells as other mammals, namely, 2.5% to 3%.

The K stream has been proposed as the primate homolog of the W population in the cat visual system (Irvin et al., 1986), because many of its cells are sluggish (White et al., 2001). However, because both K and W have a rather heterogeneous morphology and physiology, the value of such a homology in establishing the function of either stream is difficult to establish.

NONLINEAR RESPONSES In addition to the spatial nonlinearity mentioned above, it had been reported (Lee et al., 1989) that the receptive field surround of retinal M cells produces nonlinear responses if a large enough portion of it is stimulated. A thorough investigation of linear and nonlinear responses of the center and surrounds regions of both M and P cells (Benardete et al., 1992; Benardete and Kaplan, 1997a, 1997b, 1999) found evidence for nonlinear components in both populations. One type of nonlinearity, called *contrast gain control*, which was described earlier in cat retinal ganglion cells (Shapley and Victor, 1978), was found in some M cells but not in P cells. This mechanism affects the dynamics of the cell’s response: at higher contrasts, the response to low temporal frequencies is attenuated, and the response phase is advanced (Benardete et al., 1992). It seems reasonable to ascribe the nonlinear components to input from amacrine cells, which are known to produce nonlinear responses. This would suggest that the surround mechanism, and perhaps the center mechanism as well, are made up of at least two components, one originating in the outer and the other in the inner plexiform layers, as suggested by Kaplan and Benardete (2001, their Figure 10).

FIGURE 30.6. Contrast gain decreases with decreasing retinal illumination. At scotopic luminance levels the responses of most P cells drown in the noise, whereas M cells still respond to patterns. Shown are the responses of typical M (*left*) and P (*right*) cells to drifting achromatic gratings as a function of contrast (from Purpura et al., 1988).

Light adaptation in M and P cells

Like contrast gain, the adaptation state of a visual neuron is intimately connected to the size of its receptive field, because larger receptive fields collect more photons (Enroth-Cugell and Shapley, 1973). The adaptation state has a profound effect on the dynamics of the response (De Lange, 1958; Dodge et al., 1968; many others). One would expect, then, that M cells would be more light adapted and therefore more transient than P cells at any given luminance level. Purpura et al. (1988, 1990) have shown that, as expected, M cells are always more transient (band pass) than P cells at a given luminance, and that lowering the luminance lowers the steady-state contrast gain of both cell types. These properties are illustrated in Figure 30.5. It is not yet established whether the different dynamical properties of the M and P cells can be attributed entirely to the difference in their size and resulting adaptation level, or whether other factors, such as biophysical properties and/or synaptic input, may contribute as well.

Scotopic (low light) vision

As luminance decreases, the gain of all retinal ganglion cells decreases (Figure 30.6 and Figure 30.7). Because the gain of M cells at all luminance levels is higher than that of P cells, eventually the response of P cells drowns in the noise of their spontaneous activity. Under those conditions, only M cells can still signal the appearance of patterns in the visual field. Note that there are roughly eight times as many P cells as M cells, so if their responses were summed together in the cortex, they could, in principle, compensate for their poorer gain. However, recall that the coverage factor of P cells is

FIGURE 30.7. The contrast gain (slope of functions like the ones in Fig. 30.6) of M cells is higher than that of P cells at all luminance levels (from Purpura et al., 1988).

roughly 1 (Dacey, 1993), so any pooling will have to sacrifice spatial resolution.

Chromatic selectivity

REPRESENTING SPACE AND COLOR It was clear from the very beginning that the M/P populations differ in their chromatic selectivity (Gouras, 1968). Much subsequent work has shown that most P cells are wavelength selective, whereas the selectivity of the M population is more broad-band. Wiesel and Hubel (1966) recognized that cells with antagonistic center-surround receptive fields had to represent two distinct features: space and color. There are only three sensible permutations of center-surround with space/color: cells that care only about *color*, cells that report only about *space*, and cells that represent *both*. Cells that ignore both are useless to a visual system. Wiesel and Hubel (1966) reported that the cells in the macaque LGN indeed fell into these three groups. They called those cells that were chromatically and spatially opponent (77% of parvocellular cells) *type I*, those that were chromatically but not spatially opponent *type II* (7%), and those that were spatially but not chromatically opponent *type III* (16%). The magnocellular cells were mostly of the *type III* variety, although some were reported to have a red-sensitive inhibitory surround, and those were labeled *type IV*.

A subsequent investigation by DeMonasterio and Gouras (1975), who used small spots and annuli of various colors to explore the receptive fields of retinal ganglion cells, has reported a rich variety of chromatic types. However, some of these results might have been contaminated by the use of chromatic adaptation, which attempted to desensitize some

of the cones by bright illumination with light of the color that they are most sensitive to.

Derrington et al. (1984) revisited the subject of chromatic selectivity from the perspective of a theory that transformed an earlier suggestion of MacLeod and Boynton (1979). Derrington et al. postulated three intersecting axes: constant red/green cone excitation, constant blue cone excitation, and a luminance axis that is perpendicular to the two chromatic axes. They have measured the elevation and azimuth of a plane that includes the stimuli that can be silently exchanged for each LGN cell they have studied. The azimuth and elevation values for the various cells clustered around two main groups: red/green and blue/yellow. The measurements were repeated with drifting gratings of various spatial frequencies to assess the cone inputs to the center and surround separately. The authors concluded that *all* cells in the macaque LGN, parvocellular as well as magnocellular, show both chromatic and spatial antagonism.

These results, together with the reports of magnocellular cells (type IV) that show a chromatically selective surround, call into question the widely accepted notion that the M stream does not participate in the analysis of chromatic information, and is blind to isoluminant stimuli.

CONE INPUT TO THE RECEPTIVE FIELD SURROUND The wavelength selectivity of the surrounds of P receptive fields has attracted much attention and is still a rather controversial issue, because anatomical and physiological studies of the primate retina have produced conflicting expectations. Several physiological studies (Benardete and Kaplan, 1999; Reid and Shapley, 1992; Wiesel and Hubel, 1966) have reported that the surrounds appear to receive input from only one cone type. However, several other studies (Boycott et al., 1987; Calkins and Sterling, 1996; Dacheux and Raviola, 1990) have reported that the cellular elements that are believed to generate the surround response of ganglion cells (horizontal and amacrine cells) show remarkable promiscuity, and are innervated by all the cones within the reach of their dendritic trees. This apparent contradiction between the physiological results and the anatomical findings still awaits resolution.

It is worth noting, however, that a chromatically nonselective surround is sufficient for color vision (Lennie et al., 1990; Paulus and Kröger-Paulus, 1983). In addition, the clumpy nature of the random cone mosaic (Roorda and Williams, 1999) will cause many cells with nonselective cone inputs to show strongly biased physiological selectivity.

Multiplexing chromatic and luminance information

The discovery of two (or more) distinct neuronal populations suggested that they subserve distinct visual functions. However, Gouras and Zrenner (1979) reported that ganglion

cells that were color opponent at low temporal frequency lost their chromatic opponency at high temporal frequency, and attributed that change to a progressive increase in the phase lag between the responses of the center and its antagonistic surround. This increase of phase lag with temporal frequency was, indeed, reported by Benardete and Kaplan (1997a). The view that the P channel might multiplex chromatic and luminance information was formalized in the analysis of Ingling and Martinez-Uriegas (1983, 1985), who argued that the spatiotemporal chromatic organization of parvocellular receptive fields allows them to communicate both chromatic and luminance information to the cortex, depending on the spatiotemporal specifics of the stimulus. Note that this analysis requires the cells to be strictly linear; as mentioned above, recent studies have uncovered some nonlinear components in the responses of P cells (Benardete and Kaplan, 1997b).

Homogeneity of the M, P, and K populations

The visual neuroscience literature often treats the M/P streams as if they were monolithic, homogeneous neuronal populations. This is especially true when scientists discuss the roles that the various streams play in the analysis of visual information, or when they attempt to design visual stimuli that will selectively excite or bias one stream at the expense of the other(s). This view is at odds with reality, and much of the controversy in the literature could be attributed to heterogeneity within these major types. The P cells (the parvocellular-projecting), in particular, are probably quite heterogeneous (Rodieck and Watanabe, 1993), and include some of the largest cells in the retina, although the majority of them are probably midget ganglion cells. This heterogeneity is anatomical, and to it one must add functional differences. The M (magnocellular-projecting) cells also seem to comprise at least two populations, based on the amount of amacrine synaptic input they receive (Calkins and Sterling, personal communication), the linearity of their spatial summation (Kaplan and Shapley, 1982), or the pattern of the cortical projection of their LGN targets, which includes a population of larger axons that project to a separate sublamina of 4C α (Blasdel and Lund, 1983).

The physiological properties of K cells have been studied primarily in bushbabies (*galago*) (Irvin et al., 1986; Norton and Casagrande, 1982; Norton et al., 1988), and more recently in owl monkeys (Xu et al., 2001) and marmosets (White et al., 2001). These studies report that the physiological properties of the K stream are quite diverse, although in some respects (size, contrast gain) they appear closer to the M than to the P stream. This diversity makes it especially difficult to study them in isolation or to ascribe a specific visual function to the K stream.

The fact that the K stream has been discovered only recently (Hendry and Yoshioka, 1994; Irvin et al., 1986) is a

reminder of the need for caution when viewing the P and the M cells as homogeneous populations or when considering the visual system as made up of only these three populations. With the advent of new anatomical markers or analysis techniques, it is likely that these populations will be shown to include new subgroups. Another reminder is the intriguing report by Calkins et al. (1994) of two types of midget cells, with distinct patterns of synaptic inputs. The functional significance of these two cell groups is still elusive, although the association of these synaptic types with green-sensitive and red-sensitive cones is suggestive.

Some studies (e.g., Levitt et al., 2001) have argued that, because the distribution of the various parameters they investigated (nonlinearity, conduction velocity, and so on) had unimodal distribution, the neuronal populations should not be subdivided. However, the rather broad distributions of some parameters of receptive field or morphology suggest that the splitters will have more to say before the lumpers' word is final. For example, the analysis of clustering of parameters of the receptive fields in the marmoset LGN by White et al. (2001, Fig. 10) showed considerable overlap among the three major streams.

FUNCTIONAL IMPLICATIONS

What roles might the various pathways play in vision?

The assignment of distinct visual functions to the various neuronal streams has proven to be irresistible to vision scientists, and several similar suggestions have been made. These attempts were based on two very different types of evidence: (1) the clustering of anatomical and physiological properties of the three major streams and (2) lesion studies.

NOTIONS BASED ON CLUSTERING OF FUNCTIONAL PROPERTIES

The small receptive fields and chromatic organization of P cells has suggested, initially, that they participate in the analysis of form and color; while the broad-band, phasic M cells were relegated to detecting motion and conveying information about (achromatic) luminance. In view of the proposed division of the visual system into "what" (dorsal) and "where" (ventral) streams (Ungerleider and Mishkin, 1982), the pattern of cortical projections of the M, P, and K streams suggested that they provide the initial inputs to these two main visual pathways (Livingstone and Hubel, 1984a, 1988; Zeki and Shipp, 1988), with the P stream feeding the *what* pathway and the M stream answering the question *Where?* (see Figure 30.4).

NOTIONS BASED ON LESION STUDIES Several groups (Lynch et al., 1989; Merigan and Maunsell, 1993; Schiller et al.,

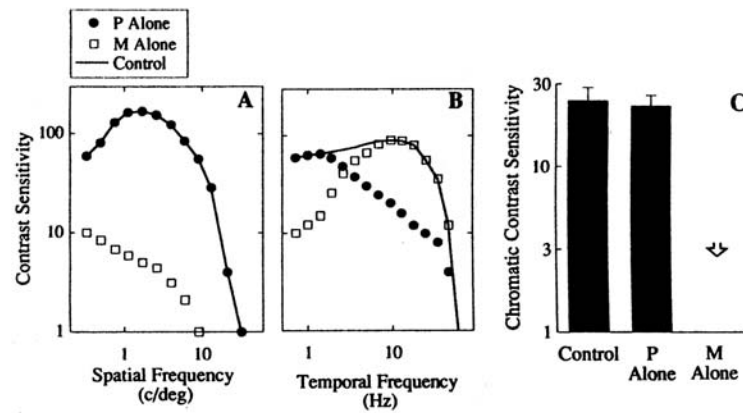

FIGURE 30.8. The effects of selective lesions of the P or M layers of the monkey LGN on spatial (A), temporal (B), or chromatic (C) modulations (from Merigan and Maunsell, 1993). The results support the notion that the P stream is important for spatial and chromatic analysis, and the M stream is involved in temporal analysis.

1990) have used various agents, either systemically or through localized injections, to damage one or the other of the M or P streams. Their results were interpreted as support for the notion that the M and P streams played different roles in vision. The overall impression was that the clusters of anatomical and physiological properties were distinct enough to justify such a view.

In addition, the notion of distinct visual functions implied the independence of the various functions and streams. Thus, movement analysis was said to be independent of color, and so on. An example that illustrates the results of such an approach is shown in Figure 30.8, from the work of Merigan and his colleagues. The data support the notion of specialized function of the P and M pathways along the lines mentioned in the previous section.

However, in evaluating such results today, we should note that the existence of the K channel was unknown at the time of these studies, and the location of its layers makes it virtually impossible to disentangle K lesions from lesions of the overlaying P or M layers.

DYSFUNCTIONS ATTRIBUTED TO SPECIFIC STREAMS The different physiological properties of the various streams have given rise to several hypotheses that related specific neural dysfunctions to one of the three pathways. Two prominent examples are glaucoma and dyslexia, both of which have been attributed to malfunctions or specific damage to the magnocellular pathways (e.g., Livingstone et al., 1991; Quigley, 1999; Yücel et al., 2000; Jenner et al., 1999; Willis and Anderson, 2000). However, despite rigorous research efforts, doubts remain regarding the notion that such damage represents the only (or major) cause of these two serious dysfunctions, and the issue is still quite controversial. The difficulties of validating these hypotheses are similar to those of establishing the functional specificity of any of the streams in vision, as discussed below.

Are the three neural streams functionally distinct and independent?

The seductive simplicity of the association of the visual streams with distinct visual roles has won it broad and rapid acceptance. Many now view the M system as the luminance channel of psychophysics and believe that it is probably involved in motion detection and analysis. The P system seems to be involved in color and form analysis, although which cells within it are responsible for chromatic analysis is still being debated (see, e.g., Rodieck, 1991). The K system is involved in at least some aspects of color vision. The remaining aspects of the visual world are said to be analyzed by both P and M.

However, we should note that the evidence in support of these views is rather weak. The reasons are as follows: (1) The various streams are rather heterogeneous, and it is likely that future research will uncover additional new substreams, perhaps with their own role in vision; (2) much evidence points to interaction among the various visual functions that were said, initially, to be performed in parallel by the various streams (as one of many examples, see Krauskopf and Farell, 1990); (3) the anatomy provides a substrate for numerous pathways to support such interactions among the streams (Figure 30.4). In short, the visual system is a dynamical (and nonlinear) network, and in such a network it is difficult at best to ascribe a specific function to a given element. The evidence from lesion experiments is especially difficult to interpret, because the brain is a plastic, adaptable network, and removing, damaging, or otherwise inactivating any of its parts tells you not what that part is doing, but rather what the brain can (or cannot) do without that part. There are also recent physiological data that suggest that inputs from the P and M streams are combined linearly in the primary visual cortex to detect motion (De Valois and Cottaris, 1998). In short, although the three streams flow

separately from retina to cortex, there is little doubt that their messages are intermingled in the cortex, as they blend to form unified perceptions.

We note that the difficulties in clear-cut assignment of functions to pathways also impact our ability to design stimuli that affect one pathway without affecting others.

CONCLUSIONS

What else do we need to know about visual streams?

Although much has been learned about the various neuronal streams that comprise the early primate visual system, much remains to be learned. Some of the remaining issues are listed below:

1. Are the M, P, and K *all* the streams that exist?
2. How *homogeneous* are they?
3. *Which aspects* of the visual world are handled by each stream?
4. What other ganglion cells, besides the bistratified ganglion cells, project to the LGN K cells?
5. How is the information *integrated* into a uniform percept?
6. Which of the streams' distinct properties are due to biophysical/morphological characteristics, and which emerge from the network in which the cells are embedded?
7. How is the development of the separate streams controlled?

The next few years will undoubtedly provide exciting answers to these questions. However, we should recall that the visual system, like the brain itself, is a highly interconnected, nonlinear dynamical network, and in such a network it might be difficult to allocate a particular function to a specific anatomical entity.

31 Parallel Visual Pathways: A Comparative Perspective

VIVIEN A. CASAGRANDE AND XIANGMIN XU

IN SPITE OF OBVIOUS differences between species, our knowledge of the structure and function of the human visual system is based almost entirely on extrapolation from studies in a very limited set of animal models. Although a variety of species have been used, the principal models for visual system studies continue to be domestic cats and macaque monkeys. These species, and others used less commonly, differ from humans in a number of respects including millions of years of separate evolutionary history, brain size, and visual behavior. The continued use of just a few species as models for the human visual system is defensible if the organization of the visual system is basically the same among species. Many differences, however, have been documented. For example, in cats the lateral geniculate nucleus (LGN) of the visual thalamus appears to have much more widespread connections with extrastriate cortex than in macaque monkeys or other primates. Differences in visual cortical architecture also have been documented among different primate groups including New and Old World simians and between Old World simians and apes and humans (Preuss, 2000).

Why have so few species been accepted as adequate models? Other than issues of practicality, one reason is that many features of the visual system of mammals appear to be shared across a range of species. Hubel and Wiesel, beginning with their seminal work more than 40 years ago, showed that the basic receptive field organization of cells in the LGN and the primary visual cortex (also called *striate cortex*, *area 17*, or *V1*) of cats and macaque monkeys is quite similar (see Hubel and Wiesel, 1998, for review). They demonstrated that LGN cells respond well to spots of light presented to one eye and, like their retinal ganglion cell inputs, demonstrate center-surround receptive fields of two types: ON or OFF center, with surrounds of opposing sign (Wiesel and Hubel, 1966). In V1 of cats and macaque monkeys, they demonstrated that cells tend to be binocular, are selective for the orientation of a bar of light, and exhibit a systematic organization of orientation preference across cortex. These same features have now been demonstrated in a wide range of mammals, suggesting that they represent general features of the mammalian visual system (LeVay and Nelson, 1991). Nevertheless, as we learn more details about

the visual system, more species differences are being uncovered. The important issue is how we interpret both similarities and differences. In this chapter, we argue that species differences as well as similarities can provide important clues, not only about the organization of the human visual system, but also about how the visual system works. A comparative approach is particularly important in translating findings to humans since the possibilities of direct investigations in humans are so limited.

In this chapter, we focus primarily on primate relatives of humans. The chapter is further limited to an analysis of parallel pathways at the early levels of visual processing from the retina through the LGN to V1. The main purpose of the chapter is not to rehash current views on parallel visual pathways in primates but to point out key issues that remain to be resolved, as highlighted by the comparative perspective. Given that the cat visual system has been studied in the most detail, especially at these early levels of visual processing, comparisons with this species are included. Where relevant, other nonprimate species are also mentioned. Some issues have been omitted, and those concern the segregation of ocular inputs and the segregation of pathways concerned with ON-center and OFF-center responses.

This chapter is divided into six sections in addition to this introduction. The first of these sections highlights key findings from different schools that led to today's views of parallel processing within the visual system. The second section outlines how newer findings have altered the two-pathway view of retinogeniculocortical organization in primates. The third section discusses how the different pathways exiting the LGN are organized within the primary visual cortex (V1). The fourth section considers the functional significance of the parallel LGN pathways within V1. The final two sections are devoted to summaries of key points and an outline of the main questions that remain to be resolved.

Separate visual pathways: a little history

Beginning with the prize-winning work of Gasser and Erlanger (1929) on the somatosensory system, it has been recognized that different qualities within a sensory modality can be transmitted via parallel pathways that are

morphologically distinct. In the somatosensory system, it was suggested that different sensations within a single cutaneous nerve (e.g., pain and temperature versus light touch and pressure) might be carried via axons of different caliber and conduction velocity. By analogy, George Bishop (1933) subsequently argued that the three groups of axons that he identified in the optic nerve of the rabbit, based on axon size and conduction latency, were evidence of parallel processing for visual qualities, although he later changed his mind and argued that axon fiber size reflected evolutionary history (Bishop, 1959). Today the idea that separate retinal ganglion cell classes transmit different sensory messages to the brain is accepted as a basic organizational principle. The issues that remain controversial concern the number of pathways that exist, homologies among pathways across species, the exact content of these pathways, and how these pathways relate to different perceptual attributes.

How we think about parallel processing is a product of several distinct approaches to the problem. Outlined below are four lines of investigation that have strongly impacted our views of parallel processing in the visual system. First, in the mid-1960s, Enroth-Cugell and Robson (1966) sparked a revolutionary shift in thinking about visual processing. Approaching the visual system from an engineering standpoint, they proposed that the visual system works as a series of spatial filters, namely, as spatial-frequency analyzers. The idea was that the visual system represents objects by tuning different cells to different ranges of spatial frequency. Enroth-Cugell and Robson (1966) used this linear systems approach to analyze the responses of ganglion cells in the cat retina. This, in turn, was followed by the application to visual psychophysics of Campbell and Robson (1968). This general approach then led to a flood of studies based on the idea that the visual system's response to any pattern could be predicted from its response to more basic components. In their original work, Enroth-Cugell and Robson (1966) subdivided concentrically organized ON- and OFF-center retinal ganglion cells in cats into two types on the basis of their spatial summation properties. Those that summed luminance changes linearly across their receptive fields were called *X cells*, and those that did not were called *Y cells*. In their report, the authors also described other features that distinguished Y from X ganglion cells including the higher conduction velocities, sensitivity to higher speeds and lower contrasts, lower spatial frequency cutoffs, larger average receptive field center sizes, and more transient responses of Y versus X cells (Enroth-Cugell and Robson, 1966). More than a decade of studies on X and Y cells followed these seminal findings. These studies showed that X and Y cells also could be distinguished based on different distributions in the retina, parallel central projections, and morphology (reviewed by Stone, 1983). From this constellation of traits, it was proposed that X cells were part of a channel

to cortex that subserves high-resolution pattern vision, while Y cells were part of a channel that subserves crude form and motion vision (Stone, 1983). Also during this time, other cell types were discovered in the cat retina that were collectively called *W cells*. From the beginning, it was clear that unlike X and Y cells, which show relatively low within-group variability, the response properties of W cells varied widely, having perhaps little more in common than the attribute of low conduction velocity (see Kaplan, 1991; Stone, 1983, for review). Because many W cells were shown to have heavy projections to the midbrain, it was proposed that they subserved a more primitive form of vision referred to as *ambient vision*. X and Y cells, by contrast, provided *focal vision*, or vision that required cortex. *Ambient vision* was seen as an almost unconscious primitive ability to orient to objects and move through the environment found in all vertebrates, while *focal vision* was seen as the conscious vision used to identify objects typical of primates. The analysis of X, Y, and W cells in cats also led later to a similar set of investigations in primates, where both similarities and differences between cats and primates were uncovered (see Casagrande and Norton, 1991, for review). We will return to the issue of species differences in parallel processing in the next section.

The ambient/focal vision idea was actually linked to a second very influential set of investigations that also began in the 1960s. In 1969 Schneider published an important article in which he proposed that there was an anatomical separation between visual coding of the location of a stimulus and its identification. Based on behavioral/lesion work in hamsters, he argued that there were two pathways: a *where* pathway involving the superior colliculus and a *what* pathway involving the visual cortex (Schneider, 1969). The *where* versus *what* or ambient versus focal pathways were subsequently modified and described as independent pathways, one involving a pathway from colliculus to pulvinar to extrastriate cortex and the other involving the geniculostriate pathway (Casagrande et al., 1972; Diamond and Hall, 1969). The idea that these pathways were capable of independent operation was demonstrated clearly in tree shrews, in which complete removal of striate cortex and complete degeneration of the LGN does not impair discrimination of simple patterns or acuity (Ware et al., 1972, 1974). The dual pathway idea more recently has been suggested as an explanation for the *blind sight* exhibited by humans in the absence of visual cortex (Ungerleider and Mishkin, 1982).

In 1982 the idea of two visual systems *where* versus *what*, took a different form. Ungerleider and Mishkin (1982) proposed that visual object identification (*what*) depended on connections to the temporal cortex, while object location (*where*) required the parietal cortex. They also argued that both areas required primary visual cortex (V1) based on their own data from other lesion studies in monkeys, as well as from human clinical studies. The cortical version of the

FIGURE 31.1 LGN projection patterns to visual cortex of cats and macaque monkeys. *Left*: projections from the LGN to V1 in the cat. X and Y LGN cells send axons to layers 4 and 6. W cells project CO blobs in layer 3 and to layers 1 and 5a. *Right*: projections from the LGN to V1 in macaque monkey. M and P cells project, respectively, to layers 4C α and 4C β while K cells project to the CO blobs in layer 3 and to layer 1. In addition, P cells have been proposed to send axons to layer 4A. LGN projections to layer 4A are missing in apes, humans, and some other primates. Some M and a few P cells have collateral branches terminating sparsely in layer 6. See text for details. (*Left*: Data from Boyd and Matsubara, 1996; Humphrey et al., 1985; Kawano, 1998; *Right*: modified from Casagrande and Kaas, 1994, with permission of the publisher.)

what versus *where* hypothesis suggested that if the two visual systems originated subcortically, they must both pass through the LGN.

A third avenue of investigations involved efforts to define pathways based on anatomy. The advent of new technologies for tracing degenerating pathways in the 1950s and 1960s, and for anterograde and retrograde transport of tracers in the 1970s and 1980s, provided details of the connections of parallel pathways from retina to the LGN and from the LGN to the cortex in several species. For example, these studies clearly showed that different retinal ganglion cell classes projected to separate cell classes in the cat LGN and to separate layers of the LGN in all primate species examined (Casagrande and Norton, 1991). In addition, studies showed that the parallel arrangement of connections from the retina continued to V1, where X, Y, and W LGN cells in cats, and parvocellular (P) and magnocellular (M) and subsequently koniocellular (K) LGN cells in primates, were shown to project in parallel to separate layers of V1 (Fig. 31.1; see Casagrande and Kaas, 1994; Sherman and Guillery, 2001, for review).

Finally, in the 1980s, a set of studies was published by Livingstone and Hubel (1988) outlining their hypothesis that different attributes such as form, color, and motion were

segregated within the layers and cytochrome oxidase (CO) blob compartments of V1 (Fig. 31.2). They linked various ideas described above together in a very satisfying model. According to this model, the P retinogeniculocortical pathway (form and color) projects ultimately to the what pathway ending in the temporal lobe and the M retinogeniculocortical pathway (motion) to the where pathway in the parietal lobe. Evidence to support the links between the P pathway and form/color and the M pathway and motion came primarily from physiology and connectional anatomy. Physiological studies had shown that P LGN cells exhibit chromatic opponency and have high spatial resolution, and that M cells are not selective for wavelength but exhibit high temporal resolution (reviewed in DeYoe and Van Essen, 1988; Livingstone and Hubel, 1988). Livingstone and Hubel and others provided evidence that linked the P pathway to the CO blob and interblob compartments in cortical layer 3 with appropriate output pathways to the what hierarchy of extrastriate visual areas, as well as evidence that the M pathway connected to the where hierarchy of visual areas via connections within V1 layer 4B (Fig. 31.2). The K pathway was ignored, in part, because it did not fit well with the model and had not been studied in as much detail (Casagrande, 1994; Hendry and Reid, 2000). Nevertheless, it was already known at that time that the K LGN pathway terminated in patches that appeared to coincide with the CO blobs in V1 in macaque monkeys (Livingstone and Hubel, 1982).

The degree of synthesis provided by Livingstone and Hubel's (1988) view of the visual system had a powerful impact on current thinking about the organization of the human visual system. Because of the simplicity of the model, things that did not fit were set aside as ever more streamlined diagrams of the original appeared in textbooks. Recently, however, as more data have been gathered in a variety of primates and in other species, findings have been presented that raise questions about the model. Examples are provided in the next section.

How many parallel retinal pathways project to and through the primate LGN?

In the parallel processing model of Livingstone and Hubel (1988), P and M pathways are the only pathways considered. Since their model was first published, a number of studies have appeared that have added controversy and complexity to the original proposal. Instead of just 2 major retinal pathways (P and M) to the LGN, as many as 10 morphologically distinct classes of ganglion cells have now been identified that project to the macaque monkey LGN, excluding ON-center and OFF-center cells of the same class (see Dacey, 1999, 2000; Dacey et al., 2001; Rodieck and Watanabe, 1993). Of these, at least five types have also been physiologically classified.

Figure 31.2 Diagram of the functional segregation of the primate visual system. *MT*, middle temporal area; *V4*, visual area 4; *LGN*, lateral geniculate nucleus. (From Livingstone and Hubel, 1988, with permission of the publisher.)

Within the LGN of all primates studied, it is now recognized that P and M LGN cells can be distinguished from K LGN cells based on their neurochemical signatures (Casagrande, 1994; Hendry and Reid, 2000). P and M relay cells contain the calcium binding protein parvalbumin, and K cells contain the calcium binding protein calbindin-D28k. K layers distinguished by the immunomarker calbindin are located primarily (although not exclusively) below all P and M layers. For ease of identification, these small cell layers are numbered from K1 to Kn beginning at the optic tract (Ding and Casagrande, 1997). It is now also established in several simian primates that cells in K3 project principally, although not exclusively, to the CO blobs in cortical layer 3, while those in K1/K2 project mainly to cortical layer 1 (Casagrande et al., 1997; Ding and Casagrande, 1997). It is not entirely clear, however, which LGN cell classes receive input from the 10 ganglion cell classes currently identified as projecting to the LGN from the retina in macaque monkeys. In a number of primate species, midget ganglion cells project to P LGN layers and parasol ganglion cells project to M LGN layers (Dacey, 1999; Rodieck and Watanabe, 1993; Yamada et al., 1998), but the question remains, which LGN cells receive input from the other ganglion cells that project to the LGN?

There is evidence to suggest that the small bistratified ganglion cells, identified as excited by S cone inputs (blue ON),

project to the K3 LGN layer in marmosets (Martin et al., 1997; White et al., 1998) and to layers K3 and K4 in macaque monkeys (Reid et al., 1997). Because K3 axons terminate within the CO blobs, a revision of the Hubel/Livingstone model has been proposed in which the K channel now becomes an S cone color channel (Dobkins, 2000). According to this revised view, S cone signals are sent directly to the CO blobs by means of the K pathway, while L and M cone signals reach the CO blobs indirectly from P channel projections that terminate within 4C β . This still leaves the P pathway performing both as a color and as a high-resolution spatial vision channel. Calkins and Sterling (1999) have gone one step further by proposing that midget ganglion cells that innervate P LGN cells cannot transmit chromatic opponency to the LGN due to the wiring of their surrounds (Dacey, 1996). The surrounds depend on either horizontal or amacrine cell connections; both horizontal and amacrine cells have been found to receive mixed-cone, not single-cone, connections (see Calkins and Sterling, 1999; Dacey, 2000, for review). According to this model, the L and M cone (red and green) channels must project through a nonmidget ganglion cell class: perhaps another type of ganglion cell that sends input to the K pathway. This could mean that all chromatic information reaching V1 travels through the K pathway to the CO blobs (Hendry and Reid, 2000). Other than evidence that the midget to P LGN cell

pathway may not carry pure cone opponent signals, this proposal has appeal if one assumes that true color opponent cells occur in low numbers in the retina and LGN (Calkins and Sterling, 1999). A sparse projection could force cortical terminations to become patchy in order to maintain retinotopic coverage in cortex, thus explaining the presence of CO blobs (Calkins and Sterling, 1999). It is noteworthy in this regard that, even in cats, the only chromatically sensitive retinal ganglion and LGN cells that have been identified are W cells, and these were found to be excited by S cones and inhibited by M cones (Cleland and Levick, 1974). W cells in cats also project to CO blobs (Boyd and Matsubara, 1996).

Appealing as this new proposal is, there are several issues that do not fit. The first concerns the number of K cells required to support both the S and L/M cone channels in macaque monkeys. Counts of K cells immunolabeled with calbindin and α CamII kinase (another marker for K cells in macaque monkeys) have provided evidence that there are too few cells within the foveal and parafoveal representation in macaque LGN to support the acuity of both color channels to cortex (Song et al., 2001). Moreover, in marmosets, only 20% of the total K cell population were found to carry S cone signals; none were found to be L/M cone opponent (White et al., 1998). In the same study, however, two types of P cells were identified: P cells that were L/M opponent and P cells that did not respond selectively to different cone inputs but had good spatial resolution. These same two classes bear a resemblance to the type I and type III P LGN cells identified originally by Wiesel and Hubel (1966). Taken together, these findings suggest that there are two classes of P cells and two classes of K cells but that both P and K channels transmit information related to one color channel, at least in Old World macaque monkeys and New World marmosets. Add to these data new findings indicating that there are two ganglion cell classes in addition to the small bistratified ganglion cells that transmit S cone signals to macaque LGN (Dacey et al., 2001), as well as older data showing that cells responding to S cones as well as to L/M cones have been identified in P layer targets in V1 in macaques and squirrel monkeys (reviewed in LeVay and Nelson, 1991), and the picture becomes even more complex.

Another issue concerns the function of K cells in nocturnal primates that lack S cones such as bush babies and owl monkeys (Jacobs et al., 1996). Both of these primate species have only a single cone type (an M cone), and both have morphologically identified midget and parasol ganglion cells as well as a variety of smaller ganglion cells, although owl monkeys apparently lack small bistratified ganglion cells that carry some of the S cone signals (Yamada et al., 2001). Both bush babies and owl monkeys have well-developed calbindin-positive K layers within the LGN that project to well-defined CO blobs (Casagrande, 1994; Johnson and Casagrande, 1995). Presumably some K cells and some CO

blob cells perform noncolor functions that are defined by inputs from as yet to be classified ganglion cells. Additional evidence for heterogeneity among K cells comes from detailed physiological studies of their spatial and temporal properties in bush babies (Norton et al., 1988), owl monkeys (Xu et al., 2001), and marmosets (White et al., 2001). Given the proposal that diurnal primates arose from a nocturnal common ancestor, it seems likely that the origin of the K pathway and projections to the CO blobs arose originally to support some function or functions other than the processing of chromatic signals, with color processing being added later in evolution (Heesy and Ross, 2001). We consider this issue and the evidence for and against continued functional segregation of LGN parallel pathways within V1 in the next section.

How are parallel LGN pathways organized in V1?

As reviewed above, at least three classes of cells can be distinguished within the LGN based on morphology and physiology in all primates examined, as well as in cats. The basic patterns of geniculate to V1 projections that have been documented in primates and cats suggest that X/P medium-sized LGN cells send axons principally to the lower half of cortical layer 4, Y/M large LGN cells send axons principally to the upper half of cortical layer 4, and K/W small LGN cells send axons mainly to layers above 4 (Fig. 31.1). This pattern of projections appears to represent a basic mammalian plan since it has been identified (with some variation) in several other species (Casagrande and Kaas, 1994). Given the ever-increasing number of classes of retinal ganglion cells that project to the macaque LGN, as well as the many types that have been found previously to project to the LGN of cats (discussed in Isayama et al., 2000), it seems reasonable to suggest that more than three ganglion cell classes is the rule, not the exception. Unfortunately, markers such as the calcium binding proteins parvalbumin and calbindin, even combined with cell size, are not sufficient to distinguish the targets of all of these ganglion cells within the LGN of any species, assuming that the pathways remain separate at this level. Clues about how many pathways are maintained in parallel to and through the LGN to cortex can be gained by examining detailed termination patterns of these axons in primate V1 and connections within V1 itself. Several examples follow.

Within primate V1, there is evidence that projections within and among layers and compartments are more precise and complex than was originally believed. For example, in both macaque monkeys and owl monkeys there is evidence that the main recipient layer, Brodmann's (1909) layer 4C, consists of three, not two, tiers. Morphologically, this tripartite organization was originally noted in Nissl-stained sections in macaque monkeys (Lund, 1988). In owl

Figure 31.3 Projections from layer 4C to the supragranular layers in V1 of owl monkey. Layer 4C α projects principally to layer 4B, 4C β to 4A, and 4Cctr to 3B. Layer 3A, the major output layer to area V2, receives signals from layer 4 only indirectly via other subdivisions of layer 3 and layer 5. See text for details. (From Boyd et al., 2000, with permission of the publisher.)

monkeys, in vivo studies tracing connections based on small laminar injections revealed that the three tiers of layer 4C projected to different targets within the upper cortical layers (Boyd et al., 2000). As shown in Figure 31.3, cells in 4C β project to 4A, cells in 4Cctr project to 3B, and cells in 4C α project to 4B (Boyd et al., 2000). Intracellular filling of cells in slice preparations within layer 4C in macaque monkeys has identified similar sets of projections (Yabuta and Callaway, 1998). There is also evidence from axon reconstructions in macaque monkeys (Blasdel and Lund, 1983) and in bush babies (Florence and Casagrande, 1987) that axon arbors of some P and some M LGN cells extend through layer 4Cctr, while others are restricted to the top and bottom tiers. Add to these anatomical data the physiological evidence given above that there may be two P LGN cell classes, one color opponent and the other not, as well as evidence suggesting that there are two M LGN cell classes based on linearity of spatial summation in macaque monkeys (Kaplan and Shapley, 1982), and we now have four LGN cell classes projecting to layer 4C of V1.

Examination of LGN projections and connections to cortical layers above layer 4C adds to the complexity. Layer 4A has been proposed to receive input from P cells in macaque and squirrel monkeys (Lund, 1988), yet recent data suggest that cells in this layer in macaque monkeys are excited by S cone stimulation (blue ON), indicating that these cells also could receive input from a class of LGN K cells (Wandell et al., 2002). It is noteworthy that apes (e.g., chimpanzees) lack LGN input to layer 4A (Tigges and Tigges, 1979) and that humans probably also lack such input based on CO stain-

ing (Horton and Hedley-Whyte, 1984; Wong-Riley et al., 1993), even though 4A has been described cytoarchitecturally in humans (Yoshioka and Hendry, 1995). If this is true, it suggests that humans and apes lack this particular blue ON channel since they appear not to have LGN projections to cortical layer 4A, projections that are also lacking in the nocturnal primates owl monkeys and bush babies (Casagrande and Kaas, 1994). Why humans and apes that clearly have S cones would not also have a projection to layer 4A remains a mystery, although the recent discovery of a second class of blue ON ganglion cells in macaques suggests that S cones may not be restricted to a single channel (Dacey et al., 2001). Nevertheless, the fact that layer 4A is morphologically distinct and has unique intracortical projections, even in primates that lack direct LGN input to this layer, would indicate that layer 4A performs a specialized role in most primates.

Cortical layers above 4A receive projections from at least two classes of K axons, those that project primarily to the CO blobs within layer 3B and those that project primarily to cortical layer 1 from the ventral most K layers, LGN layers K1/2 (Ding and Casagrande, 1997). The latter pattern has been demonstrated in both nocturnal (owl monkeys) and diurnal (macaque and squirrel monkeys) Old and New World primates, so it appears to remain independent of lifestyle or phylogenetic history (Casagrande, 1994; Hendry and Reid, 2000). In prosimian bush babies, K layer connections also have been demonstrated to project to the CO blobs and layer 1 (Lachica and Casagrande, 1992). In bush babies, however, no investigations have been done of the more ventral K layers to see if these send axons primarily to layer 1. Given the heterogeneity of the axon projection patterns of K cells even in macaque monkeys (Fig. 31.4A) and the physiologically demonstrated heterogeneity of K cells in the LGN level in several primate species (see above and Fig. 31.4B,C), it seems likely that more than two K axon classes project above cortical layer 4A.

Combining the above data, the following picture of parallel input pathways emerges (Fig. 31.5A). Four classes of LGN axons project to cortical layer 4C, two P and two M classes. Layer 4A receives input from either K or P axons or both, but only in a subset of nonhominid primates. LGN axonal projections above layer 4A come from two or more classes of K axons. Interestingly, in other species such as cats, there also is evidence that X, Y, and especially W cells contain subgroups. Lagged and nonlagged X and Y cells have been described (Saul and Humphrey, 1990). Evidence also suggests that the Y cells within the C lamina and/or the medial interlaminar nucleus (MIN) in cats are not functionally equivalent to those in the A laminae (Boyd et al., 1998). W cells within the parvocellular C laminae of cats have been subdivided into at least two classes, W1/Q and W2, or tonic and phasic cell classes, as well as other types (Rowe and Cox,

Figure 31.4 Morphological and physiological heterogeneity of K cells. *A*, In macaque monkeys, the geniculocortical projections from different K layers are morphologically distinct; axons from LGN layers K1/K2 mainly project to cortical layer 1, while axons from LGN layers K3/K4 chiefly terminate in cortical layer 3. *B*, Responses of different K cells to a short-wavelength-sensitive (SWS) isolating stimulus and luminance stimulus (LUM). About 20% of K cells in the marmoset LGN are blue ON cells (shown in *B* on the *left*) and respond to the SWS stimulus; 80% of K cells

[also called *interlaminar zone* (ILZ) cells] show no response to the SWS stimulus (shown in *B* on the *right*). *C*, Spatial and temporal characteristics of owl monkey K cells in different LGN layers exhibited differences. Cells in K1/K2 tend to be selective for lower spatial frequencies and higher temporal frequencies than cells in layer K3. (*A* from Casagrande et al., 1997; *B* modified from White et al., 1998, with permission of the publisher; *C* modified from Xu et al., 2001, with permission of the publisher.)

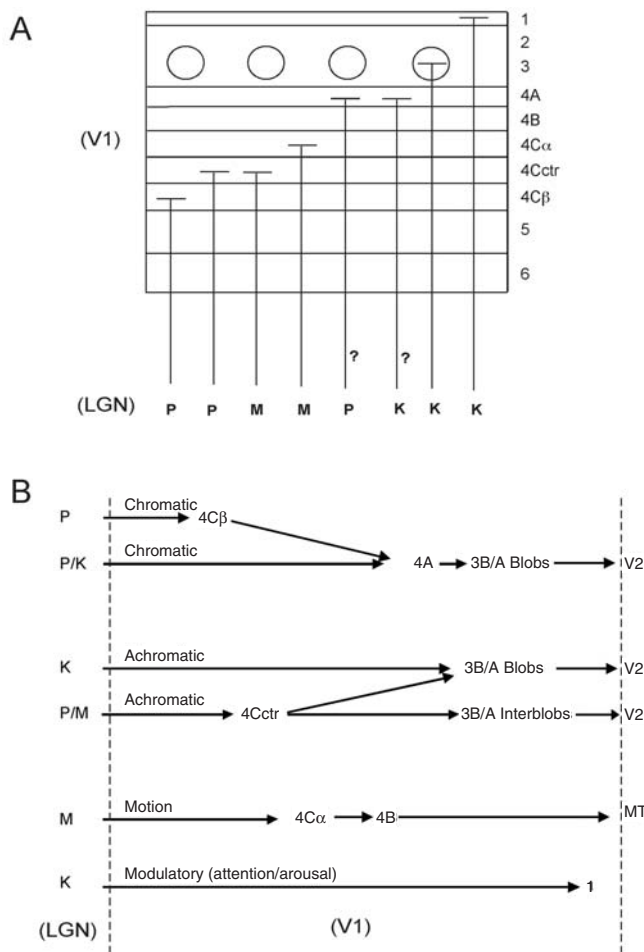

Figure 31.5 Parallel pathways from the LGN to V1 in macaque monkey. *A*, Eight parallel pathways are shown from the LGN to the cortical layers of V1 in macaque monkey: three P channels, three K channels, and two M channels. The circles within layer 3 represent the CO blobs. It is unclear whether K, P, or both pathways project to layer 4A. It is noteworthy that LGN projections to layer 4A represent a specialization of some simians only; chimpanzees, humans, owl monkeys, and bush babies lack this pathway. The layers of cortex are indicated by Arabic numerals. *B*, Connections and possible functions of the eight parallel pathways within V1. In this diagram the ventral to dorsal sequence of layers in V1 is laid out from left to right. V1 projects directly to different compartments within V2 and to area MT. Not shown: V1 also sends axons to DM/V3a which exit from CO blob columns, to area V3, and to area V4. See text for details.

1993; Sur and Sherman, 1982; Troy et al., 1995). All of these data argue against a simple two-channel model for parallel pathways to and through the LGN.

Functional implications of multiple LGN channels to V1

WHY HAVE TWO M CHANNELS? If primates have multiple M, P, and K channels to V1, what are the functional implications of such a model? First, beginning with the M LGN

cells, Blasdel and Lund (1983) found two classes of M axons terminating in layer 4C α in macaque monkeys. The majority of axons arborized throughout layer 4C α , with minor or no collateral input to layer 6, while the arborizations of the others were restricted to the upper half of layer 4C α , with extensive collaterals in layer 6. Later, it was theorized that differences in receptive field sizes and contrast sensitivities in these two populations could account for changes in these properties with depth in layer 4C (Bauer et al., 1999; Lund et al., 1995). Cells at the top of 4C α have larger receptive fields and higher contrast sensitivity than cells deeper within 4C α . In addition, like cells in 4B, many cells at the top of 4C α are orientation and direction selective. This arrangement suggests that the M LGN cells projecting to 4C α are part of a channel allowing for rapid transmission of information important to stimulus motion directly to dorsal stream areas like the middle temporal (MT) visual area via cortical layer 4B or possibly even via synapses on dendrites of large 4B pyramidal cells that dip into 4C α (Fig. 31.5*B*). In cats, the class of Y cells that projects beyond area 17 may play a similar role, providing rapid transmission of motion information to higher areas. One could speculate that in the latter case the transmission is even more direct and unfiltered simply because the lifestyle of cats requires a very rapid reaction to motion.

Why then would one need two M channels? In the most basic sense, P and M populations of LGN cells represent two ends of a continuum in the spatial and temporal frequency domains (Schiller et al., 1990). Either channel alone allows for a much more limited sampling of spatial and temporal frequencies, a limitation imposed at the retina simply because ganglion cells cannot have both small and large dendritic fields simultaneously. The second M channel terminating within layer 4C β could, along with an achromatic P channel, provide the full range of basic spatial and temporal information to cells in the ventral stream concerned with object identification through connections with cortical layer 3 cells.

WHY HAVE TWO P CHANNELS? Dacey (2000) has proposed that the unique midget cell architecture of the fovea evolved first to permit high spatial resolution, which demands cones, and only recently evolved to carry color opponent L/M channels in Old World primates. If one P channel is transmitting information about spatial detail, the other is presumably a color channel. P input in 4C β , with its heavy projections to layer 4A, could represent such a chromatic channel, at least in those primate species that have color vision (Fig. 31.5*B*). Color-selective nonoriented cells have been reported in layers 4C β and 4A, at least in macaque monkeys (see LeVay and Nelson, 1991, for review). As mentioned earlier, it is unclear whether layer 4A also receives input from a subset of K cells, from P cells, or from

both cell classes. Interestingly, physiological studies have noted two populations of cells within layer 4A (Blasdel and Fitzpatrick, 1984). Perhaps both P and K LGN cells project to 4A. Unfortunately, older studies claiming that P LGN cells project to layer 4A were based on tracer injections that included the K layers lying below each P layer (Lund, 1988).

WHY SEGREGATE K AXONS TO THE CO BLOBS? The only documented direct input (based on axon reconstruction) to the cortical layers dorsal to layer 4A are K axons in primates. These K axons are restricted to CO blobs within layer 3B, leaving the interblob columns in layer 3 free of any direct LGN input; K axons also appear to project to all of layer 1 (Casagrande et al., 1997; Ding and Casagrande, 1997; Lachica and Casagrande, 1992). This arrangement certainly suggests that CO blobs and interblobs within layer 3 perform different functions. Also, the fact that CO blobs can be distinguished neurochemically in several other ways from interblobs (Wiencken and Casagrande, 2000) argues that these two compartments do different things. The original proposal from Livingstone and Hubel (1988) was that the CO blobs send signals to extrastriate areas that are relevant to color, while the interblobs are concerned with putting together signals to support form vision. Although this scenario would fit data from diurnal monkeys, it does not fit data from nocturnal primates that appear to have the same direct K LGN projections to CO blobs and the same basic arrangement of intracortical connections in V1 (Casagrande and Kaas, 1994). Interestingly, one difference was found between diurnal and nocturnal simians in the microcircuitry of the CO blobs (Shostak et al., 2002). The subset of K axons that synapse on dendritic shafts in diurnal macaque and squirrel monkeys synapse on significantly larger shafts than in the nocturnal owl monkey. Shostak et al. (2002) have argued that it is possible that the latter shift represents a loss of K axons that carry S cone signals in owl monkeys. Since the majority of K LGN cells probably do not carry color signals anyway (see above) and cannot carry these signals in nocturnal species, we are still left with the question of why the CO blobs exist. Clearly, CO blobs are not necessary for good color vision since many species, such as tree shrews and ground squirrels, have excellent color vision but no CO blobs (Jacobs, 1993; Wong-Riley and Norton, 1988). CO blobs, however, appear to be a universal feature of primate V1. What primates do, more than other species, is to use vision to analyze objects that they manipulate. Cortical layer 3, which sends information into the ventral stream, is particularly well developed in primates. One possibility is that the special demands of high-level object vision require that stimulus attributes be combined in several different ways to support the variety of analyses performed by the ventral stream hierarchy of areas. The compartments within the

CO blobs and interblobs that extend throughout layers 2 and 3 may provide the substrate of the variety of combinations necessary. Further support for this scenario comes from the fact that so many distinct extrastriate visual areas receive input directly from cells located within cortical layer 3, including different compartments within area V2 and areas V3 and V3a and its presumed homolog, the dorsal medial area (DM) (Beck and Kaas, 1999).

An interesting proposal by Allman and Zucker (1990) on the function of CO blobs suggested that cells in CO blobs are designed to analyze scalar variables related to the intensity of the stimulus such as brightness, color contrast, and texture, while interblobs are designed for analysis of geometrical variables such as orientation preference and possibly more complex binocular interactions. From a phylogenetic perspective, this proposal still has considerable appeal since this segregation of function could have evolved first in the absence of color vision, with color contrast added later. CO-blob cells are in a position to integrate the full range of information from different K axons directly and P and M axons indirectly. In this respect it is noteworthy that in cats Cleland and Levick (1974) recorded from an S cone-driven W cell that appeared to substitute rod input for S cone input under scotopic conditions. There have also been other reports in primates that LGN cells carrying S cone signals exhibit rod input under dark-adapted conditions (Virsu et al., 1987). M cells also carry rod signals (Virsu et al., 1987) and tend to have a larger input to CO blobs than to interblobs. Taken together, all of these inputs could provide CO-blob cells with the ability to maintain constancy over a very broad range of stimulus intensities and wavelengths under both scotopic and photopic conditions. From this perspective, it would be interesting to know whether there are any differences in the responses of CO-blob and interblob cells under photopic versus scotopic conditions, as would be predicted by such a model.

WHY SEND LGN SIGNALS TO CORTICAL LAYER 1? As reviewed earlier (Casagrande, 1994), the K axons that project to cortical layer 1 are in a position to modulate activity within many pyramidal cells throughout the depth of V1 since the apical dendrites of some cells in almost all layers extend into cortical layer 1 (Lund, 1988). The K axons that have a branch in cortical layer 1 have been described following injections involving almost all of the K layers (Fig. 31.44; also see Ding and Casagrande, 1997), but the bulk of these projections appear to come from K layers 1 and 2. Jones (1998) has stated that there is a correlation between calcium binding protein content in thalamic relay cells and projection patterns to cortex, with the calbindin-positive cells having projections above layer 4 and being part of a more diffuse system serving a role in recruitment of more widespread areas of cortex, in contrast to the parvalbumin-

containing cells, which are dedicated to sensory transmission. In the K pathway, this scenario would hold only for cells projecting to layer 1 since other K cells clearly project to very limited areas of cortex. Regardless, this hypothesis is of interest given the long history of proposals implicating cortical layer 1 in attention, arousal, and other forms of modulation (Vogt, 1991). Interestingly, both K LGN cells and cells in the adjacent inferior pulvinar are immunoreactive for calbindin, receive input from the superficial colliculus (also implicated in attention), and send axons to cortical layer 1 of V1 (Ogren and Hendrickson, 1977). Evidence for the pulvinar's involvement in attention has a long history (Robinson and Petersen, 1992).

DO DIFFERENCES IN VISUAL LATENCIES OFFER FUNCTIONAL CLUES? One issue that has not been considered is that of differences in visual latencies between pathways and the impact this may have on the responses of cortical neuron targets. Clear differences in the visual onset latencies of K, M, and P cells have been demonstrated at the level of the LGN (e.g., Irvin et al., 1986). As discussed by Maunsell et al. (1999), it is difficult to predict the cortical impact of these differences because stimulus attributes, stimulus intensity, and degree of convergence of inputs on the postsynaptic cell all affect response latency. It is still possible, however, that V1 takes advantage of these timing differences to increase the probability that cells reach threshold. For example, one could imagine that within the CO-blob cells might receive signals from the slower K axons that have direct projections at the same time as signals from the faster M and P pathways that must traverse several synapses. Due to greater convergence from larger numbers (Maunsell et al., 1999), signals from P cells would arrive at about the same time as those from M cells. From this perspective, it would be of interest to know how removal of one of these pathways affects the thresholds of cells within the output layers of V1. The timing differences may also be important in combining signals from the feedforward parallel pathways and the multiple pathways that feed back to V1.

Conclusions

Parallel pathways from the retina via the LGN to V1 presumably act to maintain the integrity of signals that can only be combined at later stages of processing. Since V1 is concerned with local feature analysis, the layer and compartmental geometry of V1 provides a substrate for such independent processing and for the creation of different combinations of output pathways. The evidence reviewed above suggests that there may be as many as 10 pathways that pass through the LGN that could impact V1 processing in different ways; good evidence for at least 8 now exists. The puzzling question is why there are so many. In some cases,

evolutionary history may offer a possible explanation. Cones would be expected to provide input to any system designed for high-resolution vision, like midget ganglion cells. The addition of another cone type would simply provide a potential substrate for transmission of color signals along the same pathway. It is less easy to explain why K cells might carry S cone signals, except that this appears to happen earlier in evolutionary history if one considers that W cells also carry these signals. The coevolution of M and P cells or X and Y cells (and perhaps other subtypes as well) also may be, as mentioned earlier, the result of incompatibility (e.g., sensitivity often is incompatible with spatial resolution). The variety of conventional and unconventional responses of different K cell populations to visual stimulation suggests that LGN channels may do more than perform a simple analysis of spatial and temporal frequencies. The challenge for the future is to understand how V1 cells use the different views of the visual world that each of the parallel pathways provide. This can only be done by taking into account the dynamic aspects of the system by sampling from multiple cells at different levels within the system while the system is exposed to a variety of visual stimuli.

Unanswered questions

- How many pathways project from the retina to and through the LGN? How many of these pathways generalize across primates or across other mammals like the cat?
- If 10 ganglion cell classes project to the LGN in macaque monkeys, are there 10 separate target cell classes in the LGN? If so, what criteria can be used to distinguish them?
- To what extent do different LGN cell classes carry redundant information to V1?
- What is the functional significance of different calcium binding proteins within the different layers of the LGN?
- Why are there so many types of K cells?
- Why do K and W cells get input from the superior colliculus?
- Do LGN K cells and P cells both carry chromatic signals in diurnal primates?
- Why are LGN projections to layer 4A seen in only some primates?
- Why are S cones missing in nocturnal primates?
- Do CO-blob cells function differently in diurnal and nocturnal primates or in cats?
- Why do K cells in primates and W cells in cats send axons to the CO blobs and not to the interblobs?
- V1 projects to three compartments in V2 and also to compartments in V3, V3a/DM, MT, and V4. Do all of these projections arise from separate groups of cells in V1?
- How many extrastriate target areas of V1 are homologous across primates?

Acknowledgments

We are especially grateful to Julia Mavity-Hudson for help with figures and proofing the manuscript, to Shirin Pulous for secretarial help, and to Jennifer Ichida for helpful comments. This research was supported by NIH grant EY01778 (VAC) and core grants EY08126 and HD15052.

32 Organization of Visual Areas in Macaque and Human Cerebral Cortex

DAVID C. VAN ESSEN

THE MAMMALIAN visual system contains numerous visual areas that collectively occupy a large fraction of cerebral cortex. For cortical cartographers interested in vision, a fundamental set of objectives is to identify in key species of interest the overall extent of visual cortex, the total number of visual areas, the identities of these areas, and their location in relation to one another and to various gyral and sulcal landmarks. Over the past three decades there has been much progress in this endeavor for a number of primate and nonprimate species. However, the task remains far from complete. Numerous qualitatively different partitioning schemes abound, even for the most intensively studied species. Our fragmentary and rapidly evolving understanding is reminiscent of the situation faced by cartographers of the Earth's surface many centuries ago, when maps were replete with uncertainties and divergent portrayals of most of the planet's surface.

The primary objective of this chapter is to summarize our current understanding of visual cortical organization in two primate species, the macaque monkey and the human. The macaque is the most intensively studied nonhuman primate and has been charted using a wide variety of approaches. Human visual cortex, largely terra incognita until the past decade, is now accessible thanks to modern neuroimaging methods, especially functional magnetic resonance imaging (fMRI; see Chapter 79). A secondary objective, more methodological in nature, is to illustrate the utility of computerized surface-based atlases in elucidating visual cortical organization. In brief, surface-based atlases offer many advantages over conventional atlases (e.g., stereotactic atlases and pictorial representations). These include the ability to (1) visualize the cortical surface in multiple configurations, including smoothed and flattened maps, (2) view any number of partitioning schemes and open-ended amounts of complex data in a convenient and electronically accessible format; (3) represent various types of spatial uncertainty that are associated with real experimental data; (4) compensate for individual variability, and (5) make objective interspecies comparisons of cortical organization.

Visual areas in the macaque monkey

Figure 32.1 shows the estimated extent of visual cortex

in the macaque and its relationship to other sensory modalities and to motor cortex. This is displayed on a surface-based atlas of the right cerebral hemisphere that was generated from a high-resolution structural MRI volume (Van Essen et al., 2002; Van Essen, 2002; see legend to Fig. 32.1 for details). The top panels show lateral and medial views, respectively, of the fiducial (three-dimensional) configuration; the lower left panel (Fig. 32.1C) is a flat map that shows the entire surface in a single view.

The dotted lines on the flat map represent the estimated boundary between regions dominated by different modalities, based on the analysis of Felleman and Van Essen (1991). These boundaries are not sharply defined, as there is considerable intermixing of function in transitional regions between modalities. The blending of colors on the maps in Figure 32.1 qualitatively reflects this functional overlap. Cortex that is predominantly or exclusively visual (blue shading) occupies about half (52%) of the cortical surface area (as measured on the fiducial surface rather than on the flat map, which contains significant distortions). This greatly exceeds the amount devoted to other modalities: somatosensory (green, 10%), auditory (red, 3%), motor (magenta, 8%), and olfactory (brown, 1%). Unassigned cortex (gray, 25%) is mostly cognitive or emotional in function but is not subdivided along these lines in the figure.

Figure 32.1 also shows latitude and longitude isocontours that are determined on a spherical map (*Panel D*) and projected to the flat map (*Panel E*). As with earth maps, spherical coordinates provide a concise and objective way to specify precise locations on the map (Drury et al., 1999; Fischl et al., 1999a, 1999b; Van Essen et al., 2001a).

The identification of distinct visual areas is generally based on finding reliable differences in one or more characteristics related to (1) architecture, (2) connectivity, (3) visual topography, and/or (4) functional characteristics (Felleman and Van Essen, 1991; Kaas, 1997). Using various combinations of these criteria, numerous partitioning schemes for visual cortex in the macaque monkey have been published over the past century. Figure 32.2 shows 10 such schemes

FIGURE 32.1. Visual cortex and other functional modalities mapped onto a surface-based atlas of macaque cerebral cortex. The atlas was generated from a high-resolution (0.5 mm^3 voxels) structural MRI volume generously provided by N. Logothetis (Case F99UA1, *M. mulatta*), using the SureFit segmentation method for surface reconstruction and Caret software for surface manipulation and flattening (Van Essen et al., 2001a). This atlas has many advantages over its predecessors, which include manually generated maps (Felleman and Van Essen, 1991; Van Essen and Maunsell, 1980) and surface-based atlases from a hemisphere that lacked corre-

sponding structural MRI data (Van Essen et al., 2001a). *A*, Lateral view. *B*, Medial view. *C*, Flat map. Surface coloring represents different functional modalities, as identified on the flat map; darker shading represents cortex buried in sulci. *D*, Lateral view of the atlas spherical map, with latitude and longitude isocontours. By convention, the lateral pole is set at the ventral tip of the central sulcus. *E*, Latitude and longitude isocontours displayed on the flat map. Data for Figures 32.1 to 32.3 can be accessed via http://brainmap.wustl.edu:8081/sums/archivelist.do?archive_id=448857 (see color plate 11).

that were mapped to the atlas using a surface-based registration method (Van Essen et al., 1998, 2001b; see legend to Fig. 32.2 for details). *Panels A–C* illustrate three schemes that encompass most or all of the visual cortex. The Felleman and Van Essen (1991) and Ungerleider and Desimone (1986) schemes are based on anatomical and physiological data from many sources. The Lewis and Van Essen (2000a) scheme is based on an architectonic analysis of multiple hemispheres, with the atlas map generated via surface-based registration of a particular individual map. *Panel D* shows several schemes that cover more restricted regions, including a connectivity-based analysis of occipital cortex (Lyon

and Kaas, 2002) and architectonic analyses of temporal and parietal cortex (Seltzer and Pandya, 1978, 1980, 1986). *Panel E* shows two additional architectonic schemes covering temporal (Baylis et al., 1987) and parietal (Preuss and Goldman-Rakic, 1991) regions, plus a visuotopic mapping analysis of dorsal occipital cortex (Galletti et al., 1999). While far from an exhaustive compilation, Figure 32.2 includes most of the partitioning schemes in current use that have been reported in a format suitable for registration to the atlas.

Although there are many similarities, these partitioning schemes differ in many ways for reasons that reflect various

technical impediments faced by cortical cartographers. (1) *Subtle boundaries*. The distinctions between neighboring regions are often subtle, even when evaluated with the most sensitive anatomical and physiological techniques available. (2) *Internal heterogeneity*. Many (perhaps most) visual areas are internally heterogeneous. This heterogeneity may be manifested by *modularity* (repetitive organization at a finer scale than the overall areal dimensions); *asymmetries* (differences between the representations of the upper [superior] and lower [inferior] visual fields); or internal *gradients* (gradual shifts in characteristics rather than discrete modularity). (3) *Individual variability*. The overall size of well-defined visual areas such as V1 and MT can vary twofold or more from one individual to the next (Maunsell and Van Essen, 1987; Van Essen et al., 1984). This is compounded by substantial variability in the exact pattern of convolutions and in the location of areal boundaries relative to gyral and sulcal landmarks.

A compelling case for areal identification entails finding region-specific characteristics that are robust, consistent across multiple approaches, and replicated by multiple laboratories. The diversity among partitioning schemes signifies that a consensus has been achieved for only a minority of the visual areas illustrated in Figure 32.2. Several well-defined areas (V1, V2, V4, and MT) are shown by different colors in Figure 32.2; others are included as part of a regional coloring pattern that includes six clusters discussed below.

The differences among partitioning schemes can be categorized along four lines. (1) *Terminological equivalence*. Some differences are essentially terminological in that different labels are assigned to what is fundamentally the same visual area. For example, area 17 is equivalent to area V1; MT (Fig. 32.2A–C) is equivalent to V5 (Shipp and Zeki, 1985); and PO (Fig. 32.2A–C) is equivalent to V6 (Fig. 32.2F). (2) *Lumping versus splitting*. Some regions are considered a single area by some investigators (the lumpers) but as two separate areas by other investigators (the splitters). This is an issue, for example, for subdivisions V3d/V3v, V4d/V4v, and LIPd/LIPv. In some cases, it can be helpful to use the term *zone* to describe a consistently identifiable region whose status as a distinct area is uncertain, ambiguous, or contentious (Lewis and Van Essen, 2000a). The term *subdivision* can then encompass both zones and well-defined cortical areas. (3) *Boundary uncertainty*. Even when there is a consensus on the identity of an area and the main criteria for its identification, the location and extent of any particular area on the atlas map vary substantially across schemes (cf. V2 and MT in Fig. 32.2A–D). These differences may reflect (a) the choice of criteria or emphasis among different criteria available for delineating boundaries; (b) variability in the size and location of areas in the individuals studied; (c) inaccuracies in portraying areal boundaries on a

summary diagram in the original publication; and (d) inaccuracies or distortions arising when registering data to the atlas. (4) *Genuine incompatibility*. In some regions, partitioning schemes differ more profoundly than can be explained by the factors just mentioned. For example, in inferotemporal cortex (blue) there is rather little correlation between the areal boundaries in *panel A* versus *panel E*; hence the schemes are largely incompatible.

OCCIPITAL VISUAL AREAS V1 and V2 are both large, well-defined areas, with V1 occupying 13% and V2 occupying 10% of the total cortical surface area (12.6 cm²) in the right hemisphere of the atlas. V1 and V2 have a mirror-symmetric visuotopic organization, with the vertical meridian represented along their common boundary, and with upper fields represented ventrally and lower fields dorsally in each area. In addition, both areas have prominent internal modularity related to the processing streams that course through these areas (Felleman and Van Essen, 1991; Van Essen and Gallant, 1994; Chapter 34). Interestingly, there are significant asymmetries between dorsal V2 (V2d) and ventral V2 (V2v): V2v is notably wider than V2d (Fig. 32.2A–D), and the two subregions differ in the global pattern of thick stripes, thin stripes, and interstripes (Olavarria and Van Essen, 1997).

Area V3 was originally identified as a strip of cortex that adjoins V2 and has mirror-symmetric visuotopic organization (Zeki, 1969). Subsequent studies confirmed this visuotopic organization but revealed that the dorsal and ventral subdivisions are physically separated from one another by the interposition of area V4 (cf. Fig. 32.2A–C). More significantly, evidence for pronounced dorsoventral asymmetries in connectivity (especially with V1), myeloarchitecture, and physiological properties prompted the classification of these dorsal and ventral subdivisions as distinct visual areas: VP (or V3v) and V3 (or V3d), each containing a partial representation of the visual field (cf. Burkhalter et al., 1986). In contrast, Lyon and Kaas (2002) reported relatively symmetric projections of V1 using more sensitive tracers, and they support Zeki's original proposal that V3d and V3v are subdivisions of a single area V3. A sensible interim strategy is to designate these subdivisions as zones V3d and V3v while awaiting additional data on the overall magnitude and nature of V3d/V3v asymmetries, along with insights regarding the asymmetries encountered in other regions and other species (see below). Independent of this terminological debate, it is noteworthy that V3d and V3v vary considerably in location and size among the various maps shown in Figure 32.2.

V4 is a moderately sized area whose lower-field (V4d) and upper-field (V4v) representations are contiguous with one another, in contrast to the physical separation of V3d and V3v. The visuotopic organization of dorsal V4 appears

to be more complex and variable across individuals than that of ventral V4 (Boussaud et al., 1991; Gattass et al., 1988; Maguire and Baizer, 1984; Van Essen et al., 1990). Because analogous but more pronounced dorsoventral asymmetries have been reported for the corresponding region of human cortex (see below), Tootell and Hadjikhani (2001) have suggested that macaque V4d and V4v might themselves constitute distinct visual areas.

Five additional areas adjoin or closely approach V2 along its dorsomedial and ventromedial boundaries. The dorsomedial cluster (magenta in Fig. 32.2) includes areas V3A, PIP, and PO, each of which includes an upper-field as well as a lower-field representation (Colby et al., 1988; Felleman and Van Essen, 1991; Lyon and Kaas, 2002). Area PO, as charted by Colby et al. (1988), corresponds to area V6 of Galletti et al. (1999). The ventromedial cluster (brown in Fig. 32.2) includes areas TF and TH (near the bottom of the flat map), both of which receive visual inputs (see Felleman and Van Essen, 1991). The posterior portion of TF, identified as VTF by Boussaud et al. (1991), is visually responsive but has at best a crude visuotopic organization.

DORSAL TEMPORAL AND POSTERIOR PARIETAL CORTEX The *dorsal stream* of visual areas (Chapter 34) includes cortex in and near the intraparietal sulcus, plus the dorsal part of the superior temporal sulcus. Area MT, the most extensively studied area in the dorsal stream, contains a complete visuotopic map, but with a bias toward lower versus upper visual fields (Maunsell and Van Essen, 1987). Though MT is well defined by several criteria (including a high incidence of direction-selective cells), its precise location and extent on different summary maps vary significantly (cf. Fig. 32.2A–D; see also Desimone and Ungerleider, 1986). Adjoining MT on its lateral side is a narrow strip that has been identified

as V4t (Felleman and Van Essen, 1991; Ungerleider and Desimone, 1986) or MTc (Lyon and Kaas, 2002). Within V4t, architectonically distinct zones V4ta and V4tp have been described (Lewis and Van Essen, 2000a).

A major target of MT is the MST complex (orange in Fig. 32.2), which lies dorsal and medial to MT and is implicated in higher-order motion analysis. MST is heterogeneous both anatomically and physiologically, but it remains unclear whether there are two subdivisions (MSTd and MSTl of Komatsu and Wurtz, 1988a, 1988b, and Felleman and Van Essen, 1991; MSTc and MSTp of Boussaud et al., 1990) or three (MSTdp, MSTm, and MSTl of Lewis and Van Essen, 2000a) and whether these constitute distinct areas or zones within a larger MST complex. Area FST lies ventral to the MST complex and medial to MT, but its position differs markedly in different partitioning schemes (Fig. 32.2A versus 32.2B, C).

Posterior parietal visual cortex (yellow in Fig. 32.2) includes several elongated areas in and near the intraparietal sulcus, plus additional areas in more posterior regions that are represented in some schemes. The most fine-grained scheme (Lewis and Van Essen, 2000a; Fig. 32.2C) is based on immunohistochemical as well as cyto- and myeloarchitecture and includes seven distinct areas (7a, LIPd, LIPv, VIP, MIP, MDP, and DP) plus additional architectonic zones. In the region previously described as area LIP (Blatt et al., 1990), subdivisions LIPd and LIPv differ from one another in architecture, connectivity, and physiological characteristics and are thus likely to constitute separate visual areas (cf. Lewis and Van Essen, 2000a, 2000b). Area VIP, along the fundus of the intraparietal sulcus, contains lateral (VIPl) and medial (VIPm) architectonic zones, but these are not considered distinct areas on the basis of current evidence (Lewis and Van Essen, 2000a, 2000b). Areas LIPd, LIPv, and VIP

FIGURE 32.2. Ten partitioning schemes for macaque visual cortex registered to the atlas and displayed on flat map views. See the abbreviations list for full names of areas. Data were registered to the atlas using a surface-based registration method in which geographic (gyral and sulcal) landmarks were used to constrain the registration (Van Essen et al., 2001b). Depending on the data source, this method was applied to computerized maps (spherical or flat maps) and to scanned images of manually generated flat maps or drawings of the hemispheric surface and of schematically opened sulci. Thus, there are substantial differences in the fidelity of the published representations and in the distortions and uncertainties involved in registering to the atlas, but visualization on a common substrate nonetheless remains advantageous. *A*, Felleman and Van Essen (1991) partitioning scheme for visual areas. Areal boundaries were originally charted on a physical model of an individual hemisphere (case 79O). They were transferred to a computerized surface reconstruction of the same hemisphere and then were registered to the Case F99UA1 atlas using spherical maps of each hemisphere. *B*, Ungerleider and Desimone (1986) scheme (their Figure 1; see

also Figure 2 of Desimone and Ungerleider, 1989). Registration was achieved using geographic landmarks on a manually generated flat map. *C*, Lewis and Van Essen (2000a) scheme from Case 95DR (their Figure 14) registered from the computerized flat maps. *D*, A composite map of partitioning schemes for occipital cortex (Lyon and Kaas, 2002, their Figure 4), parietal cortex (Preuss and Goldman-Rakic, 1991, their Figure 4C) and temporal cortex (Baylis et al., 1987, their Figures 2 and 3). The Lyon and Kaas map was based on a visuotopic analysis of V1 projections as displayed on sections of physically flattened cortex. The Preuss and Goldman-Rakic maps were derived from their illustrations of schematically partially unfolded sulci; the Baylis et al. maps were based on cortex flattened using a *straight-line* unfolding technique. *E*, A composite map of dorsomedial cortex (Galletti et al., 1999, their Figure 17), and parietal and temporal cortex (Seltzer and Pandya, 1978, 1980, 1986), all illustrated on schematically unfolded sulci. Data can be accessed via http://brainmap.wustl.edu:8081/sums/archivelist.do?archive_id=448857 (see color plate 12).

of Lewis and Van Essen (2000a) largely correspond with POa–e, Poa–i, and IPd of Seltzer and Pandya (1980, 1986), except that they are more restricted anteroposteriorly. The relationships with other schemes are somewhat confusing because of “cross-talk” in the terminology: area VIP* of Ungerleider and Desimone corresponds to LIPv of Lewis and Van Essen; areas LIP and VIP of Felleman and Van Essen correspond to LIPd and LIPv/VIPi, respectively, of Lewis and Van Essen.

A second group of areas, near the posterior end of the intraparietal sulcus, includes areas MDP, MIP, and DP, plus zone LOP (Fig. 32.2C). Area MDP corresponds to V6A of Galetti et al. (1999). Zone LOP may correspond to the cIPS subdivision identified physiologically by Taira et al. (2000) based on surface orientation selectivity.

VENTRAL TEMPORAL AREAS Cortex ventral to area MT and anterior to V4 is generally considered part of the ventral processing stream (cf. Chapter 34). This region includes a cluster of inferotemporal areas (blue in Fig. 32.2) that are implicated mainly in pattern recognition and form analysis (Desimone and Ungerleider, 1989; Tanaka, 1997). Another cluster of ventral-STS areas (green in Fig. 32.2) includes polysensory regions and regions involved in both form and motion processing (Cusick, 1997; Oram and Perrett, 1996). The five schemes in Figure 32.2 subdivide ventral temporal cortex along both anteroposterior and dorsoventral axes, but the number of identified subdivisions ranges from 4 to 10 and the location of areal boundaries varies widely as well.

The simplest scheme (Ungerleider and Desimone, 1986; Fig. 32.2B) includes a visuotopically organized area TEO that contains a lower-field and an upper-field representation (see also Boussaoud et al., 1991), plus three areas (TEc, TEr, and TEm) that lack clear visuotopic organization. The Felleman and Van Essen (1991) scheme, based mainly on topographic and connectional data, includes three areas (VOT, PITd, and PITv) in the region corresponding to TEO of Ungerleider and Desimone (1986). VOT contains only an upper-field representation, whereas PITd and PITv are reported to each contain a crude topography with lower-field and upper-field inputs (Van Essen et al., 1990). Areas CITd and CITv of Felleman and Van Essen (1991) together correspond approximately to TEc of Ungerleider and Desimone (1986) but are distinguished from one another by differential connections. More anteriorly on the atlas map, there is reasonable correspondence between AITd and TEr in the two schemes but poor correspondence between AITv and TEm.

The Seltzer and Pandya (1978) architectonic scheme (Fig. 32.2E) includes five inferotemporal areas (TEa, TEm, TE1, TE2, and TE3), plus four additional areas in the superior temporal sulcus (TAa, TPO, PGa, and IPa). The Baylis et al. (1987) scheme (Fig. 32.2D) uses the same criteria and terminology as Seltzer and Pandya (1978), but the areal boundaries

differ significantly on the atlas map. The Lewis and Van Essen (2000a) scheme, like that of Cusick (1997), identifies three subdivisions within TPO (TPOc, TPOi, and TPOr). In inferotemporal cortex, the Lewis and Van Essen (2000a) scheme does not discriminate among TE1, TE2, and TE3 but does identify dorsoventral subdivisions TE1-3d and TE1-3v. The latter correspond approximately to subdivisions TEad and TEav of Yukie et al. (1990) and Saleem and Tanaka (1996).

FRONTAL AREAS Felleman and Van Essen classified areas 8 (FEF) and 46 as part of visual cortex. Areas 8 and 46 have both been partitioned into multiple subdivisions, including eight zones (8A, 8Am, 8Ar, 46d, 46v, 46dr, 46vr, and 46r) by Preuss and Goldman-Rakic (1991) and zones 8Ac, 46p, and 46v by Lewis and Van Essen (2000a).

It remains unclear which of the aforementioned schemes for inferotemporal and parietal cortex best reflect the underlying neurobiological reality. Indeed, alternative possibilities worth bearing in mind are that much of inferotemporal and frontal cortex might contain gradual gradients of properties rather than sharply defined areas, or else irregular clustering whose arrangement varies markedly from one individual to the next.

Figure 32.3 shows a composite map in which all of the 10 schemes represented in the preceding panels are superimposed and displayed in lateral (Fig. 32.3A), medial (Fig. 32.3B), and flat map (Fig. 32.3C) views. Besides the individually colored areas, the composite map includes the six clusters discussed in preceding sections: the dorsomedial occipital complex (DMOcx), posterior parietal complex (PPcx), MST complex (MSTcx), ventral superior temporal complex (VSTcx), inferotemporal complex (ITcx), and TF/TH cluster.

HOW MANY VISUAL SUBDIVISIONS ARE THERE? It is naturally of interest to have a current estimate of the total number of cortical areas and subdivisions associated with visual processing. Given the diversity among partitioning schemes, it is impractical to arrive at a definitive single number. Altogether, there is substantial evidence for more than 40 anatomically and/or functionally distinct subdivisions of visually responsive cortex, but for some the evidence does not warrant identification as separate areas. A conservative lumpers can argue that the number of convincing visual areas is only about two dozen. A more generous splitter can make a credible case for at least three dozen distinct areas. The number of areas that show clear visuotopic organization is also difficult to determine precisely but is in the range of 10–12, depending on the designation of zones versus areas.

COPING WITH MULTIPLE SCHEMES, AREAL UNCERTAINTIES, AND INDIVIDUAL VARIABILITY Several general observations emerge from the preceding discussion. First, a multiplicity

FIGURE 32.3. *A–C*, Lateral, medial, and flat map views of a composite map obtained by superimposing the data from Figure 32.2. Although the specific areal assignments at each location cannot be ascertained by viewing this image, they can be readily obtained using a node-identification option in the Caret visualization software. See the abbreviations list for full names and Figure 32.1 legend for data access information. (See color plate 13.)

of competing partitioning schemes will likely persist for years, because many of the issues remain difficult to resolve with currently available techniques. Second, it is becoming increasingly important to have objective methods for quantifying and visualizing the uncertainties associated with charting areal boundaries and the variability associated with individual differences in cortical organization. This leads to the notion of probabilistic surface-based maps of cortical organization. The composite map in Figure 32.3 constitutes one step in this direction, as it includes many different schemes in a common coordinate system. Another important aspect of a probabilistic approach is to incorporate information about individual variability by registering maps of many individuals on the atlas (Van Essen et al., 2001a).

Another important issue involves the options for accessing and extracting information from surface-based atlases. The fundamental challenge is that existing atlases already contain far more information than can be easily gleaned from static pictorial images such as those shown in this chapter. Moreover, the amount of information represented on such atlases is likely to grow exponentially over the next decade. An attractive alternative is to use computerized visualization software to access atlas data more efficiently and flexibly. For the atlases illustrated here, this can be done by downloading specific data sets (using hyperlinks included in the figure legends) and viewing the maps using the freely available Caret software (Van Essen et al., 2001b; <http://brainmap.wustl.edu/caret>). Existing visualization options in Caret include zooming in on regions of interest; rapid toggling between different partitioning schemes; laying one scheme directly over another; listing areal identities for multiple partitioning schemes when clicking on locations of interest; specifying location by latitude and longitude (cf. Fig. 32.1E); encoding

uncertainty limits for each boundary; and encoding variability by combining maps from different individuals.

HUMAN VISUAL CORTEX The analysis of human visual cortex has benefited greatly from the advent of structural and functional MRI methods that can be routinely carried out on normal subjects. In the top half of Figure 32.4, the extent of visual cortex and other functional modalities is charted on the right hemisphere of a surface-based atlas (the HumanColin atlas) that was generated from high-resolution structural MRI of a particular individual (Holmes et al., 1998; Van Essen, 2002; Van Essen et al., 2002). The surface displays include lateral and medial views of the fiducial surface (Fig. 32.4*A, B*) and the inflated surface (Fig. 32.4*C, D*), plus a flat map (Fig. 32.4*E*). The assignment of different functional modalities was estimated mainly from functional neuroimaging data that were mapped onto the atlas using a combination of methods applied to a number of published data sets (see the legend to Fig. 32.4). Based on these provisional assignments, cortex that is predominantly visual in function occupies about 27% of the total extent of cerebral cortex (950 cm²) in the right hemisphere of the atlas. By comparison, about 8% of cortex is predominantly auditory, 7% somatosensory, and 7% motor. The remaining half (51%) includes major domains associated with cognition, emotion, and language.

Human area V1 (area 17) has a well-defined architectonic boundary that runs near the margins of the calcarine sulcus but with considerable individual variability (Rademacher et al., 1993). The estimated surface area of V1 on the atlas map (charted using the most likely boundary in the Rademacher et al. study) is 21 cm², or 2.2% of cerebral cortex. This is about one-sixth of its fractional occupancy on the macaque atlas.

FIGURE 32.4. Visual cortex and other functional modalities mapped onto a surface-based atlas of human cerebral cortex. The atlas was generated from a high-resolution structural MRI volume provided by A. Toga (Case Human.colin) using SureFit and Caret software (cf. Fig. 32.1). This atlas (Van Essen et al., 2002) is higher in quality and supersedes the Visible Man surface-based atlas previously published (Van Essen and Drury, 1997; Van Essen et al., 2001a). Modality assignments were based on (1) stereotactic mapping of fMRI volume data onto the atlas surface from the studies of Corbetta et al. (1998), Lewis and DeYoe (2000), and

Lewis et al. (2001); (2) stereotactic projection of published Talairach coordinates of activation focus centers (Ishai et al., 1999; Kanwisher et al., 1997; Van Essen and Drury, 1997); and (3) manually transposed boundaries related to local geographic and/or functional landmarks from surface maps published by Burton and Sinclair (2000), Press et al. (2001), and Tootell & Hadjikhani (2001). Data for Figures 32.4 and 32.5 can be downloaded via http://brainmap.wustl.edu:8081/sums/archivelist.do?archive_id=449900 (See color plate 14).

Neuroimaging studies have revealed numerous visuotopically organized extrastriate areas in human occipital cortex in an arrangement that shows many similarities to the pattern found in the macaque. Corresponding areas that have fundamentally similar visuotopic organization in the two species include V1, V2, V3 (V3d), VP (V3v), V3A, and V4v (DeYoe et al., 1996; Hadjikhani et al., 1998; Sereno et al., 1995). In addition, tests for motion-related activation have consistently demonstrated a prominent focus in or near the posterior inferotemporal sulcus. This focus is generally presumed to correspond to macaque MT plus part of the MST complex and has therefore been identified as human MT+ (Tootell et al., 1995) or as V5 (Watson et al., 1993).

Figure 32.5 includes many visuotopic areas that were mapped onto the human atlas using surface-based registration of an individual case from Hadjikhani et al. (1998). For technical reasons these maps do not include the representation of the fovea or far periphery, so the extent of the extrastriate areas is likely to be modestly underestimated. Interestingly, the sizes of V3d, V3v, and V3A relative to V1 and V2 are all substantially greater in humans than in the macaque, suggesting a marked evolutionary divergence in the relative sizes of nearby cortical areas. In the region adjoining dorsal V3, Smith et al. (1998) and Press et al. (2001) found evidence for two representations, V3A and V3B, instead of a single V3A, with V3B being located more posterior (lower on the flat map). Area V7 (Press et al., 2001; Tootell and Hadjikhani, 2001) is a visuotopically organized area that lies anterior to V3A; its location and extent are displayed on the atlas using dotted boundaries to signify greater uncertainty.

Human area V4v lies anterolateral to VP/V3v and contains a mirror-symmetric upper-field representation. Interestingly, cortex lateral and dorsal to V4v, identified as LO (Van Oostende et al., 1997) or as the LOC/LOP complex (Tootell and Hadjikhani, 2001), evidently lacks a complementary lower-field representation equivalent to that described for macaque V4d. Instead, the LOC/LOP region represents both upper and lower fields, but with an irregular and inconsistent map of the polar angle and an apparent discontinuity in the transition between central and peripheral eccentricities. LO as described by Grill-Spector et al. (1998a,b; 2001) includes much of LOC/LOP but extends further ventrally and anteriorly (down and to the right on the flat map). Area V8 lies anterior to V4v and contains a complete visuotopic map with a foveal representation near its anterior margin to the right on the flat map (Hadjikhani et al., 1998; but see Wade et al., 2002).

Tests using a variety of stimuli and behavioral paradigms besides those just discussed have revealed several additional regions of functional specialization. Ventral occipitotemporal cortex contains a region preferentially activated by object versus nonobject stimuli. Based on published stereotactic (Talairach) coordinates, foci involved in analysis of faces,

houses, and chairs are concentrated in a region (red dotted outline in Fig. 32.5E) that partially overlaps V8 on the atlas map but extends more anteriorly (Haxby et al., 1999; Ishai et al., 1999; Kanwisher et al., 1997). This region has been proposed to include a fusiform face area (FF) and a parahippocampal place area (PP) (Epstein and Kanwisher, 1998; Kanwisher et al., 1997) and is accordingly identified as FF/PP in Figure 32.5E. Other studies suggest that these may not constitute distinct areas but rather a functional gradient within a larger subdivision (Haxby et al., 2001).

In the parietal lobe, visually related activations have been reported in a large swath of cortex in and near the intraparietal sulcus, dorsal and anterior to the known visuotopic areas. Paradigms effective in activating this region include shifting visual attention, target-directed eye movements, visual motion, and spatial analyses (Corbetta et al., 1998; Haxby et al., 1994; Lewis and DeYoe, 2000; Lewis et al., 2001). This region presumably includes a number of functionally distinct areas or subdivisions that have not been clearly discriminated using existing paradigms and analysis methods.

Macaque-human comparisons

While there are many striking similarities in visual cortical organization between macaque and human, there are numerous differences as well. Some of the differences are in relative size and in the geographic location of areas, but others presumably reflect fundamental differences in the existence of areas or in their topological relationships to one another. A useful general strategy for examining these relationships and candidate homologies is to use surface-based registration between species (Van Essen et al., 1998, 2001a). While neither proving nor disproving any particular homology, interspecies registration of surfaces provides a good testbed for exploring any particular set of proposed homologies implied for the relationships among areas in intervening regions.

In Figure 32.6, the macaque and human maps were registered to one another using explicit landmarks that are likely to reflect genuine homologies. These landmarks (colored contours in Fig. 32.6) include the fundus of the central sulcus (near the boundary between somatosensory and motor cortex); the fundus of the Sylvian fissure (near the boundary between somatosensory and auditory cortex); the boundaries of V1, V2, and MT+; and the boundaries of neocortex along the medial wall (Fig. 32.6A, B). To avoid confounds associated with artificial cuts on the flat maps, the landmarks were first projected to macaque and human spherical maps (not shown); the registration was applied to the spherical maps; and the deformed visual areas were then projected back to the flat maps. This is shown in Figure 32.6D for the human visual areas deformed to the shape of the macaque flat map (and superimposed on the macaque sulcal map). In Figure 32.6D, the corresponding relationships are shown with the macaque visual areas deformed to the shape of

FIGURE 32.5. Identified visual areas on the Human.colin surface-based atlas. See the abbreviations list for full names. The boundary of MT+ on the atlas map was estimated by projecting the motion-related activation foci tabulated by Van Essen and Drury (1997) onto the atlas surface. The visuotopic map from Figure 5A of Tootell and Hadjikhani (2001) was then registered to the atlas using the V1/V2 boundary and the posterior boundary of MT+

as landmarks. Additional areas LO and V7 were drawn manually onto the atlas, based respectively on the studies of Tootell and Hadjikhani (2001) and Press et al. (2001). *A*, Lateral view. *B*, Medial view. *C*, Inflated lateral view. *D*, Inflated medial view. *E*, Flat map view. The red dotted contour represents the main cluster activation focus center involved in face and place analysis (see text). (See color plate 15.)

FIGURE 32.6. Comparisons between macaque and human visual cortex using interspecies surface-based registration. *A*, Macaque atlas flat map showing the composite map of visual areas (same as Fig. 32.3*C*) plus the boundaries of the Lewis and Van Essen scheme (same contours as in Fig. 32.2*C*) and the landmarks used to constrain the registration. *B*, Human atlas flat map showing visuotopic and functionally defined areas plus the landmarks used to constrain

the registration. *C*, Deformed human visual areas overlaid on the macaque flat map. *D*, Deformed macaque visual areas overlaid on the human flat map. Data can be accessed via <http://brainmap.wustl.edu/sums/sums-cgi?specfile=Human.colin.Cerebral.R.ATLAS.VanEssen02.Fig6.spec> and http://brainmap.wustl.edu:8081/sums/archivelist.do?archive_id=450135. (See color plate 16.)

the human flat map (and superimposed on the human sulcal map). The macaque map (before and after deformation) includes the composite of all 10 partitioning schemes painted onto the map, plus the Lewis and Van Essen partitioning scheme (black contours). The human map includes the same visuotopic areas delineated in Figure 32.5.

The deformation between species necessarily involves highly nonlinear distortions, mainly because V1 and V2 are much smaller (relative to overall cortical size) in humans versus macaques, and also because the location of MT (relative to foveal V2 and to the Sylvian fissure) is more posterior and ventral in the human versus the macaque map. Consequently, in Figure 32.6*D*, there is considerably more expansion of parietal areas than of inferotemporal areas on the deformed macaque map. The parietal lobe as defined by conventional geographic landmarks is slightly larger in the human atlas compared to the macaque (21% vs. 19% of

total neocortical surface area on the fiducial surface), whereas the size of region bounded by V2, MT, and the fundus of the central sulcus is substantially larger in humans (27% vs. 21% of neocortex). The species difference is even larger in the frontal lobe, which occupies 36% of human neocortex but only 25% in the macaque.

Several potential homologies can be evaluated by comparing individual areas and clusters of areas in the deformed macaque visual areas in Figure 32.6*D* to the human map in Figure 32.6*B* (or, equivalently, comparing the deformed human areas in Fig. 32.6*C* to the macaque map in Fig. 32.6*A*). One particular issue of interest is the relationship between macaque areas V4 and TEO/VOT, on the one hand, and human areas V4v, LOC/LOP, and V8, on the other hand. Deformed macaque V4v overlaps extensively with human V4v, and deformed macaque V4d overlaps with human LOC/LOP, consistent with the proposed homologies

for these areas. In contrast, deformed macaque V4 differs greatly in size and location from human V8. As emphasized by Tootell and Hadjikhani (2001), these and other differences argue strongly against a homology between macaque V4 and human V8, as proposed by Zeki et al. (1998).

Based on its location just anterior to V4v, human V8 is a candidate for homology with area TEO in the Ungerleider and Desimone scheme and with VOT in the Felleman/Lewis/Van Essen schemes. However, the visuotopic organization of human V8 is not in accord with that reported for either TEO or VOT, making a homology implausible on those grounds. For human V7, its location just anterior to V3A makes areas DP and zone LOP the most plausible candidates for homologs in the macaque, but a visuotopic map consistent with that in V7 has not been reported in this region.

Parietal visual cortex in the deformed macaque map overlaps extensively with human parietal visual cortex but is shifted somewhat more lateral (lower on this part of the map). Candidate homologies have been suggested between macaque LIP and human parietal areas involved in attention and eye movements (e.g., Corbetta et al., 1998; Sereno et al., 2001). These and other candidate homologies can be used as additional constraints to test for mappings that bring the overall parietal regions into closer register and may suggest additional homologies.

Deformed macaque inferotemporal and ventral superior temporal areas (blue and green in Fig. 32.4D) lie well anterior (to the right on the flat map) to the known visually responsive regions of human occipitotemporal cortex. One possible explanation for this discrepancy is that human visual cortex extends farther anterior in the temporal lobe than was previously recognized. Alternatively, the homologs of the macaque inferotemporal complex may lie within currently designated human visual cortex, anterior to V8 and/or flanking it. If so, this would signify an even more pronounced overemphasis on parietal visual areas and underemphasis on inferotemporal visual areas in humans compared to macaques.

OTHER SPECIES Although the focus of this chapter has been on the macaque and human, there is an enormous amount to be gained by obtaining a better understanding of visual cortex in other primate and nonprimate species. There has been substantial progress in elucidating visual cortical organization in other nonhuman primates, most notably the owl monkey but also several other species as well (Kaas, 1997; Rosa, 1997). In brief, these reveal similar patterns, especially for occipital visual areas, but also many indications of significant differences.

Rodents, particularly the mouse, are likely to become increasingly important as model systems for studying many aspects of cortical organization. Studies of the rat and

mouse have revealed a primary visual area surrounded by a modest number of extrastriate visual areas (Coogan and Burkhalter, 1990; Wagor et al., 1980). However, the magnitude of differences in the overall number and layout of visual areas from species in different orders remains to be determined. A mouse surface-based atlas, akin to those for the macaque and human illustrated here, has recently been generated (Van Essen et al., 2002) and should aid in charting the detailed organization of mouse visual cortex.

Concluding remarks

Progress in elucidating visual cortical organization is likely to accelerate markedly in the next few years, particularly with the use of fMRI and other imaging methods that can be applied to monkeys (Logothetis et al., 1999; Vanduffel et al., 2001) and to rodents as well as to humans. Because these data are represented digitally from the outset, registering such data to surface-based atlases should be easier and more accurate than for many of the data sets illustrated in this chapter. As the richness and complexity of such atlases and associated databases grow, the ways in which neuroscientists routinely access the data will likely evolve to be progressively more web-based, analogous to how molecular biologists use search engines and large databases to access an increasingly large fraction of the information they use in their research.

Abbreviations

Cortical Areas

DP	dorsal prelunate area
FST	floor of superior temporal area
IPa	area IPa from Cusick et al. (1995)
LIPd	lateral intraparietal (dorsal)
LIPv	lateral intraparietal (ventral)
MDP	medial dorsal parietal area
MIP	medial intraparietal area
MST	medial superior temporal area
MT	middle temporal area
PIP	posterior intraparietal area
PO	parietal-occipital area
TAa	area TAa from Cusick et al. (1995)
TEad	anterodorsal division of TE
TEav	anteroventral division of TE
TF	temporal area F
TH	temporal area H
Tpt	temporoparietal area
TPOc	temporal parietal occipital (caudal)
TPOi	temporal parietal occipital (intermediate)
TPOr	temporal parietal occipital (rostral)
VIP	ventral intraparietal
VIP*	heavily myelinated subdivision of VIP
V1	visual area 1
V2	visual area 2
V3	visual area 3
V3A	visual area V3A

V4	visual area 4
V4t	V4 transitional area
VOT	ventral occipitotemporal area
VP	ventral posterior area
7a	visual area 7a
46	visual area 46
7al	lateral area 7a
DMOcx	dorsomedial occipital complex
IPd	
ITcx	inferotemporal complex
MSTcx	medial superior temporal complex
MTc	caudal to middle temporal
OAA	
PGA	
POa-e	external division of area POa
POa-i	internal division of area POa
PPcx	posterior parietal complex
TE1	subdivision 1 of TE
TE1-3d	dorsal subdivision of TE1-3
TE1-3v	ventral subdivision of TE1-3
TE2	subdivision 2 of TE
TE3	subdivision 3 of TE
TEa/m	subdivisions a and m of TE
TEm	medial division of TE
TPO	temporo-parietal-occipital area
V2d	dorsal division of V2
V2v	ventral division of V2
V3d	dorsal division of V3
V3v	ventral division of V3
V6	visual area 6
V6A	visual area 6A
VSTcx	ventral superior temporal complex
Cortical Zones	
LOP	lateral occipital parietal
MST	medial superior temporal area
MSTd	dorsal subdivision of MST
MSTl	lateral subdivision of MST
MSTda	dorsoanterior subdivision of MST
MSTdp	dorsoposterior subdivision of MST
MSTm	medial subdivision of MST
VIPl	lateral subdivision of VIP
VIPm	medial subdivision of VIP
V4ta	V4 transitional area (anterior)
V4tp	V4 transitional area (posterior)

33 Communications between Cortical Areas of the Visual System

JEAN BULLIER

THE MAMMALIAN visual cortex is composed of numerous functional areas that contain a more or less complete representation of the contralateral visual hemifield or, in the case of the inferotemporal cortex, of the entire visual field. Information transmitted by the retinal ganglion cells is relayed by neurons of the dorsal lateral geniculate nucleus (LGN) and, with very few exceptions, is sent to layer 4 neurons of area V1. Thus, the first population of neurons to be activated by the onset of a visual stimulus is found in layer 4 of area V1 (Maunsell and Gibson, 1992; Nowak et al., 1995). After processing in area V1, activity is relayed to a few other cortical areas located close to V1 which themselves transmit activity to additional cortical areas. This pathway that starts in area V1 and spreads information to all visual cortical areas is the feedforward pathway. It will be shown that feedforward connections carry the main excitatory drive to cortical neurons and that they transmit information at different speeds in different regions of the visual cortex.

Cortical neurons do not simply transfer information to other visual areas with feedforward connections; they also process it. This operation is achieved by two sets of connections: the intrinsic, or horizontal, connections that connect together neighboring neurons in a cortical area and the feedback connections that connect cortical areas in the direction opposite to feedforward connections. Little will be said in this chapter about the function of horizontal connections because that is the subject of another chapter (see Chapter 46). On the other hand, the organization and function of feedback corticocortical connections will be examined closely because this has recently been the subject of much discussion and research.

Practically all the connections between areas are made by pyramidal neurons which also send recurrent collaterals to neighboring neurons within a few millimeters (Fig. 33.1). These connections, together with those of inhibitory GABAergic interneurons, constitute the horizontal connections (also called *local* or *intrinsic connections*). Therefore, processing between areas and processing within areas are inevitably related by the simple fact that whatever message is sent by a cortical neuron to neurons of another cortical area is also transmitted by horizontal connections to neighboring neurons within the same area. The local contacted

neurons appear to be almost exclusively pyramidal cells, some of them projecting to the same cortical area as the neurons to which they are connected. Thus, neurons with a common cortical target appear to be interconnected by horizontal connections. They also receive reciprocal connections from the target area (Johnson and Burkhalter, 1997), thus defining a specific network across and within areas.

The first processing stages (areas V1, V2, V3, V4, V5, or MT) contain neurons that have relatively small receptive fields confined to the contralateral visual hemifield. Neurons at higher levels in the inferotemporal and parietal cortex have receptive fields that extend across the vertical meridian. This extension in the ipsilateral hemifield is due to the presence of interhemispheric or callosal connections that link together the visual areas of both cortical hemispheres. Although the anatomical characteristics of these connections are well understood, little is known concerning their function beyond that of linking together the representations of both visual hemifields and producing receptive fields that are not limited to one visual hemifield. The role of callosal connections is also examined in this chapter.

Structure and function of corticocortical connections

GENERAL CHARACTERISTICS Corticocortical connections between functional areas are made almost exclusively by pyramidal neurons. A few exceptions have been noted: in the cat, some spiny stellate cells in area 17 send projections to area 18 (Meyer and Albus, 1981). It has been reported that in the rat, a small contingent of GABAergic smooth stellate cells send connections to neighboring cortical areas (McDonald and Burkhalter, 1993). Interhemispheric connections have also been found to arise from a few presumably inhibitory interneurons in the rat (Hughes and Peters, 1992a, 1992b) and in the cat (Peters et al., 1990). Despite this anatomical evidence, no monosynaptic inhibitory synaptic potential has ever been reported in electrophysiological studies of connections between cortical areas of the same or opposite hemisphere. It can therefore be concluded that interarea and interhemispheric corticocortical connections are massively excitatory. This does not mean that these

FIGURE 33.1. Schematic representation of the laminar distributions of feedforward and feedback neurons and axonal terminal arborizations. Note the presence of axon collaterals that innervate neighboring neurons and constitute the majority of horizontal connections.

connections have a net excitatory effect on the responses of the target area because they contact pyramidal cells as well as inhibitory interneurons. Therefore, the net effect of corticocortical connections is a mixture of excitatory and inhibitory influences.

It is known that within the local network of horizontal connections, the densest projections are to immediate neighbors. This is demonstrated by placing small injections of anterograde or retrograde tracers in a given site and examining the local distribution of labeled axons and neurons. The higher density of local connections is due to the branching pattern of axons that arborize more profusely near the main axon trunk.¹

In a similar fashion, the densest interarea connections tend to be with neighboring cortical areas. For example, the strongest connections of area V2 are with neighboring areas V1 and V4 in the monkey (Fig. 33.5.4). Similarly, in the cat, the strongest connections of area 17 are with neighboring areas 18 and 19. There are, however, a few examples of adjacent areas that are not interconnected, like the retrosplenial visual area in the monkey that has no connections with area V1, although it is surrounded by it on its caudal and lateral borders. Another exception to the rule of preferential connections with neighboring areas is found in the relationship between visual areas of the occipital, parietal, and temporal lobes with areas of the frontal lobe surrounding the frontal eye field area (FEF in Fig. 33.5.4). These frontal areas, in addition to local connections in the frontal lobe, exchange long-distance connections with parietal, occipital, and inferotemporal cortex. Similarly, areas of the occipital and parietal cortex interconnect with adjacent areas and exchange long-distance connections with the frontal cortex (Jones and Powell, 1970; Schall et al., 1995). This dual set of connec-

tions (to neighboring areas and to frontal cortex) probably corresponds to the different functional roles played by posterior and frontal regions in vision.²

DIFFERENT TYPES OF CORTICOCORTICAL CONNECTIONS
Intrahemispheric corticocortical connections are often divided into two classes: feedforward and feedback. The anatomical differences between feedforward and feedback were first described by Rockland and Pandya (1979), who noted that some connections (forward-going) tend to originate in neurons located in supragranular layers (layers 2 and 3) and terminate around layer 4, whereas reciprocal connections (backward-directed) are predominantly made by neurons in infragranular layers (layers 5 and 6) and project outside layer 4 (Figs. 33.1 and 33.4). This was later formalized by Maunsell and Van Essen (1983) and Felleman and Van Essen (1991), who used the anatomical differences between feedforward and feedback connections³ to construct the hierarchy of cortical areas (see below).

Although feedforward and feedback connections are usually presented in their archetypal form⁴ (Fig. 33.1), there are many variations on the theme: feedforward connections can originate from neurons in infragranular layers (Fig. 33.4.4), and their terminals often extend into the supragranular layers. Terminals of feedback connections

¹The distribution of boutons along axonal branches, on the other hand, appears to be more or less uniform (Braitenberg and Schüz, 1991).

²Frontal cortex is supposed to be more involved in the planning and generation of eye movement than are areas of the posterior cortex, which are thought to analyze visual information transmitted by the retina.

³Felleman and Van Essen also defined a third set of interarea connections called *lateral connections*; their neurons of origin belong to infra- and supragranular layers, and their terminals arborize in all layers. These connections are relatively rare, and their role is not understood.

⁴Feedforward connections originating from supragranular layer neurons and arborizing in layer 4 and feedback connections originating from infragranular layer neurons and arborizing outside layer 4.

usually avoid layer 4, but they often originate from supra- as well as infragranular layers (Fig. 33.4*B*). Quantitative estimates of the proportions of source neurons in infra- versus supragranular layers reveal that there is a continuum in the organization of feedback and feedforward connections instead of two separate homogeneous populations (Barone et al., 2000). Although this has not been quantified, it appears that a similar continuum is found when the laminar distribution of axonal arborization is considered. As argued earlier (Salin and Bullier, 1995), the archetypal organization of feedback connections (neurons located only in infragranular layers and providing exclusive input to layers 1 and 2) is found only for the relatively rare connections between areas that are distant on the cortical surface [such as inferotemporal (IT) cortex and V1; Fig. 33.5*A*]. In contrast, feedback connections between neighboring areas, which are extremely numerous, do not follow the archetypal model. They originate from neurons in supra- as well as infragranular layers and terminate in all layers except the lower portion of layer 4 (Kennedy and Bullier, 1985; Kennedy et al., 1989).

Interhemispheric connections have morphological characteristics that place them in the feedforward group for the laminar position of the source neurons (in layers 2 and 3) and in the feedforward or feedback group for the distributions of the axon terminals. In fact, the laminar organization of axon terminals in interhemispheric connections tends to follow that of intrahemispheric connections. In general, a given area connects to the same areas in both the same and the opposite cortical hemispheres, and the laminar distributions of the terminals are similar for inter- and intrahemispheric connections (Kennedy et al., 1991).

RETINOTOPIC ORGANIZATION As mentioned above, one of the major organizing principles of the visual cortical areas is that each area contains a retinotopic representation of the contralateral visual hemifield. In addition, receptive field sizes vary greatly from one area to another. Receptive field size is smallest in area V1 and increases progressively as one moves from V1 to V2, V4, and TEO to reach receptive fields that cover almost the entire visual field in some neurons of IT cortex. Similarly, receptive fields increase from V1 to V2, MT, MST and areas of the parietal cortex (Fig. 33.2). In addition, all anatomical studies show an important degree of convergence and divergence in corticocortical connections. Typically, a cortical zone a few hundred microns wide projects to and receives from a region that is usually a few millimeters wide but can cover up to 15mm on the cortical surface of a connected area (see the review in Salin and Bullier, 1995).

This large degree of convergence and divergence, and the great variation in receptive field sizes among cortical areas, have important consequences for the retinotopic organiza-

tion of corticocortical connections. It is usually assumed that all connections in the visual system are retinotopically organized, meaning that the receptive field centers of the afferent neurons are included in the receptive field center of the recipient cell. This appears to be the case for thalamocortical connections (Reid and Alonso, 1995; Tanaka, 1983) and feedforward connections, as shown by mapping studies in the cat (Price et al., 1994; Sherk and Ombrellaro, 1988) and inactivation studies in the monkey (Girard and Bullier, 1989; Girard et al., 1991a, 1991b) (Fig. 33.3).

Such is not the case for feedback connections because of the large degree of convergence and the larger receptive field centers of neurons in areas distant from area V1 (Fig. 33.2). Earlier mapping studies showed that the organization of feedback connections is compatible with the rule that neurons tend to interconnect if their receptive field centers overlap at least partially (Salin et al., 1992). As a consequence, the extent of the visual field concerned by the feedback connections to a column of cortex corresponds to the sum of twice the average diameter of the receptive field center in the source area and the average receptive field center in the recipient area (Fig. 33.3). The progressive increase in receptive field center size with distance from V1 (Fig. 33.2) means that feedback connections concern larger and larger regions of visual field as one moves from adjacent to more distant areas. Thus, feedback from area V2 to area V1 comes from neurons coding for a limited region of visual field (a few degrees; Fig. 33.3). On the other hand, feedback projections from IT neurons (Kennedy and Bullier, 1985; Rockland and Hoesen, 1994), which have very large receptive fields, enable neurons in area V1 to be influenced by information concerning very large portions of the visual

FIGURE 33.2. Receptive field center size as a function of eccentricity in the visual field for areas of the dorsal stream. Note how the receptive field size increases with distance from area V1. (From Rosa, 1997.)

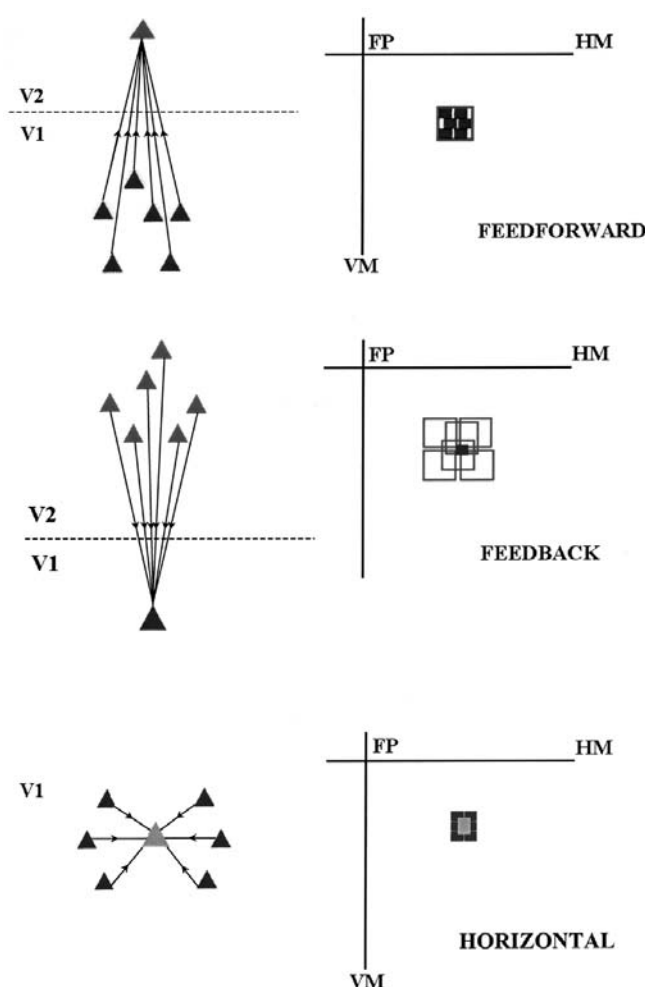

FIGURE 33.3. Retinotopic organization of feedforward, feedback, and horizontal connections. The left part of the figure schematically represents areas V1 and V2 seen from above. Triangles correspond to neuron cell bodies. The direction of the connection is indicated by the arrows on the simplified axons. The right part of the figure represents the right lower visual field of the animal (*FP*, fixation point; *HM*, horizontal meridian; *VM*, vertical meridian). For the *feedforward* connections, the large square represents the receptive field (RF) center of the V2 neuron receiving convergent information from the V1 neurons that have the small black squares as RF centers. The combination of RF centers of the afferent V1 neurons makes up the RF center of the target V2 neuron: feedforward connections are visuotopically organized. For the *feedback* connections, the small black square represents the RF center of the V1 neuron receiving convergent information from V2 neurons with the large open squares as RF centers. The RF centers of V2 neurons cover a larger region of visual field than that covered by the RF center of their target neuron in area V1: the feedback connections are only loosely retinotopic and can be used to mix information from distant regions of the visual field. For the *horizontal* connections, the gray square represents the RF center of the V1 neuron receiving convergent horizontal connections from neighboring neurons with RF centers indicated by the black squares. The combination of the horizontal afferents covers a larger part of the visual field than the RF center of the target neuron: horizontal connections are loosely retinotopic.

field. Feedback connections thus provide a sort of tiling of visual space, with further influences coming from progressively further areas.

In a similar way, but on a much smaller scale, the horizontal connections link together neurons with neighboring and partially overlapping receptive fields. The region of the visual field concerned by the horizontal connections corresponds approximately to the point image, that is, the extent of visual field covered by the receptive fields of neurons that are activated by a light point in the visual field⁵ (Angelucci et al., 2000). Thus, the extent of visual field concerned by the local connections is much smaller than that corresponding to the feedback connections from some of the most distant source areas (Fig. 33.3).

Interhemispheric connections, like horizontal connections, also interconnect neurons with overlapping and partially overlapping receptive fields, particularly around the vertical meridian. In addition, some interhemispheric connections appear to link together neurons with separate receptive fields that sometimes correspond to mirror images in both visual hemifields (Houzel and Milleret, 1999; Innocenti, 1986; Kennedy et al., 1991).

PATCHY ORGANIZATION AND AXONAL BIFURCATION Neuroanatomical tracing studies show that neurons retrogradely filled by a small deposit of retrograde tracer tend to be grouped in small patches a few hundred microns wide and separated by 500 to 1000 μm on the cortical surface, depending on the connection and the species (Fig. 33.4A). Results of anterograde tracer studies also demonstrate that terminal axons labeled by a small amount of tracer placed in a given cortical area are grouped together in small patches (Fig. 33.4C). This was originally discovered for horizontal connections (Rockland and Lund, 1982), and it was found later that extrinsic corticocortical connections also tend to be similarly organized in most species, with the possible exception of the mouse (Braitenberg and Schüz, 1991).

Patchy arborization is usually observed for horizontal (Gilbert and Wiesel, 1983; Rockland and Lund, 1982) and feedforward connections (Bullier et al., 1984; DeYoe and Van Essen, 1985; Shipp and Zeki, 1985; Symonds and Rosenquist, 1984). Coupled injections of different retrograde tracers in different cortical areas produce mostly nonoverlapping patches of labeled cells (Bullier et al., 1984; DeYoe and Van Essen, 1985; Shipp and Zeki, 1985), with very few double-labeled cells in the regions of overlap (Fig. 33.4A). This suggests that a given cortical area sends feedforward connections to several other areas through a system

⁵The point image corresponds to the average scatter of receptive field centers plus the average receptive field center diameter in the area.

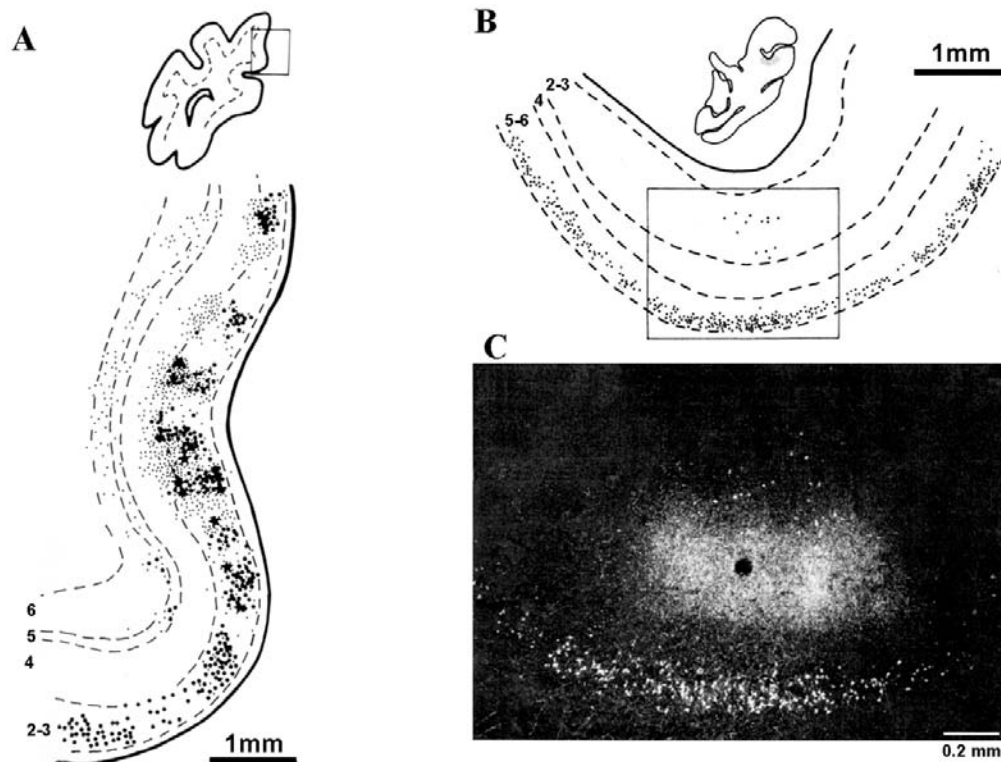

FIGURE 33.4. Patchy organization of corticocortical connections. *A*, distribution of neurons in area 17 sending feedforward connections to areas 18 and 19 of the cat visual cortex (small dots indicate neurons projecting to area 18, large dots neurons projecting to area 19, stars projecting to both areas). Note the predominance of neurons in the supragranular layers (2 and 3), the rare neurons projecting to both areas (stars). *B*, distribution of neurons sending feedback connections from area MT to area V1 in the macaque

monkey. Note the predominance and continuous nonpatchy distribution of feedback neurons in the infragranular layers. *C*, detail of *B*: retrogradely labeled feedback neurons in layers 5 and 6 (white dots) and labeling of feedforward terminal axons in layer 4 (white cloud). Note the contrast between the small patch of feedforward axon terminals and the more extensive and nonpatchy distribution of feedback neurons (*A* modified from Bullier et al., 1984; *C* modified from Kennedy et al., 1989.)

of neuronal populations organized as interdigitating neuron patches. It is likely that these populations share common functional properties and are interconnected by patchy horizontal connections. Although less frequently demonstrated because of the small number of studies using coupled anterograde tracers compared to studies using retrograde tracers, patches of terminal axons also appear to segregate at least partially in the target area for feedforward and interhemispheric connections (Goldman-Rakic and Schwartz, 1982; Morel and Bullier, 1990).

It is likely that the patchy organization and lack of axonal bifurcation in feedforward connections are the marks of the functional specificity of such connections. This is suggested by the observation that the V1 neurons projecting to area MT belong to a specific type with homogeneous properties (Movshon and Newsome, 1996). This result is comparable to that of an earlier work by Henry and his collaborators, which also demonstrated the specific functional properties of neurons projecting from area 17 to the PMLS in the cat (Henry et al., 1978). Similarly, the patchy distribution of feedforward terminals presumably corresponds to the con-

vergence of axon terminals of neurons with some common properties. This is suggested by the elegant experiments of Sherk in the LS area (which is slightly larger than the PMLS) (Sherk, 1990). Using a neurotoxin, she killed the neurons in a small region of that area and recorded from what presumably correspond to the terminals of afferent axons. She found that axon terminals group together according to direction selectivity, thus suggesting that neurons with the same optimal direction tend to terminate in common patches. The neurons innervated by this axon group presumably inherit the property of direction selectivity transmitted by the converging feedforward axons.

The prevalence of patchy organization is more variable in studies of feedback connections. In general, when relatively extensive injections of retrograde tracers are placed in a given area, neurons in extrastriate areas do not group themselves in well-defined patches, as in the case of feedforward connections (Fig. 33.4*B*; Kennedy and Bullier, 1985; Perkel et al., 1986). On the other hand, more localized injections of retrograde tracers in the supragranular layers produce patchy distributions of labeled cells in supragranu-

lar layers (Angelucci et al., 2002; Salin et al., 1995; Shipp and Grant, 1991). Similarly, injections of anterograde tracers produce patchy distributions of terminals, particularly in the supragranular layers (Henry et al., 1991; Salin et al., 1995; Wong-Riley, 1979). A continuous distribution of anterograde labeling has been reported on other occasions, but this may be due to the large size of the injection (Maunsell and Van Essen, 1983; Ungerleider et al., 1983).

There appears to be greater variability in the patchy distribution of feedback than in feedforward. The reason for this difference may be that different categories of feedback connections, concerning different sets of layers, show variable degrees of patchiness. Indeed, direct comparisons of the distributions of labeled cells or axon terminals in different layers for feedback connections show that patchy distributions exist in the connections between supragranular layers, whereas connections from infragranular layers appear to be less segregated (Fig. 33.4*B*), and afferent terminals in lamina 1 always project in a diffuse manner (Henry et al., 1991; Salin et al., 1992; Shipp and Grant, 1991). Similar differences between the topographic organizations of terminals in different laminae are also observed when individual axonal arbors are traced in the target area, as demonstrated by the work of Rockland and her colleagues (Rockland and Drash, 1996; Rockland et al., 1994).

It is interesting that the laminar differences observed for the patchy character of feedback connections are echoed by similar differences in the pattern of axonal bifurcation. Thus, in feedback connections, the proportion of neurons sending bifurcating axons to two cortical areas is higher in infragranular than in supragranular layers (Bullier and Kennedy, 1987). Also, the results of Rockland and her associates demonstrate that some feedback axons have long axonal collaterals in layer 1 that arborize extensively over at least two cortical areas, whereas terminals in layers 2 and 3 are restricted to one cortical area (Rockland et al., 1994).

This difference in organization across layers suggests that for a given set of feedback connections between two areas, different roles are played by different subsets of connections corresponding to different laminar distributions in the source and target areas. Thus, the variability of laminar distribution among feedback connections between areas at different distances on the cortical surface may correspond to different functional roles played by distant feedback connections (e.g., TE to V1) compared to those between adjacent areas (e.g., V2 to V1).

Assuming that the patchy and nonbifurcating nature of feedforward connections reflects the necessity to organize inputs according to specific properties, the more diffuse character of the feedback connections to layer 1 suggests that it plays a more general role, such as controlling the contrast gain or membrane potential of a large population of target neurons. Such a diffuse role cannot be extended to

all feedback connections, however, because feedback connections to layers 2 and 3, with their patchy organization, probably play a very specific role in the processing of visual information.

What differentiates neurons with axonal bifurcation to several cortical areas from neurons that project to only one cortical area? This question is particularly interesting for the feedback connections from the infragranular layers that contain a sizable proportion of axonal bifurcation (Bullier and Kennedy, 1987). It is possible that such bifurcation concerns preferentially axons with fast conduction velocity. As suggested by modeling studies (Murre and Sturdy, 1995), axon size is under strong constraints in the brains of large mammals. Projection of thick axons to several areas by way of bifurcation is one way of limiting their number. Indeed, there are many examples of thick axons that bifurcate: Y cells in the cat LGN that have the largest axons send bifurcations to areas 17 and 18 (Bullier and Kennedy, 1987), and Meynert cells in layer 6 of area V1 send bifurcating axons to at least area MT, and to the superior colliculus (Fries et al., 1985). In functional terms, the bifurcation of thick axons to several cortical areas is an efficient way to coactivate several cortical areas rapidly and simultaneously.

SYNAPTIC TRANSMISSION Given the important anatomical differences between feedforward and feedback connections reviewed above, it is likely that differences also exist in the characteristics of synaptic transmission for these two types of connections. Reports on electron microscopic (EM) studies of all types of corticocortical connections all agree that they make excitatory synapses on their target neurons (Anderson et al., 1998; Gonchar and Burkhalter, 1999; Johnson and Burkhalter, 1996; Lowenstein and Somogyi, 1991). Possible differences between feedforward and feedback connections are therefore likely to be reflected in the excitatory or inhibitory type of neuron that is contacted. The morphology of feedforward connections from V1 to V5 was recently investigated by Anderson and his collaborators (1998). Terminal boutons formed asymmetric (presumably excitatory) synapses and tended to contact preferentially spiny neurons (excitatory, mostly pyramidal), but also terminated on smooth, presumably inhibitory, cells in 20% of the cases. Very similar proportions were reported by Lowenstein and Somogyi (1991) in their study of the feedforward projection from area 17 to PMLS in the cat, an area that has been considered homologous to area MT of primates (Payne, 1993). In a study of feedforward connections between visual cortical areas in the rat, Johnson and Burkhalter (1996) reported a smaller proportion of contacts onto synaptic shafts (10%).

Less is known concerning the synaptic organization of feedback connections. The early results of Johnson and Burkhalter suggested that feedback connections contact

more specifically spines of pyramidal cells (98% of the cases) and rarely terminate on dendritic shafts (Johnson and Burkhalter, 1996). However, a more recent study by the same laboratory found similar proportions of terminals on parvalbumin-rich GABAergic interneurons (10%) in both feedforward and feedback connections in the rat visual system (Gonchar and Burkhalter, 1999). Differences between feedforward and feedback were found at the site of axonal contact to GABAergic parvalbumin-rich interneurons, with feedback connections terminating on distal parts of the dendrites, whereas feedforward contacted dendritic regions closer to the cell body (Gonchar and Burkhalter, 1999). This finding is in keeping with functional data from the same group showing that feedback connections have mostly an excitatory influence, whereas electrical stimulation of intrinsic and feedforward connections tends to recruit inhibitory circuits at relatively low stimulus intensities (Shao and Burkhalter, 1996). The latter results, however, should be treated with caution, because electrical stimulation acts exclusively on axonal branches (Nowak and Bullier, 1998a, 1998b). Therefore, stimulation in one area activates the efferent axons orthodromically, as well as the afferent axons antidromically, and it is impossible to differentiate the synaptic potentials evoked by direct orthodromic activation from those evoked by recurrent collaterals of antidromically activated axons. This confusion probably explains why the laminar pattern of activation elicited in a given cortical area by electrical stimulation in another area does not always fit with that predicted from the laminar distribution of axon terminals (Domenici et al., 1995; Nowak et al., 1997).

The low proportion of terminals on dendritic shafts reported for feedback connections by Burkhalter and his colleagues contrasts with the results of an earlier EM study of the feedback connections between areas 18 and 17 in the cat (Fisken et al., 1975). In that study, the authors concluded that more than 30% of the terminals of feedback connections were located on dendritic shafts. Whether this discrepancy is related to a species difference or whether there is indeed a strong feedback projection to dendritic shafts remains to be determined by further studies.

In conclusion, much remains to be done to understand the differences between the synaptic organizations of feedforward and feedback connections. It appears that both types send excitatory connections, but whether they target different proportions of inhibitory neurons has not been clearly established. Using agonists and antagonists, it will also be interesting to determine the proportions of different receptor channels contacted by these two types of connections. As mentioned above, the task is complicated by the limits of the method of electrical stimulation and by the heterogeneity of feedback connections.

Hierarchical organization of cortical areas

The classification of corticocortical connections in feedforward, feedback, and lateral connections led Maunsell and Van Essen (1983) to define a hierarchy of cortical areas on the basis of a simple rule: the areas are arranged in a series of levels defined by their connections with each other. At the lowest level is area (V1) that receives only feedback connections and sends only feedforward connections to other areas. At the next level is area V2, which receives feedforward connections from V1 but receives only feedback connections from other areas. Above V2 is area V3, which receives feedforward connections from V1 and V2 and feedback connections from other areas. In addition, there is the possibility that two areas belong to the same level if they exchange lateral connections (see also Chapter 32).

It is remarkable that this simple set of rules is in most cases internally consistent: if area A sends feedforward connections to area B, then B sends feedback connections to A; if A sends lateral connections to B, B sends lateral connections to A. A small number of exceptions have been noted (Felleman and Van Essen, 1991). Applying these rules to the areas of the macaque monkey initially generated the pattern shown in Figure 33.5B. More recent versions (Fig. 33.5C) have a similar organization but have become more and more complicated as more connections have been discovered (DeYoe et al., 1994; Felleman and Van Essen, 1991).

This method is useful for organizing the large number of cortical areas of the monkey visual system in a small number of distinct levels, but it has two disadvantages: (1) It is an anatomical classification that says little about the functional interactions between the areas. We will come back to this question in the next section. (2) It is largely underdetermined, as pointed out by Malcolm Young and his associates (Hilgetag et al., 1996). This means that the set of rules used to construct the hierarchy does not produce a unique solution. Optimal solutions lead to smaller numbers of rule violations, but it is usually impossible to identify the optimal configurations because of the lack of knowledge concerning many connections. The consequence of the underdetermined character of the hierarchical scheme is that a given cortical area such as area MT can occupy levels 5 to 10 in the hierarchy. For most pairs of cortical areas beyond V1, V2, and V3,⁶ it is impossible to be certain that one area is at a lower or a higher level than the other, or whether they belong to the same level in the hierarchy.

An attempt has been made recently to specify the character of this hierarchical scheme more precisely by quanti-

⁶For these areas, the numbers of possible levels are small.

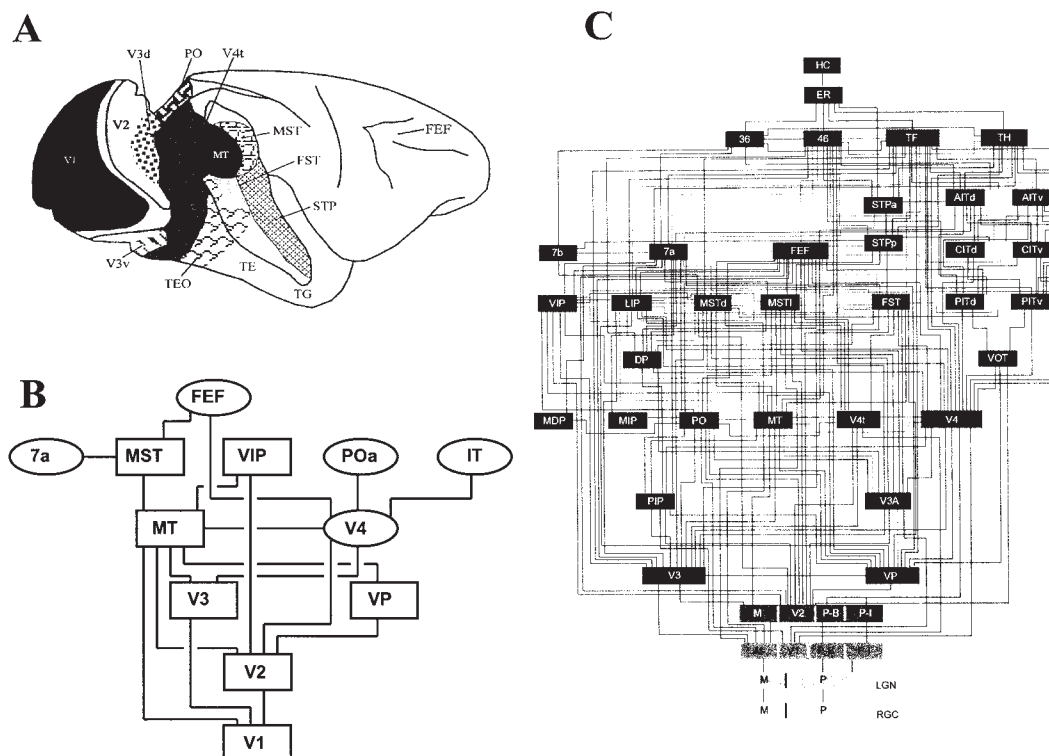

FIGURE 33.5. Hierarchical organization of cortical areas of the macaque monkey visual system. *A*, a schematic representation of the visual areas of the macaque monkey brain. *B*, the early version of the hierarchy. Boxes and ellipses correspond to cortical areas shown in *A*, lines to bidirectional connections. IT corresponds to TE in *A*; 7a, Poa, and VIP are located in the intraparietal sulcus that is located in front of PO in *A*; V3 corresponds to V3d and VP to V3v in *A*. V1 is at the lowest level, and the frontal eye field

(FEF) is at the highest level of the hierarchy. *C*, the 1991 version. Separation is made between magno- and parvocellular layers in the LGN (*M* and *P*) and in the retinal ganglion cells (*RGC*). In V1 the Magno stream (*M*) is separated from the Parvo-Blob (*P-B*) and Parvo-Interblob (*P-I*) streams. At the highest level are found the hippocampal formation (*HC*) and the entorhinal cortex (*ER*). The FEF is seven levels above V1. (*A* modified from Van Essen and Maunsell, 1983; *C* modified from Felleman and Van Essen, 1991.)

fying the proportions of source neurons in supragranular versus infragranular layers (Barone et al., 2000). When this is done, a reasonably good match to the original hierarchy of Maunsell and Van Essen is obtained and, provided that a few adjustments are made, the proportion of labeled neurons in supragranular layers is a good predictor of the level in the hierarchy. However, when the hierarchy obtained by Young and colleagues by modeling (Hilgetag et al., 1996) and that obtained by quantifying the proportion of supragranular layer neurons (Barone et al., 2000) are compared to those published by Van Essen and his colleagues, serious discrepancies are found between the levels at which a given area belongs. For example, the FEF belongs to the highest level in the original map (Fig. 33.5*B*), to the eighth level in the 1991 version (Fig. 33.5*C*), and is brought down to the fourth level when attention is paid to the proportion of supragranular layer neurons (Barone et al., 2000).

The underdetermined character and the variability in the levels occupied by areas in different classification schemes suggest that caution should be applied when attempts are

made to derive functional interpretations from the hierarchical classification. Furthermore, as mentioned below (see the next section), the latencies of neurons in different cortical areas cannot be predicted from the hierarchy of cortical areas, as would be expected if the hierarchical organization corresponded to a functional model with a succession of processing stages along the hierarchy.

An interesting interpretation of the laminar organization of neurons and axon terminals of different corticocortical connections has been proposed by Barbas (1986; Barbas and Rempel-Clower, 1997) for the connections in the monkey frontal cortex. This author claims that the laminar organization of a given connection can be predicted by the laminar organizations of the source and target areas. Most sensory areas have a classic organization with six layers and a well-identified layer 4 (or granular layer). In the frontal cortex, there are also “agranular” areas, lacking the characteristic layer 4, and several areas belonging to the limbic type of cortex with a dense population of neurons in the deep layers. It has been argued that evolutionary steps can be traced by

studying the laminar organization of different cortical regions, and that areas can be classed into different types, from ancient limbic-type cortex to agranular and to more recent granular cortex (Sanides, 1970). Barbas showed that the laminar organizations of corticocortical connections are related to the types of the source and target areas. Thus, areas of the granular type project from the supragranular layers and terminate mostly in the middle and deep layers to less laminated areas, whereas the return projections originate from the deep layers and preferentially target the upper layers (Barbas and Rempel-Clower, 1997). Thus, the differences between feedforward and feedback connections in occipital, parietal, and temporal cortex may simply reflect differences in organization between sensory cortices of the occipital cortex with well-differentiated structures (areas V1 and V2) and areas with less well differentiated structures in the parietal and temporal cortex. One advantage of this model is that it predicts the observed progressive shift toward projections from infragranular layers terminating at higher levels in the target area with increasing distance (in terms of levels of organization which reflect distance on the cortical surface).

Timing of activation in different areas

The hierarchical model of visual cortical areas suggests that information is processed through a succession of stages corresponding to the different levels of the hierarchy. This leads to the prediction that successive levels should contain neurons responding with increasingly long latencies to visual stimulation, the increase in latency reflecting processing occurring at the different levels. Direct tests of this hypothesis, however, have not confirmed such a model of a cascade of processors. Instead, important latency differences are observed between neurons of the dorsal and ventral streams. Although these are treated in detail in another chapter (Chapter 34), a rapid review is presented of the anatomical and functional differences between these two groups of areas.

DORSAL AND VENTRAL STREAMS An important subdivision of the visual system was proposed in the 1970s, that between structures subserving form and space vision. This separation was already present in the early models of the visual system based on the study of nonprimate species, with the superior colliculus involved in space vision and the visual cortex dealing with form vision (Schneider, 1969). A similar distinction was made between structures dealing with focal and ambient vision (Trevarthen, 1968). Since the beginning of the twentieth century, it was known that in humans, lesions in the parietal and temporal cortex lead to deficits in space and form vision, respectively. All these ideas were synthesized in the concept of two functional streams in the primate

visual cortex, with the ventral occipitotemporal stream dealing with form vision and the dorsal occipitoparietal stream involved in space vision. The success of this subdivision was established by the demonstration in the monkey of a double dissociation of the effects of lesions in the parietal and inferotemporal cortex (Pohl, 1973) that mirrored the clinical observations in humans, and by the tracing of anatomical connections between striate cortex and parietal and IT cortex (Ungerleider and Mishkin, 1982). The segregation of cortical connections into dorsal and ventral streams was confirmed by the results of mathematical models grouping together the most densely interconnected areas of the monkey (Jouve et al., 1998; Young, 1992).

Since then, questions have been raised concerning the roles of the two cortical streams. The initial idea was that the dorsal stream is involved in processing *where* an object is located in the visual field, whereas the ventral stream is engaged in the *recognition* of objects (the *where/what* division of Ungerleider and Mishkin, 1982). More recently, the emphasis has shifted to the visuomotor aspects of processing in the dorsal stream. In addition to dealing with where an object is located, the dorsal stream is important for grasping and manipulating an object (Goodale and Milner, 1992; Jeannerod et al., 1995). Despite these evolutions, the basic idea that parietal and IT cortex deal with different aspects of vision has stood the test of time. Anatomical studies partially confirmed this separation by showing that the two streams remain partially separate in the frontal cortex, and that there are regions of convergence in frontal cortex and in the depths of the superior temporal sulcus (Baizer et al., 1991; Bullier et al., 1996; Morel and Bullier, 1990).

THE FAST BRAIN In order to examine the flow of information transfer across the primate visual system, we collected the latencies of neurons to visual stimulation in the different visual areas, as published by research groups working on awake, behaving monkeys (Nowak and Bullier, 1997). As can be seen in Figure 33.6A, these latencies are only loosely correlated with their locations in the hierarchy of cortical areas. For example, neurons in the FEF area have latencies that are longer than those of area 17 by only a few milliseconds (Nowak and Bullier, 1997; Schmolesky et al., 1998), despite the six levels difference between the two areas (Fig. 33.5C). Similarly, latencies of neurons in MT and V2 are comparable (Raiguel et al., 1989; Fig. 33.6A), even though area MT is placed at three levels above V2 in the cortical hierarchy (Fig. 33.5C). On the other hand, areas MST, FEF, and 7a have much shorter latencies than areas of the IT cortex (e.g., TEa, TE1, TE2) that are at the same levels in the hierarchy (Fig. 33.6A).

A much better predictor of the latency to visual stimulation is whether the area is in the dorsal or ventral stream.

FIGURE 33.6. Temporal aspects of interactions between cortical areas. *A*, latencies of neurons in different cortical areas of the macaque monkey. These were behaving monkeys in all cases except (10). Small flashed stimuli were used in all cases except (7) and (12), for which motion onset was used.⁷ For each published study, the central bar represents the median and the extremities of the line represent the 10% and 90% centiles. Note that the FEF latencies are similar to those in V1 despite the large distance between these two areas in the cortical hierarchy (Fig. 33.5); the same is true of V2 and MT. Thus, the cortical hierarchy is a poor predictor of the

timing of activation of neurons in different cortical areas. *B*, cumulative distributions of visual latencies of neurons recorded in different visual areas in two anesthetized monkeys. [*A*: (1), Barash et al., 1991; (2), Baylis et al., 1987; (3), Bushnell et al., 1981; (4), Celebrini et al., 1993; (5), Funahashi et al., 1990; (6), Goldberg and Bushnell, 1991; (7), Kawano et al., 1994; (8), Knierim and Van Essen, 1992; (9), Maunsell and Gibson, 1992; (10), Nowak et al., 1995; (11), Perrett et al., 1982; (12), Raiguel et al., 1999; (13), Thompson et al., 1996; (14), Thorpe et al., 1983; (15), Vogels and Orban, 1994; *B* modified from Schmolesky et al., 1998.]

Areas of the dorsal stream tend to have short latencies to visual stimulation, whereas areas of the ventral stream have longer latencies. This is apparent in Figure 33.6*A*, with short latencies for areas MT, MST, FEF, and 7a and longer latencies for areas of the IT cortex (TEm, TEa, IT, Tpo, PGa, IPa, TE2, TE1, TAa, TS). A similar finding was reported by Leventhal and his collaborators (Schmolesky et al., 1998), who recorded neurons of many areas in the same animals

instead of pooling results from different published reports, as we had done. Their results are presented in Figure 33.6*B*: it is clear that neurons of areas V3, MT, MST, and FEF have very short latencies, which differ by only 5 msec from those in area V1, and that these latencies are much shorter than those observed in area V4, which belongs to the ventral stream. Similar results were found by simultaneous recordings in awake monkeys with microelectrodes implanted in numerous cortical areas (Schroeder et al., 1998). This difference between dorsal and ventral streams led us to propose the term *fast brain* (Fig. 33.6*A*) for the parietal cortex and FEF area (Nowak and Bullier, 1997).

⁷No difference was found between latencies to motion onset and to small flashed stimuli (Raiguel et al., 1999).

That neurons of the dorsal pathway respond rapidly to visual stimuli is in keeping with their role in visuomotor interactions: to correct a hand movement in time to catch a ball on a windy day, it is necessary to process visual information rapidly across the different cortical areas involved in the parietal and frontal cortex (Pisella et al., 2000). In contrast, areas of the ventral stream contain neurons with longer latencies to visual stimulation, in keeping with the role of this pathway in object recognition, for which speed is presumably less essential than for visuomotor interactions.

There is an interesting correlation between the short latencies of neurons in the dorsal stream and the rapidity of axons in this pathway. Staining for myelin reveals that the density of myelin is much higher in the gray matter of areas of the dorsal stream than in that of areas of the ventral stream, indicating a higher incidence on axonal ramifications of myelin sheaths that are known to increase conduction velocity (Nowak and Bullier, 1997). Indeed, the hallmark of area MT is the presence of a high density of myelin that has been observed in all primate species so far investigated. Also, it has been found that connections to the dorsal stream involve much higher densities of neurofilament protein than those to the ventral stream (Hof et al., 1996), indicating a much higher proportion of large, myelinated axons that conduct more rapidly than small axons (Nowak and Bullier, 1997). In particular, all V1 neurons projecting to area MT contain neurofilament protein (Hof et al., 1996), in keeping with the very fast conduction velocities of these axons (Movshon and Newsome, 1996).

The elevated level of neurofilament protein in callosal connections afferent to the border between areas V1 and V2 suggests that these connections are very rapid, a necessary condition given the long distance covered by callosal axons (Hof et al., 1997) and the necessity to integrate information rapidly across the two visual hemifields (Kennedy et al., 1991). The high proportion of neurofilament protein in the feedback connections from all cortical areas (Hof et al., 1996) strongly suggests that these connections are fast. Indeed, we found that in the rat as well as in the monkey, feedback connections are matched in conduction speed to feedforward connections (Girard et al., 2001; Nowak et al., 1997). This means that information is transferred as rapidly in the feedforward as in the feedback direction.

Functional roles of feedforward and feedback connections

FEEDFORWARD CONNECTIONS A number of functional studies have attempted to discover the role of feedforward connections by reversibly inactivating the source area of the connection and recording single units in the target area. In the cat, the early work was intended to probe the differences

between the visual systems of cats and primates. In cats, as in other nonprimate mammalian species, inactivating or lesioning area 17 does not lead to a complete cessation of visual responses in other visual cortical areas (see Bullier et al., 1994, and Salin and Bullier, 1995, for review), in contrast to the results reported in monkeys (see below).

The specific role of the feedforward connections from area 17 to area 18 cells in the cat was assessed by methods comparing visual responses before and during reversible inactivation of area 17. Inactivation of a large region of area 17 produced a general decrease of visual responses in numerous area 18 neurons, with a few specific effects (Sherk, 1978). In particular, it was noted that the effects of area 17 inactivation were more pronounced for low-stimulus velocities, in keeping with the finding of Dreher and Cottee (1975) that cells in area 18 are tuned to higher velocities after lesioning of area 17. These results suggest that feedforward inputs from area 17, which contains cells tuned to lower velocities than area 18 (Orban et al., 1981), potentiate the responses of area 18 neurons to low-velocity stimuli.

Similar methods were used to investigate the role of feedforward connections from area 17 to area 21a in the cat (Michalski et al., 1993). Inactivation of large regions of areas 17 and 18 led to a strong decrease in the response of many area 21a neurons and a complete silencing of others. It is quite remarkable that the orientation selectivities of area 21a neurons were retained even when the inactivation of area 17 led to an almost total cessation of the responses. This suggests that area 17 neurons providing feedforward connections to area 21a are very homogeneous in their orientation selectivity, in keeping with the homogeneous character of feedforward connections, as discussed earlier. There is also the possibility that specific mechanisms strengthen orientation selectivity within area 21a.

Some recent studies have used more localized inactivation techniques, and their conclusions point to a specific role for feedforward connections. Molotchnikoff and his colleagues presented evidence for changes in direction selectivity in many simple cells in area 18 during inactivation of a small zone of area 17 a few hundred microns wide. In most cases, this effect was due to a selective decrease in the response to the optimal direction and, in a few cases, to an increase in the nonpreferred direction (Casanova et al., 1992). They also demonstrated that local inactivation of area 17 produced changes in orientation tuning curves in area 18 neurons and that the effects were specific for the cell type (simple or complex cells) (Chabli et al., 1998). Such results confirm that feedforward connections can have a very strong driving input into cortical neurons and that they are organized in a precise column-to-column fashion. It is, however, difficult to deduce from these studies that specific properties such as direction or orientation selectivity are entirely set up by feed-

forward inputs from area 17 to area 18. Indeed, the reported changes with localized inactivation of area 17 could be due to a loss of balance between the excitatory inputs coming from different columns in area 17 converging on the recorded neurons in area 18.

The driving role of feedforward connections in the cat has been confirmed by the work of Vanduffel and collaborators (1997): in awake cats, they used radioactive 2-deoxyglucose to assess the residual neural activity in visual areas during reversible inactivation by cooling cortical areas in the suprasylvian sulcus. The results show strong decreases in activity in areas that receive feedforward connections from areas of the suprasylvian sulcus, in contrast to areas receiving feedback connections, which show a smaller decrease in activity.

In the monkey, our knowledge of the role of feedforward connections is mostly derived from the results of reversible inactivation or lesioning in area V1 and their effects on responses in other cortical areas. In contrast to the results obtained in the cat, inactivation or lesioning of V1 leads to a complete cessation of activity in a number of cortical areas belonging mostly to the ventral or occipitotemporal stream that channel information from V1 to the IT cortex (see the review by Bullier et al., 1994). In contrast, areas of the dorsal occipitoparietal stream remain visually responsive in the absence of input from area 17. At least in the case of area MT, the residual input is channeled through the superior colliculus (see the review in Bullier et al., 1994).

The present consensus is that feedforward connections carry the drive of lower-order areas and that the selectivities of neurons in higher-order areas result at least in part from the converging feedforward inputs of neurons in lower-order areas. This is well illustrated by the study of Movshon and Newsome (1996), who found that the neurons in V1 that project to area MT have receptive fields exactly superimposed on those of the recipient neurons. A similar result had been found earlier in the cat visual system (Bullier et al., 1988; Henry et al., 1978). These studies also produced interesting results concerning the cell type that projects to a given area. Both in the cat (Henry et al., 1978) and in the monkey (Movshon and Newsome, 1996), neurons that send feedforward connections away from area V1 appear to belong to a relatively homogeneous population of neurons in terms of functional properties. The findings of Sherk concerning the patchy organization of area 17 inputs to PMLS described above (Sherk, 1990; Sherk and Ombrellaro, 1988) are also consistent with such a role of convergent feedforward inputs.

This suggests that feedforward connections are important for carrying the visual drive from one neuronal population to the next and that their arrangement is important for shaping the selectivities of neurons in higher-order areas.

Thus, feedforward connections would belong to the “driver” category of the classification of connections⁸ by Sherman and Guillery (1998) and Crick and Koch (1998).

It should be noted, however, that the selective properties of cortical neurons are unlikely to be explained entirely by the properly arranged convergence of feedforward connections. This question has been central to the controversy concerning the mechanisms underlying the orientation and direction selectivity of area 17 neurons: do they result from the arrangement of their thalamic inputs, as predicted by Hubel and Wiesel (1962), or are they shaped mainly by the local network of horizontal connections? Until recently, the presence of inhibitory inputs to cortical neurons proved to be elusive, and it was thought that the orientation selectivity in area 17 neurons results mainly from the convergence of excitatory thalamic inputs (Douglas et al., 1991; Ferster et al., 1996; Hubel, 1996). This conclusion changed with the discovery of strong shunting inhibitory inputs into cortical cells (Borg-Graham et al., 1998) and the demonstration that local cortical inactivation has strong and specific effects on the orientation tuning curves of cortical cells (Crook et al., 1997). The results of Grinvald’s group with optical imaging techniques are also consistent with a major role for local horizontal connections: they showed that an area 17 neuron gives spikes when the network of interconnected cortical patches is activated. Most remarkably, this was observed for visually driven as well as spontaneous activity (Tsodyks et al., 1999). This suggests that local horizontal connections have a major impact on the excitability of cortical neurons and that the response of a neuron in area 17 cannot be explained simply by the simultaneous firing of converging afferent thalamic neurons. Instead, it appears that the cortical network controls the excitability of the cell and that the thalamic input mostly acts as a trigger. It remains to be seen whether interactions similar to those between thalamocortical and horizontal connections are observed between feedforward, horizontal, and feedback corticocortical connections.

FEEDBACK CONNECTIONS

Effects on responses to receptive field center stimulation. Fewer experiments have been devoted to uncovering the role of feedback connections. Several groups have inactivated large portions of a higher-order cortical area to assess the role of feedback connections in anesthetized animals. All concluded that feedback connections mostly tend to facilitate the

⁸In the distinction between drivers and modulators, driver connections are relatively rare and have strong, focused, rapid effects on their target neurons. Modulators have symmetrical properties: they are numerous and have weak, slow, diffuse actions.

responses of neurons in lower-order areas. Sandell and Schiller (1982) inactivated by cooling a region of area V2 in the squirrel monkey and reported effects on a third of the neurons in area V1. Most effects were decreases in responses to visual stimulation and were strongest in the infragranular layers. These results are in keeping with those of Mignard and Malpeli (1991), who concluded that feedback connections from area 18 exert a predominantly facilitatory effect upon neurons in area 17 in the cat. Similar conclusions were recently reached by Dreher and his collaborators concerning the feedback connections from area 21a to area 17 in the cat (Wang et al., 2000) and by our group concerning the feedback connections from area MT to areas V1, V2, and V3 in the monkey (Hupé et al., 1998). In general, effects were observed for a fraction of the population of recorded neurons (10% to 40%). In addition, no clear effects have been reported on orientation tuning curves during inactivation of higher-order areas (Wang et al., 2000).

Overall, inactivating feedback connections produce smaller effects than those for feedforward connections: a smaller proportion of neurons are affected, and the response changes are less dramatic. Only in very rare cases does inactivation of a cortical area lead to a complete cessation of responses in an area receiving feedback connections, as is the case for feedforward connections to the ventral stream in the monkey. As mentioned above, a direct comparison between the effect of inactivating area PMLS on cortical areas receiving feedforward and feedback connections from that area has been done (Vanduffel et al., 1997). The results show that both feedforward and feedback connections have a net excitatory role on their target areas but that the effects are stronger for areas receiving feedforward connections than for those receiving feedback connections.

Not only do feedback connections have a weaker effect on their target neurons than feedforward connections, they also do not appear to be able to drive neurons in the absence of a feedforward drive. Several lines of evidence support this conclusion. In the monkey, numerous neurons in area MT remain visually responsive when V1 is inactivated (Girard et al., 1992; Rodman et al., 1989), and there are strong feedback projections from area MT to V2 (Kennedy and Bullier, 1985). These feedback connections appear unable to drive V2 neurons when they are deprived of their feedforward drive from V1 because all V2 neurons are silenced when V1 is inactivated (Girard and Bullier, 1989; Schiller and Malpeli, 1977). Another line of evidence comes from the observation that, despite the wide spatial convergence of feedback connections (Fig. 33.3), the potentiating effect of feedback connections is present only for the excitatory center of the receptive field (Hupé et al., 2001a), which presumably reflects the converging feedforward inputs.

Such a nonlinear interaction between feedforward and feedback connections is also suggested by the results of

Mignard and Malpeli (1991) in the cat. They compared the effects of inactivating the A layers of the LGN on the responses of neurons in upper layers of area 17 when area 18 is intact or lesioned. When area 18 is intact, most neurons in the upper layers of area 17 retain strong visual responses when the A layers are inactivated (Malpeli, 1983). This contrasts with the strong decrease in the visual responses of these neurons during inactivation of the A layers when area 18 had been lesioned (Mignard and Malpeli, 1991). Without LGN blocking, direct inactivation of area 18 produces a mild response decrease in area 17 cells (Sherk, 1978). Thus, both the feedforward input from the A layers of the LGN and the feedback input from area 18 each has a relatively weak influence on the upper layer neurons of area 17, but their combination has a dramatic effect on the visual responses.

This suggests that feedback connections potentiate the responses of neurons in lower-order areas by nonlinear mechanisms such as gain control. This effect is particularly evident for weak responses, as seen in intracellular recordings (Shao and Burkhalter, 1999, their Figure 7), as well as in extracellular recordings (Bullier et al., 2001). An interesting possibility is that this nonlinear mechanism is used to gate the flow of different circuits in lower-order areas, thus allowing higher-order areas to reorganize processing in lower-order areas.

More specific effects of feedback inactivation were demonstrated by Alonso and his collaborators, who blocked a small region of layer 5 of area 18 while recording in layer 5 of area 17 in the cat (Alonso et al., 1993a, 1993b). The effects were strong and frequent when they inactivated area 18 neurons with overlapping receptive fields and the same properties as those of the recorded neurons in area 17. Effects were observed on the orientation tuning curves and on the speed selectivity of the neurons. Some effects were compatible with a facilitatory action of the feedback, and others suggested an inhibitory effect. The specificity of the demonstrated effect was particularly striking in the case of speed selectivity: Alonso and coworkers demonstrated that 40% of the neurons in layer 5 of area 17 increased their responses to high velocities when the corresponding region of layer 5 of area 18 was blocked (Alonso et al., 1993a, 1993b). This result suggests that the preference for low stimulus velocities of neurons in layer 5 of area 17 is due, at least in part, to an inhibitory input from area 18 neurons that are known to respond to high velocities. Thus, at least in that particular case, feedback connections appear to play a role in sharpening the selectivity of neurons in another cortical area.

The results of Alonso and his colleagues make the important point that feedback connections can have very specific effects and are not limited to the diffuse, unselective role that is often attributed to them. Similar experiments conducted

on the interactions between the upper layers of A18 and the upper layers of area 17 produced more variable results (Martinez-Conde et al., 1999) on orientation tuning curves of area 17 neurons. As argued above for the work of Casanova and collaborators (1992) on feedforward connections, such results could be due to the fact that only a small region of area 18 was inactivated, thus possibly producing a loss of balance of different converging inputs.

Feedback influences on center-surround interactions. So far, we have examined the contribution of feedback connections to the response of the receptive field center. However, the important degree of spatial divergence and convergence of these connections (Fig. 33.3) suggests that they might regulate the strength of center-surround interactions. This is indeed what was found in our study of the role of feedback connections from area MT to areas V1, V2, and V3. Feedback connections appear to potentiate the strength of the inhibitory influence of the receptive field surround on the response generated by stimulating the receptive field center (Bullier et al., 2001; Hupé et al., 1998). However, this effect was found to be specific for stimuli of low salience (a low-contrast bar moving on a noisy background). When the stimulus was of high salience (a high-contrast bar moving on a low-contrast, noisy background), the contribution of the MT feedback to the center-surround inhibitory interactions was small. This is in keeping with the lack of effect of feedback connections from V2 to V1 on center-surround interactions in V1 neurons for high-salience stimuli (Hupé et al., 2001b).

The relative roles of horizontal and feedback connections in shaping the modulatory regions of the receptive field surround of a cortical neuron is a subject of debate (Angelucci and Bullier, 2003; Bullier et al., 2001). It appears that the spatial extent of horizontal connections is too small to carry information from more than a few millimeters away on the cortical surface. Because of the high magnification factor in the central visual field, a few millimeters on the surface of area 17 represent only a few tenths of a degree of visual angle. This is much smaller than the size of the receptive field surround of most V1 neurons (Angelucci et al., 2002; Cavanaugh et al., 2002; Levitt and Lund, 1997). This distance in visual field is also far too small to explain the large extent of the interaction field beyond the receptive field center demonstrated by using colinear lines in a noisy background (Ito and Gilbert, 1999; Kapadia et al., 1995). Thus, it is impossible that monosynaptic horizontal connections can entirely subserve the far-reaching contextual effects demonstrated in area 17. One possibility is offered by multisynaptic information transfer through horizontal connections. However, horizontal connections are much too slow (Girard et al., 2001) to account for the rapid contextual effects seen in responses of neurons in area 17 (Ito and Gilbert, 1999). Because of the high conduction velocity of

feedforward and feedback axons (Girard et al., 2001) and the large spatial convergence and divergence of feedback connections (Fig. 33.3), it is likely that the latter play a major role in shaping the long-range center-surround interactions in the receptive fields of cortical neurons. Experiments are needed to test this prediction directly on behaving animals performing a visual task requiring attention to long-range interactions across the visual field, such as those used by Gilbert and his colleagues (2000).

Feedback influences on the synchrony of neurons in lower-order areas. A number of studies have shown that interconnected cortical neurons tend to synchronize the time of emission of their action potentials (see the review by Nowak and Bullier, 2000). As mentioned above, neurons in a given cortical column exchange reciprocal connections with several columns in other cortical areas. The exact cell-to-cell connectivity within this column-to-column network is not known, but it is likely to be similar to that of intrinsic connections: each axon gives only a few contacts to some neurons in a column, and each neuron in a target column receives convergent input from several neurons. In that case, a powerful way to modulate transfer from one column to another is to synchronize the spike discharges of the neurons belonging to the source column or to change the firing pattern from regular to bursty. In accord with this possibility, it has been proposed that feedback corticogeniculate connections switch the firing mode from bursting to tonic in LGNs through activation of metabotropic receptors (Godwin et al., 1996). The results of Sillito and his group (1994) further indicate that feedback corticothalamic connections synchronize the firing of LGN neurons. However, recent results suggest that there may be an important effect of feedback connections on slow modulation of rate changes instead of a direct effect on spike-to-spike synchronization (Brody, 1998) and specific effects on the receptive-field center mechanism (Rivadulla et al., 2002).

For corticocortical feedback connections, lesion studies showed that when higher-order areas are lesioned in the cat, certain types of synchronization between neurons located in lower-order cortical areas in the opposite hemisphere disappear (Munk et al., 1995). This suggests that feedback connections are involved in the synchronization of activity in neurons of lower-order cortical areas. We tested this hypothesis directly by measuring changes in the synchronization of spike firing induced by inactivating higher-order areas. We found changes in the cross-correlograms and the auto-correlograms of neighboring neurons showing changes in response strength (J. M. Hupé, P. Girard, and J. Bullier, unpublished observations). However, we never observed a change in the strength of the cross-correlogram peaks when there was no change in firing rate in at least one of the neurons. Therefore, despite its attractiveness, the idea that

feedback connections control specifically the synchronization of lower-order neurons independently of their firing rate does not seem tenable at the moment. On the other hand, it would be interesting to determine whether inactivation or activation of a higher-order area leads to a change in the firing pattern of neurons in a lower-order area in a similar way to the conclusions reached by Sherman and his collaborators for the corticogeniculate feedback connections (Godwin et al., 1996).

Figure-ground segregation, attention, top-down activation by internal images. A role for feedback connections in attention has been postulated in many studies but has not been directly tested. Attending to a visual stimulus increases the gain of neuronal responses in most visual cortical areas (Reynolds et al., 2000; Treue and Maunsell, 1999). These effects are strongest for low-contrast stimuli and weak for high-contrast stimuli (Reynolds et al., 2000). This is reminiscent of the effects of inactivating area MT on the responses of neurons in areas V1, V2, and V3 which were strongest for low-salience stimuli, as reviewed above (Bullier et al., 2001; Hupé et al., 1998). It is therefore possible that the mechanisms revealed by inactivation of feedback connections may be at play during modulation of the sensitivity of lower-order areas by spatially directed attention.

It has been claimed that feedback connections play a role in the modulation of responses of neurons in V1 when their receptive field is inside a square object that pops out from the background because of its difference in the orientation of the lines composing the pattern or movement direction of random dots (Lamme, 1995; Lamme et al., 1998; see, however, Rossi et al., 2001). The argument rests on the observation that such modulatory effects are delayed by 40–100 msec with respect to the beginning of the response and that these effects disappear during anesthesia. However, given that higher-order area neurons can have very short latencies (as reviewed above) and that feedback effects appear to be extremely rapid (Hupé et al., 2001a), it is not clear that delayed response modulations are necessarily due to feedback influences. The disappearance of the effect during anesthesia does not speak to the source of the effects, since several studies reviewed above show that clear influences of feedback connections can be revealed during anesthesia. Whether the modulatory effects corresponding to popout are transferred from higher-order areas by feedback connections remains to be tested by directly influencing the responses of neurons in higher-order areas.

A recent study of Myiashita and his group demonstrated a role that has been long suspected for feedback connections: that of activating lower-order area neurons with top-down signals conveying information about categorization of visual images (Tomita et al., 1999). By using a split brain preparation, they were able, in IT cortex neurons, to distinguish

activation by feedforward connections from the drive by feedback connections from the frontal cortex. This is the first direct evidence that feedback connections carry signals corresponding to internal images to lower-order areas of the visual system.

Conclusion

The functions of different types of corticocortical connections are beginning to be more precisely known. The differences at the synaptic level, and the relative functions of feedforward and horizontal connections in shaping the receptive field properties of visual neurons, remain to be determined. The role of feedback connections in modulating the gain control of neurons in low-order areas also needs to be tested directly. To understand the role of feedforward and feedback connections in vision, it will be necessary to develop methods to activate and inactivate cortical neurons while the animal performs various tasks of visual detection and discrimination.

34 Ventral and Dorsal Cortical Processing Streams

LESLIE G. UNGERLEIDER AND TATIANA PASTERNAK

MUCH OF OUR DETAILED knowledge of visual cortical organization derives from anatomical and physiological studies of the brains of Old World monkeys, of the genus *Macaca*, in which over 50 separate visual areas have now been described (Felleman and Van Essen, 1991). Similar visual areas and processing stages are now known to exist in both New World species and humans, and thus likely represent a common primate plan. In understanding the contributions of these multiple, functionally distinct visual areas, it is useful to describe two principles of cortical organization. The first principle is that the multiple visual cortical areas are organized into processing streams. According to the model originally proposed by Ungerleider and Mishkin (1982), there are two major processing streams, both of which originate in the primary visual cortex (striate cortex), V1, and both of which consist of multiple extrastriate areas beyond V1: the ventral stream is directed into the temporal lobe and is crucial for the visual recognition of objects, whereas the dorsal stream is directed into the parietal cortex and is crucial for appreciating the spatial relationships among objects and visual guidance toward them (Fig. 34.1A). A simple way to conceptualize the two streams is *what* versus *where*.

The original evidence for separate processing streams for *what* versus *where* was based on the contrasting effects of inferior temporal and posterior parietal cortex lesions in monkeys (for review, see Ungerleider and Mishkin, 1982). Lesions of inferior temporal cortex cause severe deficits on a wide range of visual discrimination tasks (e.g., discriminating objects, colors, patterns, and shapes), but these lesions do not affect animals' performance on visuospatial tasks (e.g., visually guided reaching and judging which of two objects lies closer to a visual landmark). Conversely, posterior parietal lesions do not affect visual discrimination ability but instead cause severe deficits on visuospatial performance (Fig. 34.1B). As will be described in more detail later, physiological studies of cell properties also support the functional distinction between the ventral and dorsal streams. Neurons in areas within the ventral stream respond selectively to visual features relevant for object identification, such as color, shape, and texture, whereas neurons in areas within the dorsal stream instead respond selectively to spatial

aspects of stimuli, such as the direction and speed of stimulus motion, as well as to tracking eye movements (for reviews, see Desimone and Ungerleider, 1989; Maunsell and Newsome, 1987; Merigan and Maunsell, 1993).

The second principle of cortical organization is that within each of the two processing streams, visual areas form processing hierarchies. Anatomical studies have shown that virtually all connections between successive pairs of areas within the ventral stream are reciprocal, that is, projections from one area to the next are reciprocated by projections from the second area back to the first (Felleman and Van Essen, 1991). Yet, in spite of this reciprocity, much of the processing appears to be sequential (e.g., see Desimone and Ungerleider, 1989; Desimone et al., 1985; Maunsell and Newsome, 1987; Van Essen and Maunsell, 1983). For example, neuronal response latencies found in physiological recordings increase steadily as one proceeds from the primary visual cortex (V1) toward the temporal lobe (Nowak and Bullier, 1997). Likewise, the average receptive field (RF) size increases as one moves along the ventral stream (Desimone and Gross, 1979; Gattass et al., 1981, 1988), consistent with the notion that the RFs of cells in later areas are built up from those in earlier areas. Like the ventral stream, the earlier stations of the dorsal stream, including the "motion-sensitive" areas within the superior temporal sulcus (STS), also have a hierarchical organization. Within the parietal lobe portion of the dorsal stream, by contrast, the hierarchy likely gives way to parallel processing among numerous small cortical areas (Fig. 34.2). As we will describe later, some aspects of visual processing are indeed parallel, but much of this parallel processing takes place within each cortical area rather than across areas.

It is thus possible to view much of the neural mechanism for vision, especially object vision, as a bottom-up process in which low-level inputs provided by the retina are transformed into more useful representations through successive stages of processing. In the first part of this chapter, we will describe the anatomical arrangement of components of both the ventral and dorsal streams in monkey cortex. Next, we will consider the physiological properties of neurons in each of the streams, with a focus on emergent neuronal properties as one proceeds from low-level to high-level areas.

FIGURE 34.1. Two visual processing streams in monkey cortex. *A*, According to the model originally proposed by Ungerleider and Mishkin (1982), both streams originate in primary visual cortex (V1) and both consist of multiple visual areas beyond V1. The ventral stream is directed into the temporal lobe, area TE, and is crucial for the visual recognition of objects, whereas the dorsal stream is directed into the parietal lobe, area PG, and is crucial for appreciating the spatial relationships among objects and for the visual guidance toward them. *B*, The original evidence for separate processing streams was based largely on the contrasting effects of inferior temporal and posterior parietal lesions in monkeys. Lesions of inferior temporal cortex (*left*, in *black*) cause impairments on visual discrimination tasks, such as recognizing an object seen a few seconds previously, whereas posterior parietal lesions (*right*, in *black*) cause impairments on visuospatial tasks, such as judging which of two identical plaques is located closer to a visual landmark—the cylinder. *C*, Lateral view of the monkey brain with the sulci partially opened to illustrate the location of the multiplicity of functionally distinct visual areas that comprise the ventral and dorsal processing streams. For a list of abbreviations, see Table 34.1. (*A* adapted from Mishkin et al., 1983; *B* adapted from Ungerleider and Mishkin, 1982; *C* adapted from Distler et al., 1993.) (See color plate 17.)

We will also describe the behavioral effects of selective lesions of the two streams. Then we will describe interactions between the two processing streams, as well as the differential projections from them to regions within prefrontal cortex, and the role these areas play in vision. Finally, we will conclude with evidence for the existence of homologous visual processing streams in the human cortex.

Anatomical organization of ventral and dorsal processing streams

Much of our knowledge of the areas that comprise the ventral and dorsal streams comes from anatomical tract-tracing studies in nonhuman primates. These studies have demonstrated that regions that make up the ventral stream lie directly anterior to V1 in the occipital lobe and in progressively more anterior and ventral portions of the temporal lobe, whereas regions that make up the dorsal stream also include these early occipital-lobe areas but then occupy sites within the posterior STS and include progressively more anterior sites within this sulcus and more dorsal sites within the parietal lobe. Figure 34.1*C* illustrates the location of these areas within the cortex, and Figure 34.2 diagrams their anatomical connections (see Table 34.1 for a list of abbreviations).

The cortical analysis of objects begins in V1, where information about contour orientation, color composition, brightness, and direction of motion is represented in subsets of neurons responsible for each point in the visual field (Livingstone and Hubel, 1984; Tootell et al., 1988; Ts'o and Gilbert, 1988). Information from V1 is then sent forward to subdivisions or *modules*—interdigitating thin, thick, and interstripe regions—within V2 (Livingstone and Hubel, 1984, 1987). From the thin and interstripe regions in V2, representing mainly color and form information, respectively (De Yoe and Van Essen, 1985; Hubel and Livingstone, 1985, 1987; Livingstone and Hubel, 1984; Shipp and Zeki, 1985), neural signals proceed forward to area V4 on the lateral and ventromedial surfaces of the hemisphere and to a posterior inferior temporal area just in front of V4, area TEO (Gattass et al., 1997; Nakamura et al., 1993). From both V4 and TEO, signals related to object form, color, and texture proceed forward to area TE (Desimone et al., 1980; Distler et al., 1993), the last exclusively visual area within the ventral stream for object recognition (Desimone and Gross, 1979). Together, areas TEO and TE comprise inferior temporal (IT) cortex.

Progressing forward along the ventral stream, there is a gradual shift in the nature of connectivity. Patterns of cortical projections become successively less topographic or *point-to-point*. For example, while connections from V1 to V2 maintain topographic order, they are looser between V2 and V4, and inputs to area TE from V4 and TEO retain no obvious retinotopic organization (Desimone et al., 1980; Distler et al., 1993; Gattass et al., 1997; Livingstone and Hubel, 1983; Rockland and Pandya, 1979). This loss of retinotopy within area TE means that single neurons respond to objects anywhere in the visual field. Thus, explicit information about the spatial location of an object is not retained at the highest levels of the ventral stream.

FIGURE 34.2. Anatomical connections of visual areas in the ventral and dorsal streams. Solid lines indicate connections arising from both central and peripheral visual field representations, whereas dotted lines indicate connections restricted to peripheral field representations. Red boxes indicate ventral stream areas associated primarily with object vision; green boxes indicate dorsal

stream areas associated primarily with spatial vision; and yellow boxes indicate areas not clearly allied with either stream. The shaded region on the lateral view of the monkey brain indicates the extent of the cortex included in the diagram. For a list of abbreviations, see Table 34.1. (Adapted from Ungerleider, 1995.) (See color plate 18.)

The cortical analysis of spatial perception also begins in V1, deriving largely from the motion-sensitive cells in layer 4B (Maunsell and Van Essen, 1983a). In turn, cells in layer 4B project primarily to the thick stripes within V2 (Roe and Ts'o, 1995; Zeki and Shipp, 1987) and to V3, where direction of motion information is retained. Together, these three early visual areas provide the input to the middle temporal visual area, MT (Ungerleider and Desimone, 1986), also known as the *motion-sensitive area* of the STS. From MT, information is sent forward within the STS to several additional motion-sensitive areas, including MST (the medial superior temporal area) and FST (the fundus of the superior temporal area; Maunsell and Van Essen, 1983a; Ungerleider and Desimone, 1986), both of which project to area STP (the superior temporal polysensory area) located farther forward on the upper bank of the STS (Boussaoud et al., 1990). Inasmuch as portions of STP also receive ventral stream inputs, these regions may serve as anatomical sites for the integration of visual information about form and motion.

MT is also the source of information for VIP (the ventral intraparietal area; Ungerleider and Desimone, 1986), which in turn projects to several additional parietal areas, including LIP (lateral intraparietal area) and area 7a, located in the inferior parietal lobule (Andersen et al., 1990a; Blatt et al., 1990; Boussaoud et al., 1990). Interestingly, a number of these parietal areas receive direct inputs from the peripheral field representations of V1 and V2, bypassing MT (e.g., Colby et al., 1988), and these inputs may provide rapid activation of regions mediating spatial attention.

Neural processing is not, however, a simple matter of successive elaboration of information from lower-order to higher-order areas. As described earlier, at all stages connections are reciprocal. For example, an area receiving feedforward projections from an area earlier in the ventral stream also provides feedback projections to that area. Whereas feedforward projections provide bottom-up, sensory-driven inputs to subsequent visual areas, and severing these projections disconnects subsequent areas from their

TABLE 34.1
Visual areas in the cortex of monkeys.

Areas with Abbreviations	
DP	dorsal prelunate area
FST	fundus of the STS area
LIP	lateral intraparietal area
MT	middle temporal area
MT _p	MT, peripheral visual field representation
MST	medial superior temporal area
MST _c	MST, central field representation
MST _p	MST, peripheral field representation
PO	posterior occipital area
PP	posterior parietal area
STP	superior temporal polysensory area
VP	ventral posterior area
VIP	ventral intraparietal area
VTF	visually responsive portion of area TF
V1	primary visual (striate) cortex
V2	second visual area
V3	third visual area
V3A	third visual area, part A
V4	fourth visual area
Brodmann (1909) Areas	
7a	inferior parietal
46, 9	dorsolateral prefrontal
45, 12	ventrolateral prefrontal
11, 13	orbital frontal
von Bonin and Bailey (1947) Areas	
PG	inferior parietal
TF	parahippocampal
TEO, TE	inferior temporal
TG	temporal polar

Rostral superior temporal sulcus (STS) areas TPO, PGa, IPa, TEa, and TEm are from Seltzer and Pandya (1978).

visual input (Rocha-Miranda et al., 1975; Schiller and Malpeli, 1977), the precise functions of the reciprocal feedback projections are still unknown. However, they are thought to play a top-down role in vision, such as in selective attention, by modulating activity in earlier areas of the processing stream. In addition to feedforward and feedback projections, there appear to be “intermediate-type” projections that link areas at the same level of the visual hierarchy. These are seen most notably between areas of the ventral and dorsal streams. For example, area V4 is interconnected with areas MT and MST (Maunsell and Van Essen, 1983a; Ungerleider and Desimone, 1986). Thus, there exists an anatomical substrate for interactions between the two processing streams at several levels, which we will discuss when we consider the physiological properties of neurons within the ventral and dorsal streams.

All areas within the ventral and dorsal streams also have heavy interconnections with subcortical structures, including the pulvinar, claustrum, and basal ganglia (Baizer et al., 1993; Benevento and Davis, 1977; Benevento and Rezak, 1976; Boussaoud et al., 1992; Kemp and Powell, 1970; Saint-Cyr et al., 1990; Selemon and Goldman-Rakic, 1985; Ungerleider et al., 1983, 1984; Webster et al., 1993). In addition, each stream receives subcortical modulatory inputs from ascending cholinergic projections from the basal forebrain and ascending noradrenergic projections from the locus coeruleus (Gatter and Powell, 1977; Mesulam and Van Hoesen, 1976; Webster et al., 1993). These projections are thought to play a role in the storage of information in cortex and the influence of arousal on information processing, respectively. Finally, visual information is sent from the last stations of both streams to the most ventral and anterior reaches of the temporal lobe, notably perirhinal cortex and parahippocampal areas TF and TH (Van Hoesen, 1980, 1982). These regions in turn project, via entorhinal cortex, to medial temporal lobe structures, such as the hippocampus, which contribute to forming long-term memories of visual objects and their contexts. Information is also sent from both streams to prefrontal cortex (Barbas and Mesulam, 1985; Cavada and Goldman-Rakic, 1989; Chavis and Pandya, 1976; Ungerleider and Desimone, 1986; Ungerleider et al., 1989; Webster et al., 1994), which plays an important role in working memory (Fuster, 1995; Goldman-Rakic, 1990), that is, holding an object and its location briefly in mind when it is no longer visible. Finally, there are direct projections from the ventral stream to the amygdala (Webster et al., 1993), which is important for attaching emotional valence to a stimulus, and from the dorsal stream to the pons (Boussaoud et al., 1992), which, in conjunction with the cerebellum, likely contributes to the control of eye and head velocity during tracking eye movements.

Neuronal properties within the ventral stream

CELLS ARE SENSITIVE TO INCREASINGLY COMPLEX OBJECT FEATURES Consistent with a role in object recognition, neurons in all areas of the ventral stream share a number of physiological characteristics, including sensitivity to the shape, color, or texture of visual stimuli. Progressing forward along the pathway, there is a general trend toward selectivity for increasingly complex stimulus features or combinations of features. For example, whereas many V1 neurons function as local spatial filters (e.g., signaling the presence of contours at particular positions in the visual field), some V2 cells respond to so-called illusory contours of whole figures (von Der Heydt et al., 1984); a V2 cell selective for the horizontal orientation of an edge placed in its RF may respond similarly to an edge that is perceptually suggested by stimu-

lation of surrounding regions but not physically present. Other cells in V2 are jointly selective for wavelength and small dimensions of stimuli (Baizer et al., 1977; Hubel and Livingstone, 1987); such cells represent an early stage of integration of stimulus features. Moving forward to V4, the trend continues such that a greater proportion of cells are conjointly tuned for multiple dimensions of a stimulus (such as length, width, disparity, and/or wavelength of a bar of light (Cheng et al., 1994; Desimone and Schein, 1987; Desimone et al., 1985; Hinkle and Connor, 2001; Watanabe et al., 2002). In addition, about a third of the neurons in V4 show selectivity to contour features such as curves and angles (Gallant et al., 1996; Pasupathy and Connor, 1999), suggesting an intermediate stage of processing.

Another important property of V4 neurons is the existence of large, silent suppressive zones surrounding the excitatory RFs of cells (Desimone and Schein, 1987; Desimone et al., 1985). These zones are termed *silent* because stimulation of the zones does not normally cause any change from the cell's baseline activity but can have a powerful effect on the response to a stimulus placed in the RF (what is now called by many the *classical* RF). The stimulus-selective properties of the excitatory RF and the suppressive surround are often matched. As a consequence, many V4 cells respond maximally to a stimulus only if it stands out from its background on the basis of a difference in form. This sensitivity to RF/surround differences is thought to be useful for figure/ground segregation—the parcellation of scenes into a collection of objects within them.

Moving forward successively into area TEO and then into posterior and anterior portions of area TE, there is a further increase in the complexity of the critical features needed to activate many neurons and an increase as well in the proportion of cells that are selectively driven by some kind of complex pattern or object (Desimone et al., 1984; Gross et al., 1972). Indeed, many cells in TE require moderately complex features for their activation (Tanaka, 1997). Importantly, the critical features that drive single cells are typically not complex enough to specify a particular object. To represent individual objects instead requires activation of a few to several tens of cells with different critical features.

The work of Tanaka and colleagues has shown that a key property of TE is that it is composed of columns, in many ways similar to those in V1, in which cells with related but slightly different selectivity cluster together (Tanaka, 1993). For example, some cells in a column responsive to faces might respond optimally to different face components, while others might be sensitive to the overall configuration of a face regardless of viewpoint, and still others might respond well to faces specifically in profile. Thus, a given object feature is apparently not represented by the activity of a

single cell, but by the activity of many cells within a column. Representation by multiple cells in a column in which the selectivity varies, but overlaps, from cell to cell satisfies two apparently conflicting requirements in visual recognition: robustness to subtle changes in input and precision of representation. Given this clustering of cells responsive to related features, an object in its entirety would then be represented by a pattern of activity distributed across multiple columns, each of which may participate in representing multiple objects. Whereas the image of an object projected on the retina changes in response to variations in illumination and viewing angle, the pattern of activity in TE should be largely maintained, insofar as the clustering of cells with overlapping but slightly different selectivity should serve as a buffer to absorb such changes.

SOME CELLS IN THE INFERIOR TEMPORAL CORTEX ARE FACE SELECTIVE One of the more striking characteristics of monkey temporal cortex is the presence of neurons with responses selective for face stimuli, first described by Gross and colleagues (Bruce et al., 1981) and by Rolls and colleagues (Perrett et al., 1982). Although the overall numbers of these face-selective cells are small (1% to 5% of all neurons recorded in these regions), their concentration is much higher in the cortex of the lower and upper banks of the STS, where they are found together in clumps and where they may make up as much as 10% to 20% of all cells studied (Baylis et al., 1985). The lower bank of the STS is part of area TE, whereas the upper bank is part of area STP, which responds to auditory and somatic stimuli, as well as to visual stimuli (Bruce et al., 1981).

Face-selective cells vary in the degree and nature of their preference for face stimuli (for review, see Desimone, 1991). Many respond well to both real faces and face pictures but give nearly no response to any other stimuli tested, including other complex objects, texture patterns, and images in which the features making up the face are rearranged or scrambled. Thus, at least some face-selective neurons appear to be sensitive to very general or global aspects of a face, such as the prototypical arrangement of the eyes, nose, and mouth into a face-like configuration (Desimone et al., 1984). Other neurons in TE and STP respond to specific face components, such as the presence of eyes per se, the distance between the eyes, or the extent of the forehead (Baylis et al., 1985; Perrett et al., 1982; Rolls et al., 1985). While such neurons may merely be sensitive to facial features, they are nonetheless likely to participate in circuits responsible for recognizing a particular individual. One subset of face cells that responds to whole faces is particularly sensitive to the direction of gaze of the eyes (looking back directly or turned to the side; Perrett et al., 1985a), which is an important social signal for both monkeys and humans.

THE VENTRAL STREAM EXTRACTS SOME INVARIANT ASPECTS OF OBJECTS The visual information impinging on the retina is a two-dimensional projection of a three-dimensional world, a projection that varies dramatically as a function of changes in an object's position, distance, illumination, and orientation relative to the viewer. Thus, the function of the ventral stream can be defined in large measure as determining and encoding those invariant features of objects that are useful for recognition across myriad circumstances. As described earlier, as one progresses forward from V1 to TE, RFs become larger and the retinotopic maps less precise. By the anterior portions of area TE, RFs can include the entire visual field (Desimone and Gross, 1979; Gross et al., 1972). These large, bilateral RFs signal the presence of a given feature, collection of features, or object, regardless of where in the visual field they fall. In other words, they exhibit invariance of stimulus coding across changes in retinal position (Gross and Mishkin, 1977).

In addition to invariance over position, many neurons in TE show maintained selectivity for their "preferred" stimuli over more complex kinds of transformations, such as size, distance from the subject in depth, or degree of ambient illumination (Hikosaka, 1999; Ito et al., 1995; Sary et al., 1993; Vogels and Orban, 1996), so that they show invariance over a number of the changes that normally take place as a moving object is viewed under naturalistic conditions (or as an observer moves relative to a stationary object). Also, many TE neurons show form-cue invariance: for example, a neuron selective for a particular shape defined by luminance borders (e.g., a white star on a black background) will be selective for the same form defined either by relative texture or by motion cues instead (e.g., a star-shaped region of speckles of the same average luminance as the background moving in a different direction from the background). These various types of response invariance or generalization, taken together, make it possible to understand the types of deficits seen in monkeys when IT cortex is removed (see Plaut and Farah, 1990).

One central question in object recognition has been the degree to which neural representations of objects are object centered (view independent) or viewer centered (view dependent). The question of view dependence has been addressed by a number of single-unit studies of neurons in TE. For example, in one study, monkeys were trained to recognize specific novel three-dimensional objects from any viewpoint after experience with a few prototypical views in a discrimination task (Logothetis et al., 1995). After months of such training, the monkeys were found to have neurons in TE that exhibited strong selectivity for precisely those views on which the animal had been trained. These results support the view-dependent account of object recognition (Bulthoff et al., 1995). Studies of face-selective neurons in

area TE also initially provided strong support for view dependence by finding separate populations of cells tuned for front and profile views in both adult and infant monkeys (Desimone et al., 1984; Rodman et al., 1993). However, other studies showed that at least small subsets of TE neurons respond to faces or objects independent of view, providing evidence for view-independent representations as well. Overall, the issue of view dependence remains an open question, with some evidence for both accounts to be found in the neurophysiological literature as well as in psychophysical studies.

CELLS IN THE VENTRAL STREAM ARE AFFECTED BY ATTENTION With the use of a number of simple but effective behavioral paradigms, such as change blindness (Rensink, 2000), it has become clear that visual attention is necessary for the construction of the visual world we perceive. These behavioral paradigms demonstrate that without the ability to allocate attentional resources, detecting even large changes in the visual world becomes difficult. In the laboratory, directing attention to a specific location of the visual field speeds up detection and increases sensitivity to visual stimuli presented at that location (Bashinski and Bacharach, 1980; Posner et al., 1980; Yantis and Jonides, 1984). Neurophysiological correlates of this enhancement have been found in many visual areas, including V1 (Ito and Gilbert, 1999; Luck et al., 1997; Motter, 1993; Roelfsema et al., 1998), V2 (Luck et al., 1997; Reynolds et al., 1999), V3A (Nakamura and Colby, 2000), V4 (McAdams and Maunsell, 1999; Moran and Desimone, 1985), and areas MT and MST (Seidemann and Newsome, 1999; Treue and Maunsell, 1999).

The enhancement of neural activity associated with the demands of the behavioral task has been studied most extensively in area V4. Neurons in this area show enhanced responses to a visual stimulus when it is placed in the neuron's RF and becomes the target of a saccade or is used by the monkey in a discrimination task (Fischer and Boch, 1981; McAdams and Maunsell, 1999; Moore et al., 1998; Motter, 1994; Reynolds et al., 2000). This attentional enhancement is greatest when the discriminative stimulus is presented at near-threshold contrasts, resulting in an increase in neuronal sensitivity to contrast (Reynolds et al., 2000). Attentional effects on neuronal firing are even more pronounced when two stimuli are placed within the RF of a V4 neuron; in this case, the response is primarily driven by the attended stimulus (Moran and Desimone, 1985; Reynolds et al., 1999). These observations have led to the hypothesis that, within the circuitry of extrastriate cortex, there is a mechanism that gates out unattended stimuli (Desimone, 1998), and that this gating may be due to the interaction between neighboring RFs (Connor et al., 1997). In animals with lesions of V4, attention appears to be

allocated automatically to the most salient stimulus (see below), suggesting that the mechanism that controls the gating may include neurons within V4 (De Weerd et al., 1999; Schiller, 1993).

While earlier studies identified area V4 and the ventral stream as one of the main sites of attentional influences on visual processing, a number of recent studies have demonstrated similar influences in visual cortical areas within the dorsal stream. For example, Treue and Maunsell (1999) showed that directing attention to the RF in areas MT and MST results in an increase in neuronal firing. This effect was more pronounced when two spots moving in the preferred and the nonpreferred directions were placed in the RF and attention was directed from the nonpreferred to the preferred direction. In a subsequent study, Treue and Martinez-Trujillo (1999) demonstrated that attention increases the gain of direction-selective neurons. These effects are similar to those found in area V4, and show that attention enhances the representation of attended stimuli and reduces the influence of unattended stimuli. As discussed by Kastner and Ungerleider (2000), the source of these attentional modulatory influences likely arises from a network of frontal and parietal areas.

CELLS IN THE VENTRAL STREAM ARE AFFECTED BY EXPERIENCE Thus far, we have seen how the ventral stream, especially area TE, represents features that are useful for object recognition. For example, some neurons respond selectively to the salient features in a face, or their relative positions, while ignoring aspects of stimulus appearance that depend on viewing conditions, such as absolute size and luminance. We next consider how the brain represents stimuli over time. In particular, we describe how neurons in TE and the adjacent perirhinal cortex show effects of both recent viewing history and long-term experience with stimuli.

Experiments by Miller and Desimone (1994) have shown how short-term changes in response properties of temporal neurons encode aspects of both stimulus recency and short-term stimulus significance. For example, for many of these cells, responses to an object that is presented repeatedly decrease in a systematic fashion, potentially signaling that the object has been seen recently. Such reduced signals may be useful for redirecting attention to novel objects. This kind of response decrement, termed *repetition suppression*, has been found both under anesthesia and for stimuli which an awake animal is trained to ignore. This habituation-like response is therefore a passive, automatic mechanism by which the visual system edits out recently seen objects. By contrast, if a monkey is trained to do a matching task in which it must hold a particular visual pattern in memory over a short delay, some temporal neurons increase their firing rates, specifically when the to-be-remembered stimulus is recognized. This phenomenon, termed *mnemonic enhancement*, can be thought

of as a mechanism in which bottom-up processing of the stimulus is affected by top-down, cognitive factors, namely, the animal's expectation of the relevant stimulus. Stimuli that are repeated but are not behaviorally relevant in the context of the task do not show this enhancement effect (Desimone, 1996).

Experiments such as these demonstrate that the magnitude of responses of neurons can be affected by the subject's experience with the stimulus and by its significance, at least in the short term. Other studies suggest that the kind of familiarity gained over longer periods of time—akin to the development of expertise—can also be reflected in the responses of TE cells. For example, in monkeys that have been trained for as long as a year to discriminate between objects, more than 30% of the cells show selectivity for those objects, compared to untrained monkeys, in which roughly 10% of the cells show such selectivity (Kobatake et al., 1998).

Perhaps even more fascinating is the finding that some TE cells come to represent the history of association between objects in the activity patterns they exhibit in response to members of a set of stimuli. Using paired associate tasks, in which monkeys are trained to associate arbitrary stimulus patterns with one another for a reward, Sakai and Miyashita (1991) have found that, across the population of cells, TE neurons respond best to stimuli that had been paired together during training. In other words, some cells in temporal cortex developed conjoint selectivity (pair coding) for the members of associated pairs. Further, pair coding by TE cells is decreased by surgically interrupting the feedback projections to them from the perirhinal and entorhinal cortices (Miyashita et al., 1998). Thus, feedback projections appear to play a specific role in associating objects because the pair-coding property depends on them.

Although associative learning effects typically have been seen in studies after weeks or months of training, there is evidence that small but detectable shifts in neuronal population selectivity occur even after only a day or so of experience, suggesting that TE cells tend to develop pair-coding properties more rapidly than was previously thought (Erickson et al., 2000). Thus, the pattern of selectivity shown by TE cells at any given moment in time may partly reflect a record of their exposure to stimuli seen together. Overall, TE circuits appear to represent not only complex visual features, but also the history of their meanings and relationships in a behavioral context.

Behavioral effects of ventral stream lesions

FORM AND COLOR IMPAIRMENTS Lesions of the components of the ventral stream generally result in deficits that are consistent with neuronal RF properties of this processing pathway. Thus, there is evidence that lesions of both V4 and

IT cortex elevate contrast thresholds for relatively simple orientation discriminations (Dean, 1978; Merigan, 1996; Rudolph, 1997; Vogels et al., 1997). Many studies have shown that such lesions also disrupt more complex shape discriminations, with deficits resulting from V4 lesions usually being more pronounced (De Weerd et al., 1996; Heywood and Cowey, 1992; Huxlin et al., 2000; Merigan, 2000; Walsh et al., 1992b; for review, see Merigan and Pasternak, 2003).

The specificity of the effects of IT lesions on form discriminations is well illustrated by a study by Britten et al. (1992). In this study, deficits in discrimination were found when shapes were defined by luminance but not when they were defined by relative motion. This study not only supports the general finding that ventral pathway lesions typically spare motion discriminations but also suggests that form discriminations may be partially spared from the effects of ventral pathway lesions when the form is conveyed by motion.

Although V4 has been identified as one of the areas actively involved in the processing of color information (Zeki, 1973, 1980), V4 lesions result surprisingly in transitory and relatively modest disruption of simple color discriminations (Walsh et al., 1992a, 1993). The effects of V4 lesions on color thresholds and chromatic contrast sensitivity are also relatively mild (Dean, 1979; Heywood et al., 1992; Merigan, 1996; Walsh et al., 1993). This preservation of various forms of color perception is consistent with reports that some portions of the dorsal stream of both macaques and humans have access to chromatic information (Dobkins and Albright, 1994; Gegenfurtner et al., 1994; Seidemann et al., 1999; Wandell et al., 1999). While the function of color processing in the dorsal stream may be primarily to subserve the perception of motion, that in the ventral stream is undoubtedly more related to object recognition and segmentation by color. Color sensitivity found in the dorsal stream may help account for the failure to find large, permanent color vision loss after V4 lesions. It cannot, however, account for the more dramatic, and often permanent, color deficits found after IT lesions (Heywood et al., 1995; Huxlin et al., 2000).

IMPAIRMENTS IN PERCEPTUAL CONSTANCIES Normally, one can recognize an object independent of its size, location in the visual field, viewing distance, and ambient illumination. Several studies have demonstrated that these kinds of perceptual constancies are lost in monkeys with IT lesions (Humphrey and Weiskrantz, 1969; Seacord et al., 1979; Walsh et al., 1993; Weiskrantz and Saunders, 1984). For example, monkeys with IT lesions that have been trained to discriminate between two discs of different absolute size are unable to perform the discrimination when those discs are presented at variable distances (and hence with variable

retinal image sizes). Instead, they respond on the basis of either retinal size or distance (Humphrey and Weiskrantz, 1969). Thus, they have lost size constancy. Similarly, whereas normal monkeys easily generalize a visual discrimination learned in one hemifield to the other, monkeys with IT lesions do not, indicating that they have lost neural representations for objects that are invariant across visual field locations. Finally, whereas normal monkeys are unaffected by changes in the patterns of shadow and light falling on object surfaces, variations in illumination prevent monkeys with IT lesions from seeing the equivalence of objects. These behavioral findings, together with the physiological properties of IT neurons described earlier, indicate that an important role of IT cortex is perceptual constancy, that is, representing the invariant aspects of objects independent of retinal inputs.

MEMORY IMPAIRMENTS In addition to the loss of several visual constancy mechanisms described above, it is well established that monkeys with IT lesions are impaired in learning to discriminate among visual stimuli (including colors, patterns, shapes, and objects) and in recalling previously learned discriminations (Dean, 1976, 1982). Further, these impairments cannot be explained by deficits in basic sensory capacities. Rather, the behavioral impairment seems to result from the loss of a high-level mechanism, although the precise nature of this mechanism is still in dispute.

One proposed model is that monkeys with IT lesions have fewer perceptual categories than normal (Dean, 1976; Gaffan et al., 1986). For example, a brush and a wooden block with the same general shape and color would likely fall within different perceptual categories for a normal monkey but might fall within the same category for a monkey with an IT lesion. Hence, in a visual discrimination task, learning to associate the brush with reward and the wooden block with nonreward might be as difficult for an animal with an IT lesion as learning to discriminate between two slightly different brushes might be for a normal monkey. This concept fits with some models of prosopagnosia, in which it is thought that the underlying impairment may be in discriminating among objects within the same perceptual category rather than in discriminating faces *per se* (Damasio et al., 1982).

Mishkin has argued, by contrast, that a reduction in the number of perceptual categories cannot fully explain the impairments produced by IT lesions. He has proposed that IT lesions also cause a loss of certain perceptual constancies (as described above), a reduction in the visual inputs to a *habit*-learning system involving the basal ganglia, and a profound loss of visual memories (Mishkin, 1982; Mishkin and Appenzeller, 1987). The memory loss is suggested by studies showing that monkeys with IT lesions cannot recognize an object seen as recently as 30–60 seconds

previously (Squire, 1987). Thus, according to this view, IT cortex contains the central representations for visual objects, and the loss of IT cortex leads not only to the loss of old memories but also to an inability to form new ones. Although there are some suggestive physiological data indicating that IT cortex could be the site of memory storage (Brown et al., 1987; Fuster and Jervey, 1981), definitive data on this issue are sorely lacking.

IMPAIRMENT IN VISUAL ATTENTION It is well established that responses of neurons in V4 and IT cortex are modulated by visual attention (e.g., Chelazzi et al., 1998; Connor et al., 1997; Moran and Desimone, 1985; Reynolds et al., 2000). Thus, one would expect to find impairments in visual attention following the loss of these neurons. Indeed, Schiller and Lee (1991) reported that V4 lesions severely disrupted the ability to detect a less salient (smaller, less coarse) odd stimulus in an array of stimuli, but had less effect on the ability to detect a more salient (larger, coarser) odd stimulus. This result is consistent with current views that V4 may be one site where top-down attentional influences modulate bottom-up sensory-driven inputs, such as visual salience (Desimone and Duncan, 1995). Hence, in the absence of V4, relevant but less salient stimuli would be ignored. More recently, De Weerd et al. (1999) showed that monkeys with either V4, TEO, or combined V4 and TEO lesions were minimally impaired on a grating orientation discrimination but were greatly impaired when the grating was surrounded by irrelevant disc distracters. Furthermore, the impairment was proportional to the contrast of the distracters. This result supports the idea that V4 and TEO lesions can alter perception by disrupting the role attention plays in separating visual targets from distracters (Braun, 1994).

Neuronal properties within the dorsal stream

CELLS ARE SENSITIVE TO VISUAL MOTION One of the more prominent features of neurons in the dorsal stream is selectivity for the direction of visual motion. Directionally selective neurons respond vigorously to one direction of motion and respond less or not at all when the same stimulus moves in the opposite direction (Hubel and Wiesel, 1968). This property first appears in V1, where directionally selective neurons are found primarily in layers 4C α and 4B (Hawken et al., 1988), the target layers of the magnocellular neurons of the lateral geniculate nucleus. These V1 neurons are sensitive to low contrasts and have relatively poor spatial resolution (Hawken et al., 1988; Movshon and Newsome, 1996). In area V2, directionally selective neurons are less numerous, show high sensitivity to contrast, and are localized largely in the thick stripes, suggesting magnocellular influences (Burkhalter and Van Essen, 1986; Levitt et al.,

1994a). In area V3, these neurons are much more numerous, exhibit relatively high sensitivity to contrast, and prefer coarse, relatively fast-moving stimuli, indicating a role in processing of motion information. Indeed, neurons in V3 show the ability to integrate local motion signals (Gegenfurtner et al., 1997), a feature indicative of higher-level motion analysis (Movshon et al., 1985). Because of these features, the prominent inputs V3 sends to MT, and its reactivity to CAT-301 antibody, which is characteristic of regions in the dorsal processing stream (De Yoe et al., 1990), V3 often has been associated with the dorsal stream (e.g., Felleman et al., 1997).

Processing of visual motion is even more prevalent in area MT, where selectivity for the direction and speed of motion is found in the majority of neurons (e.g., Albright, 1984; Maunsell and Van Essen, 1983c). MT neurons display directional selectivity to the motion of random dots, bars, and gratings (Britten et al., 1993; Maunsell and Van Essen, 1983c; Mikami et al., 1986), and neurons with similar directional preferences are clustered in columns (Albright et al., 1984). Furthermore, many properties of these neurons are consistent with their role in motion perception. For example, many MT neurons respond to complex motion stimuli consisting of multiple motion vectors in the same part of space, similar to the way such motion is perceived by human observers. Specifically, when presented with a plaid pattern consisting of two component gratings moving in orthogonal directions, MT neurons, unlike V1 neurons, respond to the direction of the plaid rather than to its components (Albright et al., 1984; Rodman and Albright, 1989). The RFs of MT neurons also have strong antagonistic surrounds, which, when stimulated by the same direction and/or speed as the excitatory center, show strong inhibition (Allman et al., 1985a, 1985b; Xiao et al., 1995). This property allows these neurons to code local motion signals according to the context in which this motion appears, suggesting a role in the detection of relative motion and in figure-ground segregation.

Responses of MT neurons to other types of complex motion also support their close connection to perception. In contrast to V1 neurons, which respond equally well to non-transparent and transparent motion, activity of MT neurons to the motion of transparent surfaces moving in different directions is suppressed (Recanzone et al., 1997; Snowden et al., 1991). This suppression is reminiscent of the perception of motion transparency observed in human psychophysical experiments (Qian and Andersen, 1994).

Visual motion is also processed by neurons in the medially adjacent area MST, an important target of MT projections. Its dorsal portion (MSTd) contains neurons with very large RFs, preferring the motion of full-field stimuli (Desimone and Ungerleider, 1986; Saito et al., 1986), a property that suggests a role in integrating visual motion

signals generated during the observer's movement through the environment with eye-movement and vestibular signals (Andersen, 1997). A number of studies have shown that MSTd has the machinery needed to extract and signal the direction of heading from optic flow stimuli (Lappe et al., 1996; Van Den Berg and Beintema, 2000). The evidence that the use of such information may depend on MST has come from Britten and Van Wezel (1998), who showed that electrical microstimulation of MST neurons produced biased decisions about the direction of heading provided by optic flow stimuli.

In contrast to MSTd, neurons in the lateral portion of MST (MSTl) have properties that make them more likely to be involved in the analysis of object motion in the environment (Tanaka et al., 1993) and in the maintenance of pursuit eye movements associated with this motion (Komatsu and Wurtz, 1988). RFs of neurons in this region, similar to neurons in MT, have antagonistic surrounds and respond very strongly to object motion when the motion in the surround is in the opposite direction (Eifuku and Wurtz, 1998), suggesting a role in segmenting moving objects from backgrounds.

A number of areas within parietal cortex also respond to visual motion (e.g., areas VIP and 7a), and these responses are largely reminiscent of responses at earlier stages of processing within the dorsal pathway.

CELLS ARE SENSITIVE TO BINOCULAR DISPARITY Sensitivity to binocular disparity, the property believed to underlie depth perception, is characteristic of many neurons in the dorsal stream. Although the information from the two eyes remains segregated upon their arrival in layer 4 of V1 (Hubel and Wiesel, 1977), there is substantial intermixing of inputs from the two eyes in layers above and below layer 4. This intermixing is reflected in neuronal properties, as there are many V1 neurons that respond best when both eyes are stimulated and many of these neurons are sensitive to absolute retinal disparity (Cumming and Parker, 1999; Poggio et al., 1988), an early stage of processing that leads to stereoscopic depth perception (Cumming and DeAngelis, 2001). Although sensitivity to absolute retinal disparity is still quite common at the level of V2 (Hubel and Livingstone, 1987; Poggio, 1995; Zeki, 1979), some neurons begin to show sensitivity to *relative disparity* between different locations in the visual field, a property absent from V1 neurons (Cumming and Parker, 1999). This property appears to be segregated primarily to neurons in the thick stripes of V2 (Roe and Ts'o, 1995), which project to MT. Disparity sensitivity, also present in some neurons in area V3 (Felleman and Van Essen, 1987), becomes even more prevalent in MT, where the neurons are found clustered according to preferred disparity (DeAngelis and Newsome, 1999). These neurons appear to contribute to stereoscopic depth percep-

tion, as microstimulation of similarly tuned cells can bias the monkey's perceptual judgment of depth toward the preferred disparity (DeAngelis et al., 1998). Apart from depth perception, the disparity tuning of these neurons appears to be relevant to other perceptual phenomena. For example, a difference in disparity of the display consisting of sheets of random dots creates the percept of transparent motion (Bradley et al., 1995), and changing the disparity in the surround of the classical RF modulates not only the response of MT neurons to motion but also the percept of the direction of motion (Bradley et al., 1998). It has also been suggested that MT may be involved in extracting shape from motion (Buracas and Albright, 1996; Dodd et al., 2001), and while there is evidence of the interaction between motion and disparity signals in the same neurons (Bradley et al., 1995), MT neurons do not appear to be tuned to motion in depth (Maunsell and Van Essen, 1983b).

It should be noted that sensitivity to retinal disparity is not unique to the dorsal pathway. Even though disparity in V2 neurons appears to be segregated to the thick stripes, which project to the dorsal stream, neurons in both V4 and IT cortex have been shown to be sensitive to retinal disparity as well (Hinkle and Connor, 2001; Janssen et al., 2000; Watanabe et al., 2002).

CELLS ARE INVOLVED IN PROCESSING OF VISUAL SPACE IN ACTIVE OBSERVERS Many properties of neurons within the dorsal stream point to their role in the processing of location information in active observers. For example, neurons in MSTd are capable of integrating visual information extracted during movement of the observer with signals related to eye and head movements (Andersen et al., 1999; Duffy, 1998). Area LIP, located in parietal cortex that receives inputs from MT and MST as well as from a number of regions within the ventral stream, has also been shown to play a role in sensorimotor transformations in preparation for action (Andersen et al., 1990b; Gnadt and Andersen, 1988). There is evidence that LIP neurons play a role in planning saccades to a remembered location (Mazzoni et al., 1996; Platt and Glimcher, 1997; Snyder et al., 1997) and in storing information in both eye-centered (Duhamel et al., 1992) and body-centered coordinates (Snyder et al., 1998). There is also evidence that responses of LIP neurons are modulated by the salience and behavioral significance of visual stimuli (Colby and Goldberg, 1999). Another intriguing feature of LIP neurons is that the spatial representation of a remembered stimulus is dynamic and shifts to the corresponding retinal location around the time of a saccade (Duhamel et al., 1992). Thus, neurons in parietal cortex update the retinal coordinates of remembered stimuli to anticipate the upcoming eye movement. This *remapping*, important for maintaining a continuous representation of the visual world during eye movements, is not unique to LIP,

as it has also been observed in areas V2, V3, and V3A (Nakamura and Colby, 2002).

Area VIP has also been implicated in the encoding of spatial representations. It has prominent connections with MT, MST, and FST but, unlike LIP, it receives little if any input from ventral stream areas (Boussaoud et al., 1990; Colby et al., 1993). Neuronal responses in VIP show selectivity for optic flow (Colby et al., 1993), are often modulated by eye position, and appear to reflect an encoding in head-centered coordinates (Bremmer et al., 1999; Duhamel et al., 1997). Some VIP neurons seem to prefer stimuli that are close to the animal (Colby et al., 1993), and most also respond to tactile stimuli in locations on the head congruent with their visual RFs (Duhamel et al., 1998). This observation has led to the suggestion that VIP neurons are involved in the construction of a multisensory head-centered representation of near-personal space (Duhamel et al., 1998).

Within the dorsal stream, area 7a represents the final stage in the hierarchy. It is interconnected with a wide range of cortical and subcortical regions, thereby providing visual and visuomotor signals important for the execution of visually guided behavior. Its interconnections include a number of areas in parietal (Cavada and Goldman-Rakic, 1989), prefrontal, and IT cortex, as well as the basal ganglia (Neal et al., 1990; Selemon and Goldman-Rakic, 1988). Neurons in area 7a have large, often bilateral RFs (Blatt et al., 1990) and possess properties similar to those encountered at preceding stages in the dorsal stream. For example, many neurons are sensitive to complex visual motion and optic flow (Sakata et al., 1994; Siegel and Read, 1997). Most notably, responses of 7a neurons are modulated by the behavioral relevance of the visual stimuli (Constantinidis and Steinmetz, 2001; Steinmetz et al., 1994). Since the activity of these neurons is largely unaffected by changes in body or head position during saccades to specific retinal locations, it is likely that these cells encode information in world-referenced spatial coordinates (Snyder et al., 1998).

Behavioral effects of dorsal stream lesions

Most of the lesion studies support the notion of specialization of the dorsal stream for processing of stimulus motion. They also suggest that this pathway is important for the integration of motion information to construct a representation of space that can be used in navigation and other motor behaviors.

MT LESIONS AFFECT SMOOTH PURSUIT EYE MOVEMENTS AND SPEED PROCESSING Area MT has become the area of choice for examining the effects of lesions within the dorsal stream, primarily because of its high incidence of directionally selective neurons, its clearly defined borders within the STS, and its precise retinotopy. The first studies involv-

ing lesions of areas MT and MST used ibotenic acid and examined its effects on eye movement responses. Wurtz and his colleagues reported that MT and MST lesions resulted in retinotopically specific deficits in smooth pursuit eye movements (Dursteler and Wurtz, 1988; Dursteler et al., 1987; Newsome et al., 1985). The monkeys had been trained to pursue moving targets but, after MT and MST lesions, were unable to match the speed of their smooth pursuit eye movements to the speed of the target. The animals also had problems adjusting the amplitude of their saccadic eye movements to compensate for target motion, though they had no problems making saccades to stationary targets. As these effects reflected difficulties in matching the velocity of visual targets, without evidence of motor abnormalities, they were interpreted as impaired perception of stimulus velocity. A similar deficit in smooth pursuit eye movements was later reported (Schiller and Lee, 1994). Subsequently, a number of studies examined the effects of MT/MST lesions on speed discriminations more directly by measuring speed difference thresholds. Substantial and largely permanent loss in the accuracy of speed judgments was found (Orban et al., 1995; Pasternak and Merigan, 1994; Schiller and Lee, 1994).

LESIONS OF MT/MST LEAD TO DEFICITS IN COMPLEX MOTION PERCEPTION A number of studies examined the perception of stimulus motion with displays in which coherence thresholds were measured by adjusting the proportion of coherently and randomly moving dots. For example, Newsome and Pare (1988) used such stimuli to measure motion perception in monkeys with localized lesions placed in MT while the monkeys performed a discrimination task. They found severe deficits in motion coherence thresholds when stimuli were placed in the portion of the visual field affected by the lesion. A similar inability to extract coherent motion in the presence of noise was later reported after MT/MST lesions by Pasternak and Merigan (1994). In a subsequent study, Rudolph and Pasternak (1999) found that MT/MST lesions produced deficits not only in coherence thresholds measured with random dots but also in signal-to-noise thresholds measured with drifting gratings masked by noise. This increased susceptibility to noise was specific to the domain of motion perception, as the same monkeys showed no deficit in discriminating the orientation of gratings masked by two-dimensional noise. Interestingly, monkeys with V4 lesions showed the opposite pattern of impairment (Fig. 34.3).

In addition to producing increased susceptibility to noise, MT/MST lesions result in permanent deficits both in the integration of local motion vectors (Pasternak and Merigan, 1994; Rudolph and Pasternak, 1999) and in the ability to remember such stimuli for brief periods of time (Bisley and Pasternak, 2000). MT lesions have also been shown

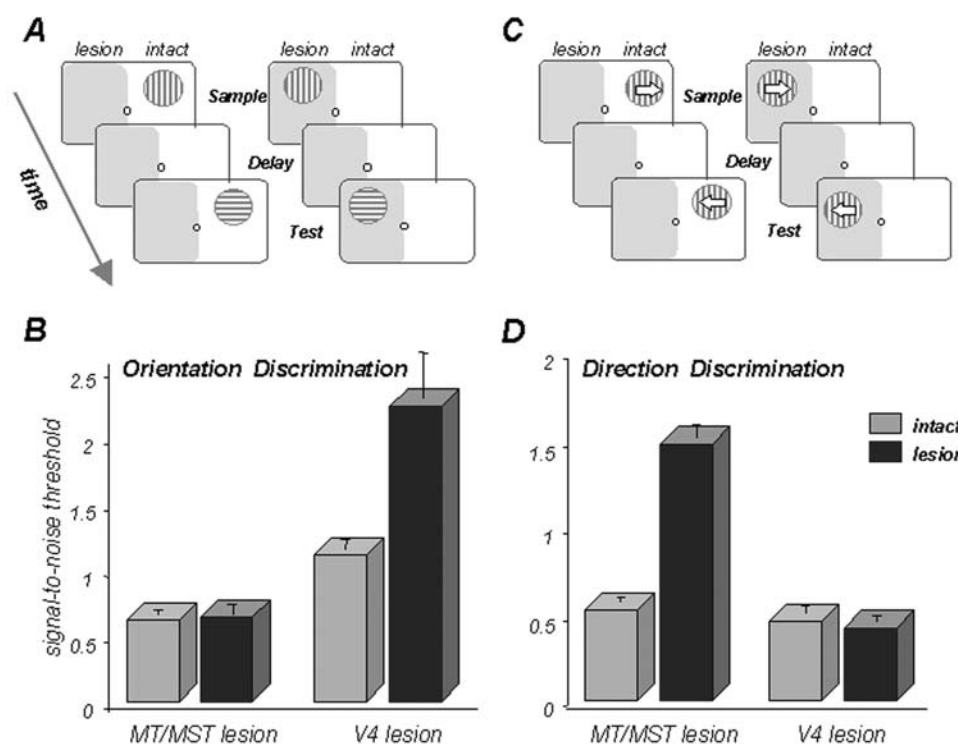

FIGURE 34.3. Effects of V4 and MT/MST lesions on the discrimination of form and motion. *A*, Psychophysical testing procedure for measuring orientation discrimination. The monkeys fixated a small spot for 1 second to initiate the trial. During each trial they viewed sample and test stimuli separated by a 0.2 second delay and indicated whether the orientation of the test was either the same as or different from that of the sample. The orientation of the sample was chosen at random from a set of six and the orientation of the test was the same as or orthogonal to that of the sample. Signal-to-noise thresholds were measured with flickering gratings (1 c/deg, 5 Hz) masked by adding varying amounts of two-dimensional noise in the sample; the test grating was of high contrast and contained no noise. *B*, Effects of a unilateral V4 or MT/MST lesion on orientation discrimination. The performance was measured with stimuli in the intact and affected portions of the visual field. The V4 lesion elevated signal-to-noise thresholds for orientation, while the MT/MST lesion had no significant effect on

performance. *C*, Psychophysical testing procedure for measuring direction discrimination. The task was identical to that described in *A*, except that drifting gratings were used. One of eight possible directions of motion was selected at random as a sample stimulus, and the test stimulus moved either in the same or the opposite direction. Signal-to-noise thresholds were measured by varying the proportion of pixels in the grating that assumed random intensities. *D*, Effect of a unilateral V4 or MT/MST lesion on direction discrimination. The MT/MST lesion elevated signal-to-noise thresholds for discriminating differences in direction. The V4 lesion had no measurable effect on direction discrimination thresholds.

Lesions were made by multiple injections of ibotenic acid. Representative data are shown for a single monkey with a V4 lesion and for another with an MT/MST lesion. (MT/MST lesion data adapted from Rudolph and Pasternak, 1999; V4 lesion data were adapted from Rudolph, 1997.)

to produce modest and largely transient deficits in the detection of motion shear and more severe deficits in the perception of structure from motion (Andersen and Siegel, 1989).

LESIONS OF POSTERIOR PARIETAL CORTEX AFFECT ENCODING OF VISUAL SPACE Neuronal properties in parietal cortex suggest a role in the integration of sensory signals and in constructing a representation of extrapersonal space in preparation for motor action; the few lesion studies performed in nonhuman primates in this region largely confirm this notion. A role of posterior parietal cortex in spatial aspects of task performance was first reported in the mid-1970s (Pohl, 1973; Ratcliff et al., 1977; Ridley and Ettlinger,

1975; for review, see Ungerleider and Mishkin, 1982). Subsequently, Lattin (1986) tested monkeys after bilateral lesions of area 7a and found deficits in the performance of a spatial landmark test. Further evidence for a role of parietal cortex in space coding was reported by Quintana and Fuster (1993), who applied cooling to areas 5 and 7 of the parietal cortex. They found that the monkeys showed decreased speed and accuracy in both reaching and eye movements during the performance of tasks that required the processing and retention of spatial information. More recently, Li et al. (1999) reported deficits in memory-guided saccadic eye movements after reversible inactivation of LIP. They concluded that LIP neurons play a direct role in processing incoming sensory information to program saccadic eye movements.

Inaccuracy in reaching toward visual targets after lesions of areas 7a, 7b, and LIP was observed by Rushworth et al. (1997). Thus, lesions of parietal cortex appear to disrupt the ability of a subject to coordinate movements relative to oneself or relative to other objects located in extrapersonal space (Milner and Goodale, 1996).

Some neurons in both streams integrate information about motion, color, and form

Although processing of the information about color/form and motion/space appears to be segregated and carried largely by segregated pathways, there is evidence of intermixing of properties at various stages of cortical processing.

Evidence of some intermixing and possibly integration of color and motion signals can be found relatively early in the visual cortex. For example, although there is functional segregation of neurons into stripe and interstripe regions in area V2 with respect to color, form, and retinal disparity, this segregation is not complete (Ts'o et al., 2001). It has been reported that the thick stripes, receiving inputs from layer 4B in V1, the magnocellular output layer, also receive inputs from layer 4A, the parvocellular output layer. Furthermore, it is likely that the extensive spread of projections supplied by pyramidal V1 neurons, as well as the horizontal connections between the stripes in V2, may provide an anatomical substrate for interactions between segregated channels in V1 (Levitt et al., 1994b; Malach et al., 1994). Thus, even at the level of V2, there may be intermixing of signals proceeding toward the dorsal and ventral streams, a notion supported by RF properties encountered both within V2 and anterior to it.

While some connections of area V3, the next stage of cortical processing, suggest an association with the dorsal stream, it is also strongly interconnected with V4, a major component of the ventral stream (Beck and Kaas, 1999). Because of this pattern of connectivity, V3 is in a good position to serve as a site where the integration of various visual signals can occur. Indeed, the high incidence of directional selectivity of V3 neurons and their preference for lower spatial and higher temporal frequencies (Gegenfurtner et al., 1997) suggest a role in processing motion information. Yet, the majority of V3 neurons are also orientation selective, and nearly half of all neurons in this area show selectivity for color (Burkhalter et al., 1986). It is interesting that many of the neurons responding to color also show directional selectivity, and a substantial number show directional selectivity to isoluminant gratings. This interaction between color and motion suggests that area V3 may represent a stage in the analysis of the visual scene where interactions between the two streams take place.

Some interactions between the processing of color and motion have also been observed in area MT, an area strongly

influenced by the magnocellular pathway (Maunsell et al., 1990), which itself does not appear to carry color-opponent signals. Thus, many MT neurons maintain significant responses to motion of isoluminant stimuli (Gegenfurtner et al., 1994; Seidemann et al., 1999; Thiele et al., 2001), and the presence of chromatic information has been shown to increase neuronal direction discrimination (Croner and Albright, 1999). While chromatic signals reaching MT are much weaker than the luminance signals, the activity of MT neurons to isoluminant gratings appears to be sufficient to explain the performance of monkeys in a color-based motion discrimination task (Thiele et al., 2001).

An area likely to represent a region of convergence and integration of form and motion information is STP, which receives inputs from both processing streams (Baizer et al., 1991; Boussaoud et al., 1990; Oram and Perrett, 1996). It is a multimodal area, containing neurons that respond to somatosensory and auditory as well as visual stimuli (Bruce et al., 1981). STP neurons have large, gaze-centered RFs and show selectivity to visual motion similar to that observed in areas MT and MST (Anderson and Siegel, 1999; Oram et al., 1993). Some neurons also respond particularly well to biological motion, that is, motion patterns consistent with what one sees when one observes the gait of another animal (Oram and Perrett, 1996; Perrett et al., 1985b). For example, these cells respond when viewing a monkey or human walking, or to equivalent motion patterns generated by so-called Johansson point-light stimuli (stimuli generated by attaching lights to the joints of a moving animal which is otherwise in the dark). These observations have led to the idea that the primate temporal lobe has evolved specialized mechanisms for the encoding and recognition of biologically significant stimuli (Fig. 34.4).

Finally, it should be noted that properties of neurons within each stream have been shown to respond to the demands of the behavioral task, and features normally not associated with a given area may emerge if they are behaviorally relevant. An interesting example of this phenomenon has been provided by Ferrera et al. (1994), who demonstrated that the activity of neurons in area V4, which rarely show directionally selective responses, was strongly modulated by the direction of a behaviorally significant motion stimulus. This observation illustrates the dynamic nature of processing by the two visual streams; under some circumstances, each stream may contribute to the processing usually associated with the other.

Beyond visual processing streams

In order to execute visually guided behaviors successfully, the information carried by the two streams needs to be integrated. While some aspects of this integration appear to take place within each stream, the integration is only partial at

FIGURE 34.4. Sensitivity to walking forward in area STP. The mean and standard error of responses (spikes/sec) to different views of the body when approaching and retreating from the monkey are shown for cell P056. The cell responded most to the body moving in a direction compatible with its orientation (i.e., in the direction it was facing). The cell responded significantly more to the front view than to the back view of the body when it moved toward the monkey ($p < .01$). The response to the back view was greater than that to the front view, however, when it moved away from the monkey ($p < .01$). (From Perrett et al., 1985b.)

best. The question arises: how and where is such integration accomplished? While this question is still the topic of active investigation, there is accumulating evidence that the answer may lie in areas located outside of the visual system, as traditionally defined.

It is well established that both processing streams, dorsal and ventral, have reciprocal connections with regions beyond the modality-specific visual system. One such set of connections includes those with the prefrontal cortex. Anatomical studies have shown that projections from areas in the dorsal stream terminate mainly in and around the principal sulcus, in Brodmann area (BA) 46 of dorsolateral prefrontal cortex (Barbas and Mesulam, 1985; Cavada and Goldman-Rakic, 1989; Ungerleider and Desimone, 1986), whereas projections from areas in the ventral stream terminate mainly on the inferior convexity, in BA 12 and 45 of ventrolateral prefrontal cortex (Chavis and Pandya, 1976; Ungerleider et al., 1989; Webster et al., 1994). Thus, from an anatomical point of view, the domain specificity of spatial versus object vision that is present in the posterior processing areas of the monkey brain appears to extend forward into the prefrontal cortex. These separate prefrontal regions are thought to play an important role in working memory, that is, briefly keeping in mind an object and its location, respectively, after it is no longer visible (Fuster, 1990; Goldman-Rakic, 1990).

Although the inputs to prefrontal cortex from the two streams are anatomically segregated and there is physiological evidence of neuronal specialization for the modality arriving from each stream (Sakagami et al., 2001; Scalaidhe et al., 1999; Wilson et al., 1993), regional intermixing of prefrontal neurons active during execution of working memory tasks for objects and spatial locations has been reported (Fuster et al., 1982). Furthermore, recent studies have documented the existence of individual prefrontal neurons that process information about both an object's identity and its location (Rainer et al., 1998; Rao et al., 1997), thus integrating the information arriving from the two streams.

Conclusions: ventral and dorsal processing streams in the human brain

The differential visual impairments produced by focal lesions in clinical cases suggest that human visual cortex, like that of the monkey, contains two anatomically distinct and functionally specialized pathways corresponding to the ventral and dorsal streams (Damasio and Damasio, 1979; Damasio et al., 1982; Newcombe and Russell, 1969; Newcombe et al., 1987; Ratcliff and Davies-Jones, 1972; Ratcliff and Newcombe, 1973; Zihl et al., 1983). The clinical syndromes produced by occipitotemporal lesions include visual object agnosia, as well as prosopagnosia, an inability to recognize familiar faces, and achromatopsia, or cortical color blindness. By contrast, syndromes produced by occipitoparietal lesions include optic ataxia (misreaching), hemispatial neglect, constructional apraxia, gaze apraxia, and akinetopsia (inability to perceive movement).

The advent of functional brain imaging, both positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has made it possible to map the organization of the human visual cortex with far greater precision than is possible with human lesion studies and without the confounding influence of compensatory responses to brain injury (e.g., see Ungerleider and Haxby, 1994). In experiments by Haxby and colleagues designed to investigate the possible existence of separate object vision and spatial vision pathways in humans, changes in regional cerebral blood flow were measured using PET while subjects performed object identity and spatial location matching-to-sample tasks (Haxby et al., 1994). In the object identity task, the subjects indicated on each trial which of two choice faces matched the sample face, whereas in the spatial location task, the subjects indicated which of two choice stimuli contained a small square in the same location, relative to a double line, as the small square in the sample stimulus (Fig. 34.5). The faces for the object identity task were contained within the small squares, so that identical stimuli were used for face and location matching, with only the task requirements changing. The results identified occip-

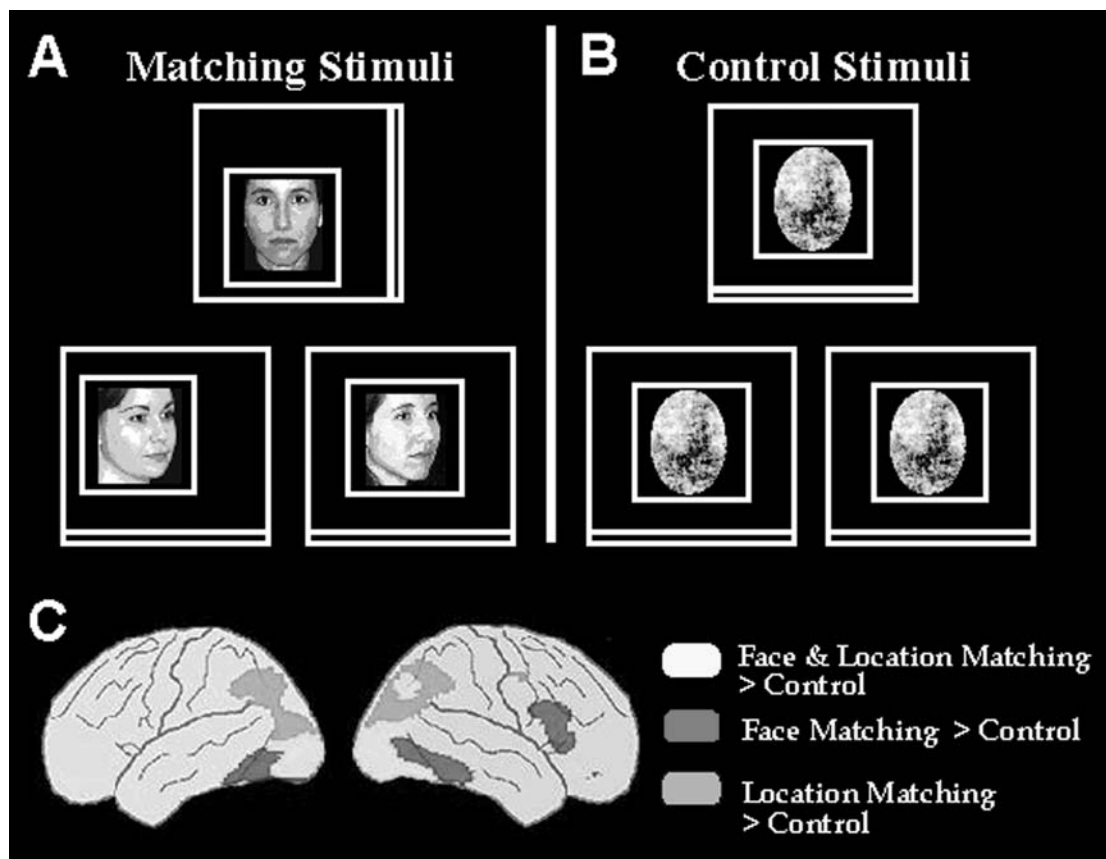

FIGURE 34.5. Two cortical processing streams in human visual cortex, as demonstrated in a PET imaging study of face and location perception. *A*, Sample experimental stimuli used for both face- and location-matching tasks. During face-matching trials, subjects had to indicate with a button press which of the two faces at the bottom was the same person shown at the top. In this example, the correct choice is the stimulus on the right. During location-matching trials, subjects had to indicate with a button press which of the two small squares at the bottom was in the same location relative to the double line as the small square shown at the top. In this example, the correct choice is the stimulus on the left. *B*, Sample control stimuli used during the experiment. During control

trials, subjects saw an array of three stimuli in which the small squares contained a complex visual image. On these trials, which controlled for both visual stimulation and finger movements, they alternated left and right button presses. *C*, Areas shown in red had significantly increased activity during the face-matching but not during the location-matching task compared with activity during the control task. Areas shown in green had significantly increased activity during the location-matching but not during the face-matching task compared with activity during the control task. Areas shown in yellow had significantly increased activity during both face- and location-matching tasks. (Adapted from Haxby et al., 1994.) (See color plate 19.)

itotemporal and occipitoparietal regions associated with face and location matching, respectively, and posterior occipital regions associated with both visual functions. In addition, regions in ventral and dorsal frontal cortex were selectively activated by face and location matching, respectively. These findings thus indicate the existence in humans, as in monkeys, of two functionally specialized and anatomically segregated visual processing streams, both of which receive their inputs from early visual areas. The findings further suggest the extensions of each into the frontal lobe, which plays a role in working memory for objects and their spatial locations.

At a finer level of analysis, functional imaging studies have begun to reveal the individual processing areas within the two streams, and many of these areas appear to be homol-

ogous to monkey visual areas, including V1, V2, V3, V3A, V4, MT, and LIP (De Yoe et al., 1994; Reppas et al., 1995; Sereno et al., 1995, 2001; Shipp et al., 1995; Tootell et al., 1997). On the other hand, it has been discovered that human visual cortex also contains regions specialized for the processing of visual letters and word forms (Nobre et al., 1994; Petersen et al., 1990). These regions could not have evolved for the purpose of reading but instead must have developed in the course of learning to read. These regions thus appear to be similar to those in the temporal cortex of monkeys in which familiarity over long periods of time, leading to expertise, alters the responses of TE neurons (Kobatake et al., 1998). Such findings in humans and monkeys highlight one challenge for future research: to understand how visual experience tunes neuronal selectivities.

V SUBCORTICAL PROCESSING

35 The Visual Relays in the Thalamus

S. MURRAY SHERMAN AND R.W. GUILLERY

THE LATERAL GENICULATE NUCLEUS¹ is the thalamic relay of retinal input to the visual cortex. It is the best understood of the thalamic relays and, because there is an overall structure shared by all thalamic nuclei, it can serve as a general model for the thalamus. We first consider the lateral geniculate nucleus and then, using this as a prototype, look at other thalamic relays on the visual pathways, the lateral posterior nucleus and the pulvinar. For convenience, both will be referred to jointly as the *pulvinar region*. We look at features that are shared by the lateral geniculate nucleus and the pulvinar region and explore the extent to which the organizational principles that are well defined for the lateral geniculate nucleus can help us to understand aspects of pulvinar organization. The lateral geniculate nucleus will be treated as a first-order relay (Guillery and Sherman, 2002b; Sherman and Guillery, 2001), sending ascending visual messages from the retina to primary receiving cortex and the pulvinar region as a higher-order relay carrying messages from one cortical area through the thalamic relay to another cortical area and thus playing a potentially crucial role in corticocortical communication. First- and higher-order relays are defined more fully below, but it suffices to note here that the former represent the initial relay of a particular sort of information (e.g., visual or auditory) to cortex, while the latter represent further relay of such information via a cortico-thalamo-cortical loop.

The complex cell and circuit properties of thalamic relays have been defined during the past three or four decades, and these are a clear indication that thalamic circuits must be concerned with significant tasks. In spite of this, thalamic relays are often still treated as they were in the nineteenth century, when it was enough to trace a pathway, such as the auditory, visual, or somatosensory pathway, to the thalamus and then conclude that the function of that part of the thalamus had been defined. Glees and Le Gros Clark (1941) described a one-to-one relationship between incoming retinogeniculate axon terminals and geniculate cells in

macaque monkeys, which suggested a relatively simple transfer of visual information. We now know that this was an error and that, as we show below, the synaptic relationships are, in fact, very complex, with the vast majority of synapses onto relay cells coming from nonretinal sources (Guillery, 1969; Van Horn et al., 2000; Wilson et al., 1984). In spite of this, when, more recently, the distinctive receptive field properties of cells in the retina and the visual cortex were being defined (reviewed in Hubel and Wiesel, 1977), the lateral geniculate nucleus was treated as a simple, machine-like relay. This reflected the great success of the receptive field approach to vision. Initially, in anesthetized animals, this approach showed that receptive fields become increasingly elaborated along the synaptic hierarchies through retina and cortex, with the one glaring exception being the retinogeniculate synapse: the center/surround receptive fields of geniculate relay cells are essentially the same as those of their retinal afferents. From this arose the misleading conclusion that nothing much of interest was happening in the geniculate relay (Hubel and Wiesel, 1977; Zeki, 1993). Indeed, this raises certain questions: Why have a geniculate relay at all? Why not have retinal axons project directly to visual cortex? Or, more generally, why bother with thalamic relays? One of the main purposes of this chapter is to provide a partial answer to these questions. A second purpose is to indicate that currently we are far from having a complete answer. It is highly probable that much of what the thalamus does still remains to be defined.

As we shall see, even on the evidence available today, there is much of interest happening in the geniculate relay, and in retrospect, the lack of receptive field elaboration seen in the geniculate relay is not evidence of nothing happening there but, rather, evidence that something completely different but important occurs. That is, this is a crucial synapse in the visual pathways doing something other than receptive field elaboration: geniculate circuitry is involved in affecting, in a dynamic fashion, the amount and nature of information relayed to cortex. One reason this was missed in earlier studies is that these functions depend largely on the behavioral state of the animal and are suppressed in anesthetized animals. This dynamic control, dependent on the animal's behavioral state and considered below, can be seen to represent the neuronal substrate for many forms of visual attention.

¹By *lateral geniculate nucleus* in this chapter, we mean the *dorsal* lateral geniculate nucleus. Like all thalamic nuclei providing a relay to neocortex, the lateral geniculate nucleus is developmentally a part of the dorsal thalamus. The *ventral* lateral geniculate nucleus, which is part of the ventral thalamus, does not send axons to cortex and will not be considered further.

Functional organization of the lateral geniculate nucleus

For those who still consider the lateral geniculate nucleus as a simple relay, the complexity of its organization will no doubt come as a surprise. The nucleus is organized into a number of layers with a detailed topographic map of visual space that cuts across layers, and its circuitry involves several cell types, many distinctive groups of afferents, and complex synaptic relationships.

MAPS There is a precise map of the contralateral visual hemifield in the lateral geniculate nucleus of all species so far studied, and in this the visual system is like other sensory systems that are mapped in their thalamic relays. The map in the lateral geniculate nucleus is laid out in fairly simple Cartesian coordinates in all species (see Fig. 35.1, where the visual field and its retinal and geniculate representations are shown as tapered arrows). Each layer maps the contralateral hemifield, either through one or the other eye, and all of these maps are aligned across the various layers that characterize the lateral geniculate nucleus of most species (see below and Fig. 35.1). Thus, a point in visual space is represented by a line, called a *line of projection*, that runs perpendicularly through all the layers. The precise alignment of these maps, which matches inputs from the nasal retina of one eye across layers with inputs from the temporal retina of the other eye, is seen in all species and is somewhat surprising when one thinks about the developmental mechanisms needed to produce such a match, which forms before the eyes open and before the two visual images can be matched. We shall see that there are nonretinal afferent axons that innervate the lateral geniculate nucleus and distribute terminals along the lines of projection. In this way, these afferents can have a well-localized action on just one part of the visual input, even though this comes from different eyes and distributes to distinct sets of layers (see the section “Afferents to the A Layers”).

LAYERING The lateral geniculate nuclei of all mammalian species so far studied show some form of layering, although there is considerable difference among species as to what the layers represent functionally. For all mammals, each layer receives input from only one eye, but the distribution of distinct functional types of retinal afferents to the layers differs greatly from one species to another. Chapters 30 and 31 describe the various classes of retinal ganglion cell that give rise to several parallel retinogeniculate pathways, and these frequently relate to specific geniculate layers. Figure 35.2 shows the layering of the lateral geniculate nucleus in the macaque monkey² and the cat, the two best-studied species. The figure illustrates the variation in layering seen across species and introduces the several parallel pathways

FIGURE 35.1 Schematic view of the representation of the retina and visual field in the layers of the lateral geniculate nucleus of a cat. The visual field is represented by a straight arrow, and the projection of part of this arrow onto each retina is shown. Small white areas of the visual field and corresponding parts of the retina are labeled “1” and “2.” The representation of this part of the visual field in the lateral geniculate nucleus is shown as a corresponding white column going through all of the geniculate layers “like a toothpick through a club sandwich” (Walls, 1953). Each such column is bounded by the lines of projection, which also pass through all of the laminae. A, A1, and C, the major geniculate layers; L LGN and R LGN, left and right lateral geniculate nuclei; LE and RE, left eye and right eye; asterisk, central point of fixation.

that are relayed through the lateral geniculate nucleus to the cortex.

Both species have three main retinal ganglion cell classes that project to the lateral geniculate nucleus. For the macaque monkey (Casagrande, 1994; Casagrande and Kaas, 1994; Hendry and Reid, 2000), these are the P (for parvocellular, meaning small-celled), M (for magnocellular; large-celled), and K (for koniocellular; tiny or dust-like cells) cells, comparable respectively to the X, Y, and W cells in the cat (reviewed in Casagrande and Norton, 1991; Lennie, 1980; Sherman, 1985). The terminology for the macaque monkey relates to the geniculate layers to which the cell classes project. P and M cells project to parvocellular and magnocellular layers, respectively. In the macaque monkey, K cells project to the ventral regions of all layers, where very small cells lie scattered, and the projections overlap with those of M and P cells. However, in *Galago*, a prosimian primate, each of the homologous retinal cell types projects to a separate set of layers (not shown)—koniocellular, par-

²Unless otherwise specified, we shall refer to this as the *monkey* in what follows, noting, however, that the macaque can be regarded as representative of Old World monkeys and that the lateral geniculate nucleus in New World monkeys has a slightly different structure.

FIGURE 35.2. Comparison of layering in lateral geniculate nucleus of cat and macaque monkey. See text for details. For simplicity, the medial interlaminar nucleus, which is part of the lateral geniculate nucleus medial to the main laminated portion, present in the cat but not in most other species, is not shown.

vocellular, and magnocellular—and it was in this species that the koniocellular pathway was first clearly recognized (Conley et al., 1985; Itoh et al., 1982; Norton et al., 1988). In the cat, X and Y cells have overlapping projections to the A layers, Y cells also project to layer C, and W cells project to layers C1 and C2; there is no retinal input to layer C3, which is therefore shown in black in Figure 35.2 (Hickey and Guillery, 1974). Strictly speaking, layer C3 should perhaps not be included in the lateral geniculate nucleus, which can be defined as the thalamic relay of retinal inputs. What is common to cat and macaque monkey is that each layer is innervated by only one eye. What is different is the partial segregation of parallel pathways through each layer. In the macaque monkey, the P and M pathways use separate layers, the parvocellular for P and the magnocellular for M; the K pathway overlaps with each and is thus represented in all layers. In the cat, the W pathway uses separate layers (C1 and C2), and the Y pathway has exclusive use of layer C, but the X and Y pathways are mingled in the A layers.

Despite the overlap within layers of many of the parallel pathways, there is no functional overlap at the cellular level; within the A layers of the cat, retinal X and Y axons innervate their own classes of relay cell. A similar pattern exists for the macaque monkey, with each of the K, P, and M retinal axons targeting separate classes of geniculate relay cell, whose axons, in turn, have distinct distributions in the visual cortex (see Chapter 31).

New World primates have a slightly different layering arrangement from that shown for the macaque monkey. So

far as we know, the human lateral geniculate nucleus is closely comparable to that of the macaque monkey, although there are commonly more than six layers (Hickey and Guillery, 1979), and we have no direct evidence concerning the distribution of distinct functional types to the different layers.

Thus, layering in the lateral geniculate nucleus separates left eye from right eye afferents and also, to a more limited extent, relates to the separation of functionally distinct parallel pathways. The binocular separation is constant across species, but the functional separation into distinct layers is highly variable, so that the number of layers, their sequence from superficial to deep, and their total number show great variability across species. Most of the information we have for cell and circuit properties of the lateral geniculate nucleus specifically and the thalamus more generally comes from the A layers in the cat, and most details presented below are from these layers. However, this focus on the A layers should not obscure two important facts. One is that in terms of the general arrangements of synaptic circuitry, there is a common thalamic plan that applies to the pulvinar region and to most other parts of the thalamus; the other is that structural details vary significantly among different layers and species. That is, there are details of functional organization that remain unknown but almost certainly will ultimately have to be added to our account of the A layers. For some details of geniculate relays beyond the A layers in the cat and in other species, see Jones (1985), Casagrande and Norton (1991), and Casagrande and Kaas (1994).

CELL TYPES WITHIN THE A LAYERS There are three basic cell types in the A layers of the cat's lateral geniculate nucleus (see Fig. 35.3). These include the two relay cell types, X and Y, and interneurons. The relay cells use glutamate as a neurotransmitter, whereas interneurons use GABA.

Relay cells. X and Y cells represent geniculate relays of two parallel and independent geniculocortical pathways, each innervated by its own retinal X or Y axons, which are excitatory. Retinal Y axons are thicker and conduct more rapidly than do X axons (reviewed in Sherman, 1985). Also, within the A layers, the terminal arbors of retinal Y axons are much larger than those of X axons and give rise to many more synaptic terminals (Bowling and Michael, 1984; Sur et al., 1987). As a result of this and because the postsynaptic relay cell types do not differ much in the number of synapses that they receive from the retina, each retinal Y axon innervates many more relay cells than does an X axon. It has been estimated that the X:Y ratio, which is roughly 10:1 in the retina (Leventhal, 1982; Wässle et al., 1975; Wässle et al., 1981), becomes 1:1 or 2:1 for geniculate relay cells (Sherman, 1985).

These geniculate relay cells differ from one another with respect to their functional and morphological properties. Both cell types have the center/surround organization for their receptive fields typical of retinal and geniculate cells generally. However, Y cells have larger receptive fields and respond better to higher temporal and lower spatial frequencies, whereas X cells have smaller receptive fields and respond better to lower temporal and higher spatial frequencies. Further, Y cells exhibit subtly more nonlinear summation (for further details, see Hochstein and Shapley, 1976a, 1976b; Sherman, 1985). All these receptive field differences are already present in the retinal afferents, and for this reason they will not be considered further.

Morphologically, there are some differences between these relay cell types (Friedlander et al., 1981; Guillery, 1966; LeVay and Ferster, 1977; Wilson et al., 1984). At the light microscopic level (see Fig. 35.3), Y cells have larger cell bodies and smooth dendrites that have cruciate branches in a relatively spherical arbor, with peripheral segments of dendrites often crossing from one layer to another. X cells have arbors that tend to be bipolar and oriented perpendicular to the layers' borders. Their dendrites also have numerous clusters of grape-like appendages located mostly near primary branch points (Fig. 35.3). The functional significance of these morphological differences remains to be defined, although the clustered appendages of the X cells represent the postsynaptic site of retinal inputs, where complex synaptic relationships are formed that are characteristic of X but not of Y cells (the *triadic* arrangements described below).

These and other differences in the microcircuitry of these cells types are described below.

Interneurons. Interneurons have the smallest cell bodies in the A layers and long, sinuous dendrites, and the dendritic arbors are always oriented perpendicular to the layers, often spanning an entire layer (see Fig. 35.3). The dendrites have the appearance of terminal axonal arbors and for that reason have been described as axoniform in appearance (Guillery, 1966). Terminals of these dendritic arbors are presynaptic to local dendrites, containing synaptic vesicles and thus resembling axon terminals, and they are also postsynaptic to other axons, generally those coming from either the retina or the brainstem (see also below and Erişir et al., 1997; Famiglietti and Peters, 1972; Hamos et al., 1985; Ralston, 1971). In addition, most, if not all, interneurons have conventional axons that terminate in the general vicinity of the dendritic arbor. The receptive fields of the few identified interneurons that have been studied are like those of X relay cells and unlike those of Y cells, which suggests that the retinal inputs responsible for their firing are X rather than Y axons (Friedlander et al., 1981; Sherman and Friedlander, 1988).

AFFERENTS TO THE A LAYERS The major sources of inputs to the A layers, besides the retina, include the thalamic reticular nucleus, layer 6 of cortex, and the parabrachial region³ of the midbrain. These are summarized in Figure 35.4. Other afferent sources not shown in Figure 35.4 include the nucleus of the optic tract (midbrain), the dorsal raphe nucleus (midbrain and pons), and the tuberomammillary nucleus (hypothalamus) (reviewed in Sherman and Guillery, 1996, 2001).

Retinal afferents. Retinal afferents to the A layers are glutamatergic (see Fig. 35.4). They are relatively thick axons and have a distinct terminal structure involving richly branched, dense terminal arbors with boutons densely distributed mostly in flowery terminal clusters (not illustrated; see Guillery, 1966). In contrast, most nonretinal inputs described below are thinner, and have an equally distinct structure with smaller terminals *en passant* or on short side branches (see Fig. 35.5, *right*). The retinal axons innervate both relay cells and interneurons in the A layers. Each retinal axon has an arbor strictly limited to one of the A layers, although Y axons and occasional

³ Another term frequently used for this area is *pedunculopontine tegmental nucleus*. We prefer *parabrachial region*, because the scattered cells that innervate the thalamus from this area do not have a clear nuclear boundary, and they are found scattered around the brachium conjunctivum.

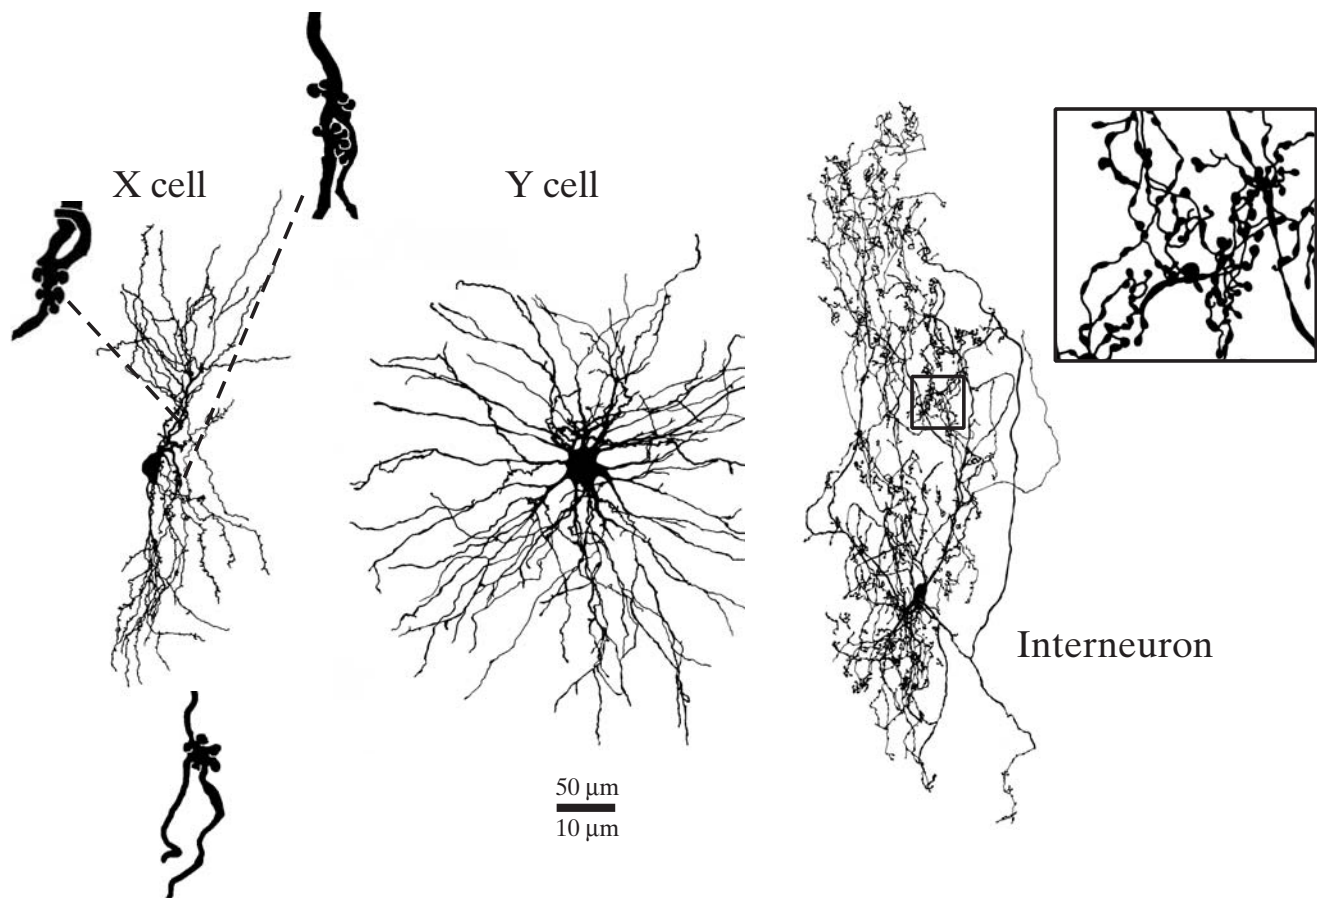

FIGURE 35.3. Reconstruction of an X cell, Y cell, and interneuron from A layers of the cat's lateral geniculate nucleus. The larger scales are for the insets for the X cell and interneuron.

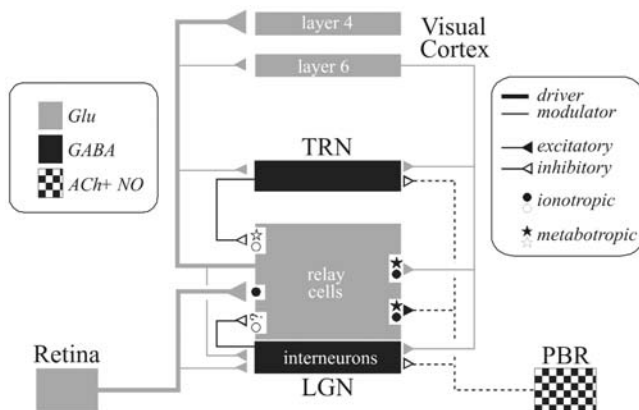

FIGURE 35.4. Neuronal circuitry related to A layers of the cat's lateral geniculate nucleus. Shown are the various inputs, the neurotransmitters associated with them, and the type of receptor, ionotropic or metabotropic, that each activates. Driver versus modulator inputs are also shown (see text for details).

X axons branch to innervate the C layers and/or the medial interlaminar nucleus⁴ as well. As would be expected from the earlier description of the lines of projection, the terminal arbors of the retinogeniculate axons are also organized so that they occupy relatively narrow columns that are bounded by lines of projection, either within a single layer or across more than one layer. Y arbors are larger and contain more boutons than do X arbors. A more subtle difference between them is that the boutons in Y arbors are fairly evenly distributed, while those in X arbors tend to be found in clusters with gaps between them (Bowling and Michael, 1984; Sur et al., 1987). All retinal X and Y axons innervating the lateral geniculate nucleus branch to innervate the midbrain as well (a point that is discussed further below; see also Guillery and Sherman, 2002a,b), but they do not innervate the thalamic reticular nucleus.

⁴The medial interlaminar nucleus is a part of the lateral geniculate nucleus found in carnivores.

FIGURE 35.5. Tracings of partial terminal arbors of three corticothalamic axons in the pulvinar region labeled by biotinylated dextran amine. The axon on the left exhibits driver morphology from cortical layer 5, and the two axons on the right exhibit modulator morphology from layer 6. (From Sherman and Guillery, 2001.)

Afferents from the thalamic reticular nucleus. The thalamic reticular nucleus is a thin shell of GABAergic neurons that surrounds the entire thalamus laterally, extending somewhat dorsally and ventrally. It derives from the ventral thalamus, together with the ventral lateral geniculate nucleus (see footnote 1), and is divided into sectors, each related to thalamic relay nuclei concerned with a particular modality or function (e.g., auditory, somatosensory, and motor), and as in the main part of the thalamus, sensory surfaces are mapped in the sectors (Crabtree, 1992, 1996, 1998; Crabtree and Killackey, 1989; Montero et al., 1977; reviewed in Guillery et al., 1998). There are strong reciprocal connections between relay cells and reticular cells linking corresponding parts of the reticular and geniculate maps (Pinault and Deschênes,

1998; Pinault et al., 1995a, 1995b; Uhlich et al., 1991), and the cortical afferents from layer 6 (next section) are mapped along the same coordinates (Murphy and Sillito, 1996). That is, the portion of the thalamic reticular nucleus innervating the lateral geniculate nucleus⁵ is mapped in retinotopic coordinates. In addition, the visual sector of the reticular nucleus is linked reciprocally to the pulvinar region (Conley and Diamond, 1990; Pinault et al., 1995a). There is some evidence that the visual sector of the reticular nucleus can be split into two parts, an inner part linked to the lateral geniculate nucleus and an outer part linked to the pulvinar region. The retinotopic mapping in the pulvinar sector of the reticular nucleus is less accurate than that for the geniculate sector, and there may be no map at all in the former.

The cells of the thalamic reticular nucleus, which lie just dorsal to layer A, have moderate to large cell bodies and dendrites oriented mostly parallel to layer A (Uhlich et al., 1991). Their axons descend into the A layers, generally along the lines of projection, with terminal arbors that are moderately branched and contain numerous boutons, mostly *en passant*. These terminals innervate geniculate relay cells, but they provide only a very sparse innervation to interneurons (Cucchiari et al., 1991; Wang et al., 2001). Thus, the thalamic reticular nucleus provides a potent inhibitory GABAergic input to relay cells (Fig. 34.4). Their receptive fields tend to be larger than those of relay cells and are often binocular (So and Shapley, 1981).

Afferents from layer 6 of the cortex. Cortical afferents from layer 6, which are glutamatergic, have thin axons with most boutons located at the end of short side branches (Fig. 34.5; see Murphy and Sillito, 1996). They are topographically organized, with each axon having terminal arbors bounded by lines of projection and passing across more than one layer. These axons enter the A layers after traveling through the thalamic reticular nucleus, where they also give off branches to innervate cells there; this projection, too, is topographic.

Afferents from the parabrachial region. Most of the input from the brainstem to the A layers derives from the parabrachial region (Bickford et al., 1993; de Lima and Singer, 1987). These axons are cholinergic but also appear to colocalize nitric oxide (Bickford et al., 1993; Erişir et al., 1997). Light microscopically, they resemble the cortical afferents more than the retinal afferents, but their terminal arbors are rather diffuse and most appear to terminate in a nontopographic

⁵In the cat, the major portion of the thalamic reticular nucleus innervating the lateral geniculate nucleus is the *perigeniculate nucleus*.

fashion. These axons contact both relay cells and interneurons in the A layers and also branch to innervate cells in the thalamic reticular nucleus.

Other afferents. Some other afferents to the A layers not shown in Figure 35.4 have been described, but they are small in number, not well documented, and will be mentioned only briefly here (for further details, see Sherman and Guillery, 1996, 2001). Lying among the cholinergic cells of the parabrachial region, there are also some noradrenergic cells that innervate the A layers. There is limited serotonergic input from the dorsal raphe nucleus in the midbrain and pons. GABAergic cells of the nucleus of the optic tract in the midbrain also provide limited input. Finally, the tuberomammillary nucleus of the hypothalamus provides a small histaminergic input (Uhlrich et al., 1993).

Postsynaptic receptors. In addition to showing the inputs and their transmitters onto relay cells, Figure 35.4 shows the associated postsynaptic receptors. Note that both ionotropic and metabotropic receptors are postsynaptic in relay cells. There are a number of differences between these two receptor types, but only a few concern us here (for details, see Brown et al., 1997; Conn and Pin, 1997; Mott and Lewis, 1994; Nicoll et al., 1990; Pin and Duvoisin, 1995; Recasens and Vignes, 1995).

Ionotropic receptors include AMPA receptors for glutamate, GABA_A, and nicotinic receptors for acetylcholine. These are complex proteins found in the postsynaptic membrane, and when the transmitter contacts the receptor, it leads to a rapid conformational change that opens an ionic channel, leading to transmembrane flow of ions and a postsynaptic potential. Activation of ionotropic receptors leads to fast responses, typically with a latency for postsynaptic potentials of less than 1 msec and a duration of a few tens of milliseconds. Metabotropic receptors include various glutamate receptors, GABA_B, and various muscarinic receptors for acetylcholine. These are not directly linked to ion channels. Instead, when the transmitter contacts the receptor protein in the membrane, a series of complex biochemical reactions takes place that ultimately leads to the opening or closing of an ion channel, among other postsynaptic events. For thalamic cells, this is primarily a K⁺ channel that, when opened, produces an inhibitory postsynaptic potential (IPSP) as K⁺ flows out of the cell and, when closed, produces an excitatory postsynaptic potential (EPSP) as leakage of K⁺ is reduced. However, these postsynaptic responses are slow: there is usually a latency of 10 msec or longer and a duration of hundreds of milliseconds or more. Also, in general, metabotropic receptors require higher firing rates from inputs to be activated. This is thought to be related to the observation that electron micrographs show these receptors to be located slightly farther from the synaptic site than are

ionotropic receptors, so that more transmitter must be released to reach them.

The more sustained responses associated with metabotropic receptors have a number of important implications. One has to do with the fact that retinal inputs activate only ionotropic receptors in relay cells. This means that retinal EPSPs are relatively fast and brief. This has the virtue that firing in the retinal afferents can reach relatively high levels before temporal summation of the EPSPs occurs, and thus each retinal action potential has a unique postsynaptic response associated with it. If, instead, metabotropic glutamate receptors were activated, the sustained EPSPs would mean that relatively low rates of firing in the afferent would produce temporal summation postsynaptically. This, in turn, means that higher-frequency information would be lost in retinogeniculate transmission or, more formally, that the retinogeniculate synapse would operate like a low-pass temporal device, filtering out higher frequencies. Thus, the fact that retinal inputs activate only ionotropic receptors serves to maximize the transfer of higher temporal frequencies. Note that the population of nonretinal inputs as a whole activates both metabotropic and ionotropic receptors (reviewed in Sherman and Guillery, 1996, 2001). However, it is not clear whether any individual nonretinal axon can activate both ionotropic and metabotropic receptors. Nonetheless, the activation of metabotropic receptors means that these inputs can create sustained changes in baseline membrane potential, which, among other things, means that these inputs can have sustained effects on the overall responsiveness of relay cells. Other consequences of these sustained postsynaptic responses are considered below.

Synaptic structures. Over 95% of all synaptic terminals in the A layers can be placed into one of four categories (reviewed in Sherman and Guillery, 1996, 2001): (1) *RL* (Round vesicle, Large profile) terminals, which are the retinal terminals, are the largest terminals in the A layers. They form asymmetric⁶ contacts consistent with their identity as excitatory inputs. (2) *RS* terminals (Round vesicle, Small profile) are smaller than RL terminals but also form asymmetric contacts. The vast majority of these come from either layer 6 of cortex or the parabrachial region. (3) *FI* terminals (*F*lattened

⁶One ultrastructural characteristic of synaptic contacts is a thickening of the postsynaptic membrane, which includes the postsynaptic receptors (Sheng, 2001). When the thickening is especially prominent, the postsynaptic membranes are much thicker than the presynaptic ones, and this characterizes an *asymmetric* synapse. When the thickening is less prominent, there is a less pronounced difference in thickness between presynaptic and postsynaptic membranes, and this characterizes a *symmetric* synapse. Typically, asymmetric synapses are excitatory, and symmetric ones are inhibitory.

FIGURE 35.6. Schematic view of triadic circuits in a glomerulus of the lateral geniculate nucleus in the cat. The arrows indicate presynaptic to postsynaptic directions. The question marks postsynaptic to the dendritic terminals of interneurons indicate that it is not clear whether or not metabotropic (GABA_B) receptors exist there.

vesicles) form symmetric contacts consistent with their origin from axons of reticular cells or interneurons. (4) F2 terminals represent the dendritic outputs of interneurons; they also have flattened vesicles and form symmetric contacts. Unlike all of the other terminals, which are strictly presynaptic, these are both presynaptic and postsynaptic, with inputs from either retinal or parabrachial terminals.

Triadic synaptic arrangements involving F2 terminals are common in the A layers (Fig. 35.6). In some triads, an RL terminal contacts both an F2 terminal and the dendrite of a relay cell, and the F2 terminal contacts the same relay cell dendrite. A slightly different kind of triad can be formed by a parabrachial terminal contacting an F2 terminal and a different parabrachial terminal from the same axon contacting a relay cell dendrite, again with the F2 terminal contacting the same relay cell dendrite (Fig. 35.6). Nearly all F2 terminals are involved in one or the other form of triad. Curiously, these triads are quite common for relay X cells and rare for Y cells, the latter thus receiving very few inputs from F2 terminals.⁷ Triads are typically found in complex synaptic zones that lack astrocytic processes but are

surrounded by sheets of astrocytic cytoplasm; these are called *glomeruli*. It is not at all clear how the triads function.

Distribution of inputs to relay cells. The dendritic arbors of relay cells can be divided into two distinct sectors with little or no overlap (Erişir et al., 1997; Wilson et al., 1984): a proximal region (up to about $100\mu\text{m}$ from the cell body or generally close to the first branch point) and a distal region (farther than about $100\mu\text{m}$ from the cell body). Retinal terminals contact the former region, whereas cortical terminals contact the latter. F2 and parabrachial terminals also contact relay cells in the proximal zone. Axonal inputs from interneurons mostly contact the proximal zone, whereas those from reticular axons mostly contact the distal zone.

A small minority of synaptic inputs onto geniculate relay cells derive from retina. In the A layers of the cat's lateral geniculate nucleus, for instance, only about 5–10% of the synaptic input to relay cells comes from the retinal axons: roughly 30% comes from local GABAergic cells (interneurons plus reticular cells), 30% from the cortical input, and 30% from the parabrachial region (Van Horn et al., 2000). In the parvocellular C layers, even fewer synapses—2% to 4%—onto relay cells derive from the retina (Raczkowski et al., 1988). If one had only the anatomical data, and for many other thalamic relays that is all we have, one might well conclude that the lateral geniculate nucleus relays parabrachial input to cortex and that the retinal input plays only a minor, undetermined role. For the lateral geniculate nucleus we know that it is the retinal input that is relayed to cortex, so we accept that the small number of retinal afferents serve as the crucial drivers of geniculate function. However, for thalamic nuclei that we do not understand as well as the lateral geniculate nucleus, the point is important, as we will see when we discuss corticocortical communication.

Drivers and modulators. It follows that not all inputs to the thalamus are equal in their action on the relay cells. We have distinguished two different types of input (Sherman and Guillery, 1998, 2001): *drivers* and *modulators*. The drivers are the information-bearing input that is to be relayed to cortex, and this is the retinal input for the lateral geniculate nucleus. All other inputs are modulators. Examples of modulation are provided below, and details of how drivers might generally be distinguished from modulators is provided elsewhere (Sherman and Guillery, 1998, 2001). One difference is seen in Figure 35.4: the driver (retinal) input activates only ionotropic receptors, whereas the modulators activate metabotropic and often ionotropic receptors. Note that, of the main extrinsic inputs to the lateral geniculate nucleus, the retinal input is a driver, but the layer 6 cortical and parabrachial inputs are both modulators. The corticothalamic input must be seen as modulatory because, among other

⁷Recent descriptions of triads that relate to Y cell terminals suggest more similarities between the X and the Y pathways than reported in the earlier studies (e.g., Wilson et al., 1984; Sherman and Friedlander, 1988). Datskovskaia et al. (2001) offer evidence that many retinal Y axons in the A layers terminate on dendritic presynaptic F2 terminals and thus are likely to contribute significantly to triads. Also a recent account of triads related to Y cell axons in the geniculate C layers (Dankowski and Bickford, 2003) adds new information on the subject, and the issue of the extent of triadic circuitry in the Y pathway remains to be resolved.

reasons, its elimination (by cooling, ablation, etc.) has only subtle effects on the receptive fields of geniculate relay cells, not altering their basic center/surround organization (Cudeiro and Sillito, 1996; Geisert et al., 1981; Jones and Sillito, 1991; Kalil and Chase, 1970; McClurkin and Marrocco, 1984; McClurkin et al., 1994). This is in contrast to corticothalamic afferents from layer 5, which go to higher-order thalamic relays but not to the lateral geniculate nucleus, and which must be regarded as drivers because their elimination essentially abolishes the characteristic receptive fields in such target thalamic relays as the posterior medial nucleus or pulvinar region (Bender, 1983; Chalupa, 1991; Diamond et al., 1992; see also the section "The Pulvinar Region as a Visual Relay").

INTRINSIC PROPERTIES OF THALAMIC CELLS IN THE A LAYERS

The relay nature of the lateral geniculate nucleus depends on the mechanisms by which retinal inputs evoke firing in geniculate relay cells, and these mechanisms are also present in thalamic relays more generally. There are three factors that largely control this retinogeniculate transmission, and they are considered below. First are the intrinsic membrane properties of relay cells, including their passive and active membrane properties, because these determine the effect of retinal EPSPs at the cell body or region of action potential generation. Second is the geniculate circuitry that, by affecting many of the intrinsic membrane properties, also controls the effect of retinal EPSPs on relay cell firing. Third, the nature of the postsynaptic receptors largely determines the postsynaptic response of relay (and other) cells to their active inputs; this feature is considered in the section "Control of Response Mode."

Generally, all thalamic cells show a wide range of intrinsic membrane properties that are found generally in neurons of the brain (reviewed in Sherman and Guillery, 1996, 2001). These include passive cable properties, voltage-sensitive and -insensitive conductances, and conductances sensitive to other factors, such as Ca^{2+} concentration. The conductances underlie transmembrane currents, including a leak K^+ current ($I_{\text{K[leak]}}$) that helps control the resting membrane potential, various voltage- and Ca^{2+} -gated K^+ currents (I_{A} , $I_{\text{K[Ca}^{2+}]}$, etc.), and a voltage-gated cation current (I_{h}). Since these are properties found widely in the brain, they will not be considered further here, but additional details of these as they apply to thalamic neurons can be found in Sherman and Guillery (1996, 2001). Two features that are of particular interest in thalamic neurons are considered below. One is the apparent cable properties of interneurons, which suggests that synaptic inputs onto their dendritic terminals affect them locally but have little effect on the cell body and axonal output, permitting these cells to provide numerous input/output routes independently and simultaneously (see below). The other is the presence in all cells of a voltage-

gated Ca^{2+} conductance based on T-type (for transient) Ca^{2+} channels that, when activated, leads to a current (I_{T}) large enough to produce an all-or-none Ca^{2+} spike (reviewed in Sherman and Guillery, 1996, 2001). This spike alters the response properties of the thalamic cells in a functionally highly significant manner.

Passive membrane or cable properties. Determining how current spreads through cells with complex geometries of their dendritic trees poses a formidable computational problem. Modeling the cell and its membranes as a cable provides a useful means of approximating current flow. Details of cable modeling for thalamic neurons can be found in Bloomfield et al. (1987) and Bloomfield and Sherman (1989) and will be briefly summarized here. Relay cells and cells of the thalamic reticular nucleus have relatively thick dendrites that branch in a way that suggests efficient current flow through the dendrites. The result of cable modeling for these cells indicates that they are electrotonically compact, meaning that EPSPs and IPSPs generated even on peripheral dendrites will produce significant voltage changes at the cell body and axon hillock (Bloomfield et al., 1987; Bloomfield and Sherman, 1989). Thus, all synaptic inputs to these cells can be considered influential in affecting the cell's firing. Since the dendrites of relay cells are purely postsynaptic structures, the only synaptic output of these cells is via their axons, so that any synaptic input to the distal dendrites that could not produce a voltage change at the spike-initiating region would be ineffective for spike initiation.

In contrast to relay cells, interneurons are built differently in two ways. First, as noted above, in addition to having a conventional axonal output, these cells have presynaptic terminals on peripheral dendrites, which provide these cells with numerous dendritic outputs. Second, these presynaptic terminals are attached to the stem dendrites by long, thin stalks; overall, the thin dendrites and the nature of the dendritic branching suggest poor current flow through the dendritic trees. Cable modeling suggests that EPSPs and IPSPs generated on the peripheral dendrites, where the retinal and brain stem axons provide significant input to the dendritic presynaptic boutons, will have little influence on the cell body and axon hillock (Bloomfield and Sherman, 1989). Thus, the interneuron appears capable of multiplexing: the axonal output is controlled by synapses located on proximal dendrites, whereas the several separate dendritic outputs are controlled locally and independently of each other by local synaptic inputs. However, this concept of the functioning of the interneuron remains a hypothesis that requires more direct evidence than currently exists (Cox and Sherman, 2000).

Properties of I_{T} in relay cells. The voltage-dependent low-threshold Ca^{2+} spikes that are based on T channels are

The Low Threshold Ca^{2+} Spike

FIGURE 35.7. Highly schematized view of the actions of voltage-dependent T (Ca^{2+}) and K^+ channels underlying a low-threshold Ca^{2+} spike. The four numbered panels show the sequence of channel events, and the central graph shows the effects on membrane potential. The T channel has two voltage-dependent gates: an *activation* gate that closes at hyperpolarized levels and opens with depolarization, and an *inactivation* gate that shows the opposite voltage dependency. The K^+ channel shown is really a conglomeration of several such channels that have only a single gate that opens during depolarization; thus, these channels do not inactivate. 1, At a relatively hyperpolarized resting membrane potential ($\sim 70\text{mV}$), the activation gate of the T channel is closed but the inactivation gate is open, so the T channel is deactivated. The single gate for the K^+ channel is closed. 2, With sufficient depolarization to reach its threshold, the activation gate of the T channel opens, allowing Ca^{2+} to flow into the cell. This depolarizes the cell, providing the upswing of the low-threshold spike. 3, The inactivation gate of the T channel closes after roughly 100 msec (“roughly,”

because closing of the channel is a complex function of time and voltage), and the K^+ channel also opens. These combined actions lead to the repolarization of the cell. While the inactivation gate of the T channel is closed, the channel is said to be inactivated. There are probably several different kinds of K^+ channels involved with different time constants, but in general, they open more slowly than does the activation gate of the T channel. Also, not shown, K^+ channels dependent on Ca^{2+} entry are probably involved. 4, Even though the initial resting potential is reached, the T channel remains inactivated, because it takes roughly 100 msec (“roughly” having the same meaning as above) of hyperpolarization to deactivate it; it also takes a bit of time for the various K^+ channels to close. Note that the behavior of the T channel is qualitatively exactly like that of the Na^+ channel involved with the action potential, but with several quantitative differences: the T channel is slower to inactivate and deactivate, and it operates in a more hyperpolarized regime.

ubiquitous to thalamic relay cells: they have been found in every relay cell of every thalamic nucleus of every mammalian species so far studied (reviewed in Sherman and Guillery, 1996). Figure 35.7 shows the voltage dependence of the T channels and that of K^+ channels also involved in the generation of the low-threshold spikes. The T channels have two voltage-sensitive gates, an activation gate and an inactivation gate, and both must be open for Ca^{2+} to flow into the cell and thus depolarize it. At the normally hyperpolarized resting membrane potentials (Fig. 35.7(1)), the activation gate is closed but the inactivation gate is open, so the channel is deactivated. The single gate of the K^+ channel is closed at this membrane potential. If the cell is

now sufficiently depolarized (e.g., by an EPSP), the activation gate pops open, and Ca^{2+} flows into the cell, providing the upswing of the low-threshold spike (Fig. 35.7(2)). However, depolarization causes the inactivation gate to close (Fig. 35.7(3)), but this takes time, on the order of 100 msec or so.⁸ The single gate of the K^+ channel, because of its

⁸Actually the opening or closing of the inactivation gate is a complex function of voltage and time (Jahnsen and Llinás, 1984), so that the more depolarized (or hyperpolarized) the more quickly the gate closes (or opens), but the important point is that under normal conditions, roughly 100 msec is required for these actions.

voltage dependency, also opens, and the combined inactivation of the T channel and activation of the K^+ channel serve to repolarize the cell (Fig. 35.7(4)). Although not shown, in addition to voltage-dependent K^+ channels, Ca^{2+} -dependent ones are also activated by the Ca^{2+} entry and assist the repolarization process. While the membrane is repolarized to its initial potential, the T channel remains inactivated, because it takes roughly 100 msec of this hyperpolarization to deinactivate these channels, after which time the initial conditions are reestablished (Fig. 35.7(1)). To reiterate: when the cell is sufficiently hyperpolarized for more than about 100 msec, the T channel is deinactivated; if deinactivated, a suitable depolarization can then activate the channel, but continued depolarization for more than about 100 msec will inactivate it; the inactivation can then be removed by suitable hyperpolarization for more than about 100 msec.

This voltage dependency of the T channels provides the relay cell with two different firing modes: if the cell is relatively depolarized, the T channels are inactivated and do not participate in the cell's responses; here the cell is said to be in *tonic firing mode*. If the cell is relatively hyperpolarized, the T channels are deinactivated and thus primed for action. They can become activated and, on the basis of mechanisms considered below, can affect how the cell fires; here the cell is said to be in *burst firing mode*.

The voltage-dependent properties of the T channels are qualitatively identical to those of the Na^+ channels underlying the action potential, but there are several important quantitative differences: (1) Opening or closing of the inactivation gate is roughly two orders of magnitude faster for the Na^+ channel. (2) The T channels are found in the cell body and membranes, but not in the axon; thus, the low-threshold spike can be propagated through the dendrites and cell body but not along the axon to cortex. That is, the T channels can affect the signal reaching cortex by the effect of the low-threshold spike on the generation of action potentials (see below). (3) The T channels operate in a somewhat more hyperpolarized regime, and their activation at more hyperpolarized levels is the reason the resultant Ca^{2+} spike is called *low threshold*. (4) The T channels operate in a slightly more hyperpolarized regime than the Na^+ channels.

Figure 35.8 shows recordings from relay cells of the cat's lateral geniculate nucleus, illustrating some of the functional consequences of I_T . When the membrane is more depolarized than roughly -60 to -65 mV for more than ~ 100 msec, I_T becomes inactivated (Fig. 35.8A), and activation by a depolarizing pulse evokes a steady stream of action potentials lasting for the duration of the stimulus: this is tonic firing. When the membrane is more hyperpolarized than about -65 to -70 mV for more than ~ 100 msec (Fig. 35.8B), I_T becomes deinactivated. Now the very same depolarizing

pulse activates I_T , leading to a low-threshold spike, which, in turn, leads to a burst of a few action potentials: this is burst firing. Note that the same excitatory stimulus produces two very different signals relayed to cortex, and the difference depends on the initial membrane potential of the relay cell, because this determines the inactivation state of I_T . The stimulus in this example is a current pulse, but the same would apply to a sufficiently large EPSP.

The size of the activated low-threshold spike depends on the extent to which the cell is hyperpolarized before being activated, because the more the cell is hyperpolarized, the more T channels are deinactivated and thus available to contribute to the low-threshold spike (Fig. 35.8C). As would be expected, the larger the low-threshold spike, the larger the number of action potentials evoked in the associated burst (Fig. 35.8C). However, in addition, the low-threshold spike is activated in an all-or-none manner, because at any one initial membrane potential, suprathreshold activating inputs activate low-threshold spikes of essentially the same amplitude, regardless of how far above threshold the activating input is (Fig. 35.8D). One implication of this for the difference in input/output relationships between burst and tonic firing is shown in Figure 35.9. This relationship is fairly linear for tonic firing, because there is a direct link between the input depolarization and activation of action potentials, leading to the monotonic relationship as shown. However, the relationship is indirect for burst firing, since it is the low-threshold spike that controls firing, and, as Figure 35.8D shows, larger activating inputs do not produce larger low-threshold spikes.

Properties of I_T in interneurons and reticular cells. I_T is present in both interneurons and reticular cells, but its action is subtly different in these cells. Its activation in interneurons is a matter of some controversy. Several studies suggest that I_T is rarely activated in these cells, because it is masked by I_A (Pape et al., 1994). I_A is a K^+ conductance with a voltage dependence similar to that of I_T : it is inactivated at depolarized levels and deinactivated at hyperpolarized levels, from which it can be activated (for details, see McCormick, 1991). However, unlike I_T , I_A creates hyperpolarization, since the current is composed of K^+ ions leaving the cell. Some evidence suggests that, in interneurons, the relative voltage dependency of these two currents is such that I_A is typically activated before I_T , thereby preventing activation of I_T (Pape et al., 1994). In relay cells, the relative voltage dependency is different, so that I_T is activated first (Pape et al., 1994). However, other evidence suggests that if the input resistance of the interneuron is high enough, low-threshold spiking is readily produced (Zhu et al., 1999). At present, it is difficult to reconcile these views. Nonetheless, it should be appreciated that tonic firing and burst firing in the interneuron, to the extent that

FIGURE 35.8. Properties of I_T and the low-threshold spike; examples from intracellular in vitro recordings of geniculate relay cells of the cat. *A, B*, Voltage dependency of the low-threshold spike. Responses are shown to the same depolarizing current pulse delivered intracellularly but from two different initial holding potentials. With relative depolarization of the cell (*A*), I_T inactivates, and the cell response is a stream of unitary action potentials lasting for the duration of a suprathreshold stimulus. This is the *tonic mode* of firing. With relative hyperpolarization of the cell (*B*), I_T deinactivates, and the current pulse activates a low-threshold spike with four action potentials riding its crest. This is the *burst mode* of firing. *C*, Voltage dependency of low-threshold spike amplitude and associated burst response. Examples for two cells are shown. The number of action potentials were recorded first in the experiment, and then the pro-

cedure was repeated after tetrodotoxin (TTX) application to eliminate action potentials and isolate the low-threshold spike for measurement. The more hyperpolarized the cell before activation (*Initial Membrane Potential*), the more action potentials (*AP*) in the burst (open circles) and the larger the low-threshold spike (filled squares and curve). *D*, All-or-none nature of low-threshold spikes in another geniculate cell, measured in the presence of TTX. After initial hyperpolarization of the cell, current pulses were injected in 10 pA incremental steps. Smaller (subthreshold) pulses produced resistive-capacitive responses, but all larger (suprathreshold) pulses evoked low-threshold spikes that are all of the same amplitude, regardless of how far the depolarizing pulse exceeded activation threshold. (*C* redrawn from Sherman, 2001; Zhan et al., 2000; *D* redrawn from Zhan et al., 1999.)

FIGURE 35.9. Input output relationship for a geniculate relay cell recorded intracellularly in vitro. The input variable is the amplitude of the depolarizing current pulse, and the output is the firing frequency of the cell. To compare burst and tonic firing, the firing frequency was determined by the first six action potentials of the response, since this cell usually exhibited six action potentials per burst in this experiment. The initial holding potentials are shown; -47 mV and -59 mV reflect tonic mode (open squares and curves), whereas -77 mV and -83 mV reflect burst mode (filled curves). (Redrawn from Zhan et al., 1999.)

they exist, describe axonal outputs of interneurons, and their dendritic outputs may follow quite different and independent patterns.

Cells of the thalamic reticular nucleus also have burst firing based on voltage-dependent T channels, but the temporal properties are slightly different from those in relay cells, leading to longer low-threshold spikes and more prolonged bursts in reticular cells (for details, see Destexhe et al., 1996).

SIGNIFICANCE OF BURST AND TONIC FIRING The first studies of thalamic bursting in vivo emphasized the presence of rhythmic bursting in thalamic relay cells during slow-wave sleep and certain pathological conditions, such as epilepsy, in which this bursting is synchronized across large cell populations. In these conditions, such bursting also interferes with normal relay functions, and it was thus considered not to be a relay mode of firing (Fanselow et al., 2001; Steriade and Llinás, 1988; Steriade and McCarley, 1990; Steriade et al., 1990, 1993).

Because such rhythmic bursting was not seen during waking behavior, this led to the notion that bursting occurs

only during sleep or pathological state and that tonic firing is the normal relay mode during waking behavior. However, it is now clear that bursting also occurs during normal waking behavior (Edeline et al., 2000; Fanselow et al., 2001; Lenz et al., 1998; Magnin et al., 2000; Ramcharan et al., 2000; Swadlow and Gusev, 2001), but because the bursting then is not rhythmic it is harder to detect, and this perhaps explains why it was not emphasized in earlier studies. It may also be that the rhythmic bursting seen during slow-wave sleep provides a positive signal to cortex that nothing is being relayed despite the possible presence of sensory stimuli, and this is less ambiguous than no activity, which could mean either no relay or no stimulus. In contrast, when the bursting is arrhythmic, this arrhythmicity can represent responses evoked by sensory stimuli.

Most relay cells during waking behavior fire more often in tonic mode, and the amount of bursting seems to go down to small values as the animal becomes more alert (Ramcharan et al., 2000; Swadlow and Gusev, 2001). Nonetheless, both modes effectively relay retinal information to cortex (Ramcharan et al., 2000; Reinagel et al., 1999; Sherman, 2001), and thus the presence in an awake animal of both modes, tonic and nonrhythmic bursting, raises the obvious question: what is the significance of these two modes? They represent very different ways in which the relay cell responds to the same input, indicating that the same message is relayed to cortex in one of two different ways. Thus, when messages arrive at the relay cell, the level of its membrane potential, which determines the inactivation state of I_T , can strongly influence the nature of the information that is transmitted to cortex. Receptive field analysis from relay cells of the cat's lateral geniculate nucleus indicates that both response modes convey comparable levels of information in the relay to cortex (Reinagel et al., 1999), although it is also clear that the nature of that information differs between modes (Sherman, 1996, 2001). There may be many differences related to these two modes, but two that have received considerable attention are linearity of the relay process and detectability of the message that is relayed to cortex.

Linearity. From the cellular properties described above (e.g., Fig. 35.9), it is clear that tonic firing represents a more linear relay mode. This is also seen in the responses of geniculate relay cells to visual stimuli. A clear example is shown in Figure 35.10, which shows the responses to a drifting sinusoidal grating of a relay cell recorded in vivo in an anesthetized cat. When the cell is in tonic mode, the response to the grating has a sinusoidal profile (Fig. 35.10*A*, lower). This means that the response level closely matches the changes in contrast, indicating a very linear relay of this input to cortex. However, when the same stimulus is applied to the same cell, but now in burst mode, the response no longer seems sinu-

soidal (Fig. 35.10*B*, lower), indicating considerable nonlinear distortion in the relay. Thus, tonic mode is better at preserving linearity in the relay of information to cortex (Sherman, 1996, 2001).

Detectability. The upper histograms of Figure 35.10 show further that spontaneous activity is lower during tonic than burst firing. Higher spontaneous activity is actually useful for maintaining linearity of response, because it helps prevent rectification of the response to inhibitory phases of visual stimulation, and rectification is a nonlinearity. Perhaps more interesting is the notion that spontaneous activity represents firing without a visual stimulus and can thus be considered a noisy background against which the signal—the response to the visual stimulus—must be detected. In this regard, the signal-to-noise ratio appears to be higher during burst firing, and indeed, the use of a method from signal detection theory involving the calculation of *receiver operating characteristic* curves (Green and Swets, 1966; Macmillan and Creelman, 1991) shows that stimulus detectability is improved during burst firing compared to tonic firing (Sherman, 1996, 2001).

Bursting as a “wake-up call.” The above differences in firing modes as regards linearity and detectability suggest the following hypothesis (Sherman, 1996, 2001). Tonic firing is better for faithful, detailed reconstruction of the stimulus,

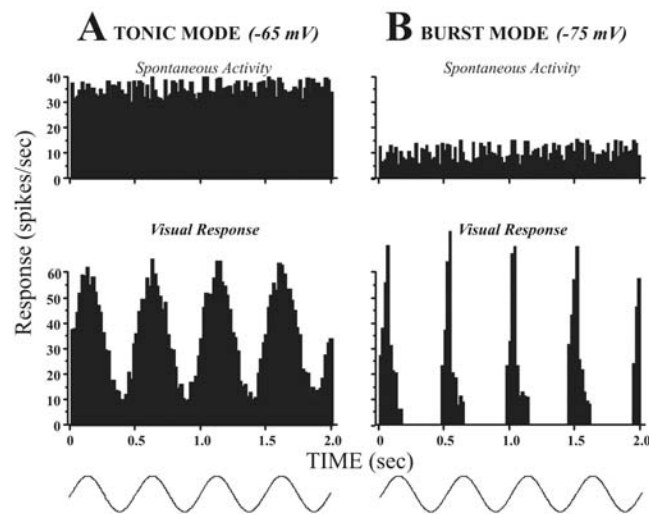

FIGURE 35.10. Tonic and burst responses of relay cells from the cat's lateral geniculate nucleus to visual stimulation. *A*, *B*, Average response histograms of responses of one cell to four cycles of drifting sinusoidal grating (lower) and during spontaneous activity (upper). The contrast changes resulting from the drifting grating are shown below the histograms. The cell was recorded intracellularly in vivo, and current injected through the recording electrode was used to bias membrane potential to more depolarized (-65 mV), producing tonic firing (*A*), or more hyperpolarized (-75 mV), producing burst firing (*B*).

because the nonlinear distortions created during burst firing would limit the extent to which cortex receives an accurate copy of the messages that are being passed through the thalamus. However, burst firing would be better for initial stimulus detectability. For instance, when an animal is drowsy, it might be advantageous to have geniculate relay cells in burst mode to maximize detection of a new visual stimulus; after detection, the relay can be switched to tonic firing for more faithful stimulus analysis (for details of this hypothesis, see Sherman, 1996, 2001). Indeed, there is evidence from the somatosensory system of awake, behaving rabbits that thalamic relay cells in burst mode are much more likely to evoke an action potential in their cortical target cells than when these relay cells are firing in tonic mode (Swadlow and Gusev, 2001). This finding that bursts punch through the thalamocortical synapse much more effectively than tonic firing is consistent with, but of course falls short of proving, the notion that bursts serve as a wake-up call.

Control of response mode. For this hypothesis to be plausible, there must be ways in which thalamic circuitry can be employed to control the firing mode. In fact, the functional circuitry shown schematically in Figure 35.4 provides this requirement. As noted above, to switch the inactivation state of I_T requires a change in membrane voltage that must be sustained for roughly ≥ 100 msec. Sustained depolarization is needed to inactivate I_T and sustained hyperpolarization for deinactivation. Activation of ionotropic receptors with their fast postsynaptic potentials seems poorly suited to this task, because without extensive temporal summation, the changes in membrane polarization would be too transient to affect the inactivation state of I_T significantly. Metabotropic receptors are much better suited for this task, since their activation would produce sufficiently sustained postsynaptic potentials. Thus, activation of metabotropic glutamate receptors from cortex or muscarinic receptors from the parabrachial region produces a sufficiently long EPSP to inactivate I_T and switch the firing mode from burst to tonic. In contrast, activation of $GABA_B$ receptors, mainly from activation of reticular inputs but also possibly from interneuronal inputs, produces a sufficiently long IPSP to deinactivate I_T and switch the firing mode from tonic to burst. Indeed, evidence for such switching from activation of these inputs exists from both in vivo and in vitro studies (reviewed in Sherman and Guillery, 1996, 2001).

Ultimately, it is the cortical and parabrachial inputs that control firing mode via their direct inputs to relay cells, which promote tonic firing, and their indirect inputs, via reticular (and possibly interneuron) inputs, which promote burst firing. At the cellular level, both inputs seem to have the same effect. However, the corticogeniculate pathway is highly topographic and purely visual, so that this pathway would presumably control firing mode for groups of genic-

ulate cells based on specific visual parameters such as different locations within the visual field. The diffuse nature of the parabrachial input suggests that its effects are more widespread in the lateral geniculate nucleus and might relate more globally to overall levels of attention (e.g., more bursting exists during states of drowsiness; see Ramcharan et al., 2000; Swadlow and Gusev, 2001) or to which sensory system is being used.

This is not to say that the only purpose of cortical and brainstem inputs is to control firing mode. For example, the corticogeniculate input seems quite heterogeneous, and several other functions have been proposed for it (e.g., McClurkin and Marrocco, 1984; McClurkin et al., 1994; Schmielau and Singer, 1977; Sillito et al., 1993, 1994). The point here is that these multiple functions are not mutually exclusive.

The functional organization of the pulvinar region

THE PULVINAR REGION AS A VISUAL RELAY Although much less is known about the pulvinar region than about the lateral geniculate nucleus, it provides an important pathway to many, possibly all, higher visual cortical areas. The cells in this complex have visual receptive fields (Bender, 1982; Chalupa, 1991; Hutchins and Updyke, 1989), and their links with extrastriate visual cortical areas have long been recognized (Jones, 1985), but the functional nature of this link has become clear only more recently. In order to appreciate the nature of this link, it is important to recall that the lateral geniculate nucleus receives modulatory afferents from layer 6 of cortex and driving afferents, providing the visual inputs, from the retina. These two types of afferent were described above, and it was shown that they are clearly distinguishable in terms of their light and electron microscopic appearance, in terms of the patterns of synaptic connections that they establish, and in terms of their driving or modulatory functions: silencing the retinal inputs abolishes the receptive field properties of lateral geniculate cells, whereas silencing the cortical inputs changes the receptive field properties of geniculate cells only slightly (Baker and Malpeli, 1977; Geisert et al., 1981; Kalil and Chase, 1970; McClurkin and Marrocco, 1984; McClurkin et al., 1994; Schmielau and Singer, 1977). Further, the receptive field properties of lateral geniculate cells are very similar to those of retinal cells but are not like those of layer 6 cortical cells.

We know from injections of retrograde tracers into the lateral geniculate nucleus that this nucleus receives afferents from cortical layer 6 but not from cortical layer 5 (Gilbert and Kelly, 1975). Further, injections of anterograde tracers into cells in layer 6 of area 17 label the axons having the characteristics of the modulatory afferents described above (Fig. 35.5, *right*), whereas injections of layer 5 cells produce no labeled axons in the lateral geniculate nucleus (Bourassa

and Deschênes, 1995; Rockland, 1996). The pulvinar region is different. Experiments using retrograde and anterograde tracers have shown that it receives afferents from layers 5 and 6 of visual cortex (Abramson and Chalupa, 1985), and apart from a very small region (the geniculate wing, which we regard as part of the lateral geniculate nucleus rather than the pulvinar; see Guillery et al., 1980), it receives no retinal afferents. The afferents from layer 6 seem quite similar to the layer 6 afferents that go to the lateral geniculate nucleus. They have the same characteristic light microscopic appearance (Bourassa and Deschênes, 1995; Ojima et al., 1996), and corticothalamic terminals with the same electron microscopic appearance, and the same distribution of synaptic contacts, have been described in the pulvinar region (Feig and Harting, 1998; Mathers, 1972a; Ogren and Hendrickson, 1979; Rouiller and Welker, 2000). We regard them as modulators, almost certainly functioning very much like the layer 6 modulators to the lateral geniculate nucleus, although currently there is little experimental evidence about their functional roles. The afferents from layer 5 of visual cortex look remarkably like the retinal afferents in the lateral geniculate nucleus in terms of their light microscopic (Bourassa and Deschênes, 1995; Ojima et al., 1996) and electron microscopic appearance (Feig and Harting, 1998; Mathers, 1972a; Ogren and Hendrickson, 1979; Rouiller and Welker, 2000). Further, they establish the same pattern of synaptic contacts. We regard them as the drivers of the pulvinar cells, and it is because these drivers come from areas of cortex classifiable as visual that we see visual receptive fields in the pulvinar region. Evidence that these layer 5 afferents function as drivers is provided by the fact that silencing the cortical areas that send layer 5 afferents to the pulvinar relay abolishes (Bender, 1983) or greatly diminishes (Chalupa, 1991) the visual responses of the pulvinar cells and by the fact that the receptive field properties of pulvinar cells are not unlike those of cells in cortical layer 5 (Chalupa, 1991).

So far, we have not specified which visual areas give rise to which afferents. In the cat, the lateral geniculate nucleus receives layer 6 afferents not just from areas 17, but also from areas 18 and 19 (Gilbert and Kelly, 1975; Murphy et al., 2000; Updyke, 1977) and from other visual cortical areas farther afield (Abramson and Chalupa, 1985; Gilbert and Kelly, 1975; Updyke, 1981). The pulvinar region receives afferents from areas 17, 18, and 19 (in the cat) and from other visual cortical areas such as posteromedial lateral suprasylvian sulcus (PMLS) and posterolateral lateral suprasylvian sulcus (PLLS) (Updyke, 1977, 1981), and many of these are characteristic layer 6 afferents (Guillery et al., 2001). Other inputs to the cat's pulvinar region, however, come from cortical layer 5 and have the characteristics of layer 5 afferents, and these also come from areas 17, 18, and 19 (Fig. 35.5, *left*; see also Abramson and Chalupa, 1985; Guillery et al., 2001).

We look at some of the details of these connections more closely for the cat in the section "The Pulvinar as a Monitor of Motor Outputs." For now, it is sufficient to recognize that the pulvinar region receives two types of cortical afferent and that the layer 6 afferents can be regarded as modulators, whereas all the layer 5 afferents are reasonably regarded as drivers, although currently only some have been tested from this point of view. Closely related to the distinct functional roles of these two cortical afferents to the pulvinar region is the fact that whereas the layer 6 afferents send a rich innervation to the modulatory cells of the thalamic reticular nucleus, the layer 5 afferents do not.

FIRST-ORDER AND HIGHER-ORDER THALAMIC RELAYS The fact that the pulvinar region receives driving afferents from layer 5 of visual cortex shows that the pulvinar serves as a relay in the visual pathways for messages that have already been through cortical processing once. For this reason, the pulvinar region has been called a *higher-order visual relay*, in contrast to the *first-order relay* in the lateral geniculate nucleus, which transfers ascending messages directly to cortex (Guillery, 1995; Guillery and Sherman, 2002b; Sherman and Guillery, 1996, 2001). This distinction between first- and higher-order relays is found not only for the visual pathways but for other relays to cortex as well. However, only the visual relays concern us here. One important point about the higher-order visual relays is that they involve a much greater volume of thalamus, and a much greater area of cortex, than does the first-order visual relay in the thalamus. That is, the pulvinar region is far larger than the lateral geniculate nucleus, and the areas of cortex in receipt of inputs from the pulvinar region are, in total, far greater than area 17.

We have described the pulvinar region as providing higher-order relays to extrastriate cortical areas. However, the possibility that there may also be first-order pulvinar relays of ascending afferents has not been excluded. The small direct input to the pulvinar from the retina was mentioned earlier but, as noted above, we regard this as part of the lateral geniculate nucleus. It clearly represents a first-order relay. The input from the superior colliculus and pretectum to a part of the pulvinar raises another problem. Are these driving or modulatory inputs?

There were strong arguments in the past (Diamond, 1973; Schneider, 1969; Sprague, 1966, 1972; Sprague et al., 1970) for the view that there are two parallel visual pathways going to the cortex. This conclusion was based on behavioral studies primarily in the cat, hamster, and tree shrew and on anterograde tract tracing studies that demonstrated axonal pathways from the region of the tectum to the pulvinar (Altman and Carpenter, 1961). One of these parallel pathways from the retina goes through the lateral geniculate nucleus to striate cortex, and the other relays through the

tectum and then the pulvinar to the extrastriate cortex. However, recordings from cells in the pulvinar region of cats and monkeys have shown that the receptive field properties of cells there are dependent on cortical inputs, not tectal inputs (Bender, 1983; Chalupa, 1991; Chalupa et al., 1972), suggesting that the tectal inputs are not drivers innervating a pulvinar first-order relay (see also Smith and Spear, 1979, on the effects of tectal lesions on responses in higher cortical areas of cats).

The morphological evidence on the structure of the tectopulvinar connections is conflicting (Mathers, 1971; Partlow et al., 1977; Robson and Hall, 1977), with some reports showing terminals like those of the layer 6 modulators and others showing terminals like those of the layer 5 drivers and the retinal terminals. This issue needs to be resolved. Since there are several distinct subdivisions of the pulvinar, which are not easily compared across species, it is possible that there are some tectal drivers innervating some first-order relays in some regions of the pulvinar, with other tectal inputs acting as modulators. It is possible that there are significant species differences in the extent to which such tectopulvinar driver afferents may or may not play a significant role in the transfer of visual information to higher cortical areas (Rodman et al., 1989, 1990). Further, since cells in layer 5 of visual cortex send terminals to the pulvinar region and to the superior colliculus (Guillery et al., 2001), it is possible that lesions or injections in the colliculus will produce changes in the pulvinar region that do not represent a tectopulvinar pathway. The possibility that parts of the pulvinar may be in receipt of drivers from the tectum and also from layer 5 of cortex raises a question addressed in the section "Parallel Pathways through the Pulvinar Region," that arises wherever one finds two driving inputs innervating the same part of the thalamus. Do they interact on single relay cells or do they, like X cells and Y cells in the A layers of the lateral geniculate nucleus, form two essentially independent parallel pathways?

THE PULVINAR REGION AS A KEY RELAY IN CORTICOCORTICAL COMMUNICATION The distinction between first- and higher-order relays outlined above shows the pathways over which the pulvinar region receives its visual inputs from the visual cortex and provides grounds for thinking of these as the drivers of pulvinar cells. Recognizing the pulvinar as a higher-order relay provides a clear functional role for the cells of the pulvinar, at least in the sense that the functional roles of visual, auditory, and somatosensory thalamic relays were assigned in the nineteenth century when the ascending afferent pathways to these relays were defined. That is, the pulvinar serves as a relay from one visual cortical area to other cortical areas. Further, the functional parallel between retinal inputs to the lateral geniculate nucleus and cortical layer 5 inputs to the pulvinar provides a useful key for

comparing these two visual relays, which we explore in subsequent sections. Before looking at these comparisons more closely, however, it is important to stress that the pulvinar as a higher-order relay takes on a vitally important role as a key participant in corticocortical communication.

The pathway that goes from layer 5 in one cortical area, through a pulvinar relay, to another cortical area provides a potentially important, but largely unstudied and often unrecognized, transthalamic route for corticocortical communication. This transthalamic pathway is likely to differ in its functional properties from the more widely studied direct corticocortical route (Van Essen et al., 1992; and see Fig. 35.11). Specifically, the thalamic relay has, as we have seen, properties that can modify transmission in accord with attentional needs, and so far as we know, these properties are not characteristic of the direct corticocortical pathways. Further, the thalamic relay is, as we show below, transmitting information that goes from cortex by a branched axon to thalamus and to lower, motor or premotor centers (Guillery et al., 2001; Guillery and Sherman, 2002a), so that the transthalamic

FIGURE 35.11. Schema showing first-order and higher-order thalamic relays and the relationship of each to effector pathways passing through the brainstem. Note the distinction between direct corticocortical pathways and transthalamic corticocortical pathways.

mic pathway can be seen as sending a copy of a motor instruction from one cortical area to another.

There are a number of reasons why the thalamic input to higher cortical areas has received much less attention than has the direct corticocortical input. One is that for many years it was simply not recognized as a possibility, because the layer 5 and layer 6 afferents could not be distinguished from each other, and there was no reason to consider the layer 5 input to thalamus as a driver. A second reason concerns the number of axons involved. The thalamocortical afferents represent a relatively small group of afferents to cortex, and thus attention was directed at the apparently much more massive, direct corticocortical connections. However, this consideration has to be viewed in relation to what we know about the first-order visual relay, where the afferents from retina represent only about 5% to 10% of the synapses in the lateral geniculate nucleus (Van Horn et al., 2000), and the geniculocortical afferents in area 17 also represent only about 5% to 10% of the synapses in cortical layer 4 (Ahmed et al., 1994; Latawiec et al., 2000). The modulators, in fact, far outnumber the drivers in these pathways, and, as noted above, a strategy that considered only the size of an input would not lead one to see the retinal input as a major source of drivers to the lateral geniculate nucleus. The large number of synapses arising from modulators probably reflects the delicate adjustments that the modulators are capable of, and may also indicate that there are modulatory functions that still remain to be explored; the numbers cannot be taken as a good indication of which pathway carries the information that the pathway is processing (the receptive fields in the visual pathways). Insofar as it is reasonable to expect some common organizational pattern to characterize all thalamocortical pathways, one should expect that the main information bearing driver input to higher cortical areas will come from the thalamus, as it does for all first-order cortical areas. That is, the driver visual inputs to area 17 come from the thalamus, not from other cortical areas, which instead are modulators there.

Another important and practical reason why the transthalamic corticocortical pathways have received much less attention than has the direct corticocortical pathway is that it is generally easier to explore the cortical surface than the depths of the thalamus, particularly when it comes to tracing the pathways. We stress in later sections ("Parallel Pathways through the Pulvinar Region" and "Projections from the Pulvinar Region to the Cortex") some of the difficult problems that need to be overcome before we can expect to understand the functional organization of the pathways that are relayed in the pulvinar region. However, looking for evidence about the nature of corticocortical processing by studying the direct corticocortical pathways, which are readily accessible on the surface, and ignoring the deeper

transthalamic pathways, which are likely to prove more difficult, can at best be justified by arguments such as those used by the proverbial drunk, searching for lost keys under the lamppost, where it was light.

So far as we know, all cortical areas receive thalamic afferents, and for almost all higher cortical areas, the functional contribution made by the thalamic afferents remains essentially unexplored. This evidence in itself suggests that schemes tracing connections to primary cortical receiving areas, and from these through corticocortical pathways progressively to higher and higher cortical areas, for perceptual processing and eventually for motor outputs (e.g., Kandel et al., 2000; Van Essen et al., 1992) represent a false view about the connections that underlie the cortical relationships of sensory inputs, perception, and movement control.

Not only do all cortical areas probably receive thalamic inputs, but most, possibly all, have descending outputs from layer 5. The axonal pathways of these layer 5 outputs have been studied for several cortical areas recently by tracing individual axons, and it has been found that where corticofugal axons provide a characteristic driver innervation for a higher-order thalamic relay, they very commonly also send a branch through the thalamus more caudally to the midbrain or pons (reviewed in Guillery and Sherman, 2002a). Although the final destination of these more caudal branches is not always defined, we have to think of the corticothalamic drivers as representing branches of an axon that also has descending, motor connections. This issue is explored in the next section. Here it is important to look at these multiple output pathways from many cortical areas as an important reason for seeing cortical processing as being continually in touch with lower motor centers (Fig. 35.12). Messages may be processed through several stages in many functionally distinct cortical areas on their way to motor cortical areas, but at almost any stage there is direct output to motor or premotor centers. Area 17 sends axons to the superior colliculus, which is concerned with the control of head and eye movements, and there are comparable outputs from many other visual cortical areas that have connections with the pulvinar.

In summary, there is an important difference between conventional views of corticocortical processing for vision and the one that recognizes the importance of transthalamic corticocortical pathways. In the conventional views, information enters striate cortex from the lateral geniculate nucleus and is then processed entirely within cortex. The processing strictly involves direct corticocortical connections among many discrete areas (more than 30 in the monkey and probably fewer in the cat) organized into several (5–6 in the monkey) hierarchical levels, with feedback as well as feedforward connections and, occasionally, with the recognition that there may be some modulatory influences from the thalamus (Olshausen et al., 1993; Van Essen et al., 1992).

there derive from terminals with driver (i.e., RL) morphology. Overall, estimates suggest that driver input in pulvinar and the lateral geniculate nucleus range between roughly 2% and 7%.

We have very little information about the membrane properties of cells in the pulvinar (but see Jahnsen and Llinás, 1984), but on the basis of the structural similarities and on the basis of the ubiquitous distribution throughout thalamus of the critical conductances described in the section “Properties of I_T in Relay Cells,” it is reasonable to conclude that generally the same ground rules for transmission to cortex apply. This is an area where detailed studies may reveal functional differences that are currently undefined. We shall assume that the pulvinar region functions much like the lateral geniculate relay in terms of how modulators act, how the burst and tonic modes are controlled, and how information is transmitted from the drivers to cortex.

LAYERS AND MAPS The pulvinar region can be divided into a number of distinct zones. Some of these zones are defined on the basis of differential staining properties, some are defined on the basis of their connections, and others are defined by mapping the visual field and identifying a new area wherever a new visual field map can be demonstrated (Adams et al., 2000; Graybiel and Berson, 1980a; Gutierrez et al., 2000; Shipp, 2001; Updyke, 1981). This last is basically the same argument that was originally and successfully used for defining cortical areas. Each functionally distinct cortical area was defined as a single map, which may have a particular distortion of the visual field and may even not include the whole visual field, but any one map contains no duplications (Lane et al., 1971; Tusa et al., 1979; Zeki, 1969). At present the differential stains, the connections, and the maps do not produce precisely matching subdivisions, and especially for the monkey, there are some problems still to be resolved before one can clearly identify the separate zones of the pulvinar region.

In the cat, Updyke's studies of receptive fields and of corticothalamic axonal projections have produced a relatively clear picture (Updyke, 1981) that allows one to distinguish a number of major subdivisions, each with its own map and each receiving distinctive patterns of afferents from several visual cortical areas or from the superior colliculus. In each subdivision, it is possible to define lines that correspond roughly to the lines of projection in the lateral geniculate nucleus. That is, the lines correspond roughly to a single point in visual space, although the accuracy of the relation is less than it is in the lateral geniculate nucleus. These lines also correspond, roughly, to single points in the cortical area from which these subdivisions receive their cortical afferents, and thalamic cells grouped around such a line have been called *isocortical columns* (Guillery et al., 2001).

Given that there are maps and lines of projection, the next question is, are there layers? If one is looking for architectonically distinguishable layers such as the A layers of the cat or the parvocellular layers of the monkey, then the answer is “no,” there are no such layers identifiable in the pulvinar region of any species. If, however, one asks whether there are identifiable functional and morphological differences as one moves from one end of an isocortical column to the other, then there is evidence that it may be possible to separate functionally distinct “layers.” In this the pulvinar region may be more like the lateral geniculate nucleus of the rabbit (Holcombe and Guillery, 1984) or the “C” regions of the cat (Hickey and Guillery, 1974), where distinct cell groupings are separated from each other along the lines of projection, but with no overt separation of layers.

The best example of this is the lateral part of the lateral posterior nucleus in the cat, where the isocortical columns run from rostradorsal to caudoventral. Several connectional differences can be recorded along this axis. The layer 5 afferents change their appearance, becoming more compact caudoventrally (Guillery et al., 2001), the cortical afferents come from different sources (cortical areas 5 and 7 most rostrally, areas PMLS and PLLS most caudally) (Heath and Jones, 1971; Kawamura et al., 1974; Robertson and Cunningham, 1981; Updyke, 1981) and whereas areas 17, 18, and 19 all send layer 5 corticothalamic afferents to the middle and ventral parts of the columns, area 19 also sends cortical afferents to the more rostral parts, but these are primarily or entirely from layer 6 (Guillery et al., 2001; Updyke, 1977). The functional implications of these connectional differences have not yet been explored for this part of the pulvinar region, but one should expect to find that, as in the lateral geniculate nucleus, the functional properties of the relay cells change as one moves from one end of an isocortical column to the other.

For other subdivisions of the pulvinar region in cat and in monkey, visual field maps or maps of isocortical columns have also been described (Adams et al., 2000; Graybiel and Berson, 1980b; Gutierrez et al., 2000; Shipp, 2001; Updyke, 1981), but there are no observations about the extent to which connectivity patterns change along the direction of any one column or line of projection. Receptive field properties have been described, and they generally resemble the receptive fields of layer 5 cortical cells. However, the extent to which they may vary from one subdivision of the pulvinar region to another or from one part of a column to another has not been explored.

CORTICAL AFFERENTS TO THE PULVINAR REGION Much of the earlier evidence about the cortical inputs to the pulvinar region comes from experiments using methods such as autoradiographic labeling, horseradish peroxidase labeling,

or axonal degeneration, which label the afferents from layers 5 and 6 together and do not allow the discrimination of one from the other. These have been useful for helping to define the maps in the relay (see above), and have helped to show the several cortical areas that send axons to this region. Only fairly recently have methods become available for labeling just a few cortical cells and their axons, and allowing identification of the cortical layer giving rise to the axons or the morphological characteristics of the axons. As indicated above, cortex sends two types of axon to the pulvinar region: layer 5 cells send axons with large, flowery terminals, and layer 6 sends finer axons with small terminals that are mostly on short, stubby side branches distributed irregularly along the length of the axons. They are readily distinguished from each other (Fig. 35.5).

Cortical areas 17, 18, and 19 in the cat all send layer 5 afferents to the lateral part of the lateral posterior nucleus (Guillery et al., 2001). Small, well-localized injections into any one of these cortical areas label a small number of corticothalamic axons, each having a single small terminal zone 100–200 μm across. These terminal zones from a single small injection site are irregularly scattered around, but not accurately along, the ventral and caudal two-thirds of the isocortical columns (Fig. 35.12). The overall terminal distributions of all layer 5 axons from areas 17, 18, and 19 overlap entirely in this region, and as indicated above, the shapes of the terminal arbors are more compact caudoventrally than rostradorsally (not shown in the figure). This part of the nucleus receives few or no layer 6 afferents from areas 17 and 18 (Abramson and Chalupa, 1985; Guillery et al., 2001), but it does receive a rich layer 6 innervation from area 19. These layer 6 axons have a far more widespread distribution in the nucleus around the areas occupied by the layer 5 terminals and also in the most rostral and dorsal part that receives no layer 5 afferents from area 19 but presumably receives layer 5 drivers from other parts of cortex. Where the cortical injections into area 19 are small, there is a striking local sparsity of layer 6 afferents in the region where layer 5 axons from the same injection site have their termination (Fig. 35.13). Of course, there is no corresponding reciprocity for the axons from areas 17 and 18, since the layer 6 terminals do not go to the same nuclear subdivision as the layer 5 terminals.

These observations on just one subdivision of the pulvinar region show that any one part of a single isocortical column can receive driver afferents from more than one functionally distinct cortical area, and that each cortical area distributes its driver terminals quite broadly along any one isocortical column. Further, the distribution of the modulators from layer 6 suggests that there is no simple rule that relates the distribution of the corticothalamic drivers to the distribution of the modulators for any one cortical region, although the relationships we have described suggest that the

layer 6 input serves to modulate layer 5 inputs that do not come from the same small column of cortex or even from the same cortical area.

PARALLEL PATHWAYS THROUGH THE PULVINAR REGION We have seen that a single small cortical injection site labels axons that have terminals widely distributed along the length of a single isocortical column. If there are functional differences along the length of a column, as the connections and the structural features of the terminals suggest there may be, then there is an interesting parallel to be drawn between the parallel pathways of the retinogeniculate connection and the corticopulvinar connection. That is, for the retinogeniculate pathway, a single small area of retina contains several functionally distinct ganglion cell types. Their axons distribute to different parts of the same line of projection in the lateral geniculate nucleus, and their differential distribution along a line of projection is a signal of their functional differences. To some extent this differential distribution of the terminals in the nucleus relates to the geniculate layers, and to some extent it relates to functional differences that are not expressed by layer separations. It is worthwhile to look at the possibility that closely comparable relationships for parallel processing obtain for the corticopulvinar projection where several functionally distinct cortical layer 5 cells can be expected in any one small cortical area or column. These cortical cells then send axons to the pulvinar region that are segregated along the isocortical columns in accordance with their functional characteristics (Fig. 35.13). This is admittedly speculative, but it provides a guide to studying the distribution of functions that is currently not available for studies of the pulvinar region.

The previous paragraph introduced the idea of parallel processing in the corticopulvinar pathways that is comparable to the parallel processing of the retinogeniculate pathways. However, we have seen that there is another, more obvious type of parallel processing that may also have to be recognized in the pulvinar. This is represented by the fact that any one isocortical column receives driving afferents from several distinct cortical areas. Each of these pathways can be seen as a separate input to the pulvinar region, so that corticopulvinar axons from separate cortical areas may also provide parallel pathways through the pulvinar. The issue of whether these represent parallel pathways like the X and Y pathways going through the A layers of the lateral geniculate nucleus with essentially no interaction, or whether there are integrative interactions between the pathways, remains to be resolved.

Although these observations of the distributions of layer 5 and layer 6 axons from cortical areas 17, 18, and 19 to one small part of the pulvinar region can show how it may be possible to analyze cortical afferents in relation to the isocortical columns, it has to be stressed that even for this one

FIGURE 35.13. The lateral part of the lateral posterior nucleus (*LP1*) and the pulvinar (*PUL*) of a cat are shown on the left. The afferents from layer 5 of cortical areas 17, 18, and 19 to *LP1* are shown as for Figure 35.12. In addition, the terminals of two layer 5 afferents from area 19 are shown shaded in the small squares in *LP1* and in *PUL*. The area of these small squares is shown enlarged on the right, where the layer 5 terminals are shown in black for *LP1* and pale gray for *PUL*, and the layer 6 terminals from the same cortical column are shown in intermediate gray. There are virtually no layer 6 terminals in the colored zone occupied by the (colored) layer 5 terminals. The layer 6 terminals extend beyond the layer 5 terminals, especially along the direction of the isocortical columns. Note that we do not know whether the terminals in *LP1* and *PUL* can arise from the same layer 5 cortical cell or always come from different layer 5 cells. They are shown in different shades here, suggesting that they come from different cells. (Based on Guillery et al., 2001.)

part of the complex (the lateral part of the lateral posterior nucleus) our information is incomplete, and for other parts of the complex the information is either entirely unknown or only very sketchy.

PROJECTIONS FROM THE PULVINAR REGION TO THE CORTEX
A vital piece of information needed to understand the function of the pulvinar region is the pattern of projections from the relay cells to the various cortical areas that receive afferents from the pulvinar. This is not merely a question of enumerating the cortical areas that receive afferents from the pulvinar region, although this information is, of course, essential. Studies of retrograde cell degeneration in the thalamus, of retrograde cell labeling, or of anterogradely labeled axonal pathways (Rockland et al., 1999; Walker, 1938; Wong-Riley, 1977) all indicate that there are widespread axonal projections from the pulvinar region to the cortex. To some extent these studies indicate pathways from particular subdivisions of the pulvinar region, but, in general, the information that would allow one to relate each pulvinar subdivision to particular groups of cortical areas is not available.

A more serious consideration arises when one looks at the comparison we have drawn between the pulvinar region and the lateral geniculate nucleus and focuses on differences that can be seen along the lines of projection in the lateral

geniculate nucleus or along the isocortical columns in the pulvinar region. We have focused on the cat's A layers of the lateral geniculate nucleus, which send their axons predominantly to area 17. However, there are also projections to area 18 from the A layers, and these come from the largest cells, which represent the Y cells (Ferster, 1990a, 1990b; Garey and Powell, 1967; Geisert, 1980; Humphrey et al., 1985; Mitzdorf and Singer, 1978; Stone and Dreher, 1973). The C layers in the cat project predominantly to area 19 and to the lateral suprasylvian cortex (Holländer and Vanegas, 1977; Laemle, 1975; Maciewicz, 1975; Raczkowski and Rosenquist, 1980). In the monkey there is also a projection to extrastriate cortical areas, and some of these axons probably arise from the koniocellular elements (Fries, 1981; Yoshida and Benevento, 1981; Yukie and Iwai, 1981). That is, there are two features that make the pattern of cortical projections difficult to analyze. One is that in any one small region along a line of projection there are neighboring cells that are functionally distinct and that also have distinguishable cortical projections. The second is that cells that lie in different sectors of a line of projection are likely to have different cortical projections. Once we have a system of parallel processing passing through a thalamic nucleus, the problem of tracing the separate but intermingled pathways through the thalamic relay becomes particularly difficult, and this applies to both the pulvinar region and the lateral geniculate nucleus. We know almost nothing about the functional significance of thalamic afferents to extrastriate cortex, regardless of whether these are first-order afferents coming through the lateral geniculate nucleus or higher-order afferents coming through the pulvinar. This will, before long, prove to be an important issue for understanding the nature of cortical processing in extrastriate visual cortical areas.

Conclusions

Clearly, the thalamus can no longer be viewed as a passive, machine-like relay of information to cortex. We have outlined a number of important functional properties of a dynamic nature that occur during thalamic relays and that relate to behavioral states such as attention and alertness. This is probably the tip of the iceberg, with many additional functions likely to emerge as our understanding of thalamic properties expands.

It is important to note in this context that the thalamus offers a last "bottleneck" for general behavioral states to have an effect on information processing. Thalamic relays represent a relatively small number of neurons and synapses compared to their target cortical areas. Thus, if the object were to increase or decrease the salience of a particular bit of information, say a visual stimulus at the expense of an auditory one, it would require orders of magnitude less synaptic

processing to modulate at the thalamic level than at the cortical level. For visual processing in mammals, there is no opportunity for the rest of the brain to affect processing in retina. The lateral geniculate nucleus is not only a convenient last bottleneck of information flow, it is the most peripheral site at which such processing can be modulated. In other sensory systems, it is possible to modulate processing more peripherally than at the thalamus, but for all pathways going to cortex, the thalamic level remains the last convenient stage at which modulation can efficiently affect information flow before it is passed to cortex.

When one looks at the visual relays in the thalamus, it is necessary to recognize that there is a quite well-studied *first-order* relay in the lateral geniculate nucleus and a series of more elusive *higher-order* relays in the pulvinar region. The lateral geniculate nucleus relays several functionally distinct, largely independent, topographically organized, parallel visual pathways from the retina to the cortex. It serves, among other possible but currently undefined functions, to modify transmission to visual cortex in accord with attentional needs, acting either in *tonic mode*, where accurate linear transfer of information from the periphery to the cortex is required, or in *burst mode*, where the need is for identification of novel signals that merit attention. Messages from the retina are carried to the lateral geniculate nucleus by the retinogeniculate *drivers*. These represent less than 10% of the afferent synapses to the lateral geniculate nucleus and have characteristic structural features, synaptic connectivity patterns, and functional relationships in terms of transmitters and receptors. The rest of the afferent synapses are formed by *modulators*, which can serve to switch transmission from burst to tonic or from tonic to burst mode. These come from several distinct sources. Some, specifically those from the neocortex and the thalamic reticular nucleus, relate closely to the topographic representation of the retina in the lateral geniculate nucleus and can thus have a local action, whereas others, particularly those from the brainstem, show no topography and appear to have a global action.

The higher-order relays in the pulvinar region serve to transmit information from one cortical area to others. The *drivers* come from pyramidal cells in layer 5 of cortex and represent branches of axons that are going to lower (motor) centers. That is, the pulvinar serves to send copies of motor outputs from one cortical area to another. We stress the likely importance of these transthalamic pathways in corticocortical communication, a role that has not been recognized in the past. Corticopulvinar driver afferents can be analyzed on the basis of comparisons with the lateral geniculate relay. They show a topographical organization between cortex and thalamus. There are multiple parallel corticopulvinar pathways coming from several cortical areas that are relayed through any one small local region of the pulvinar. In addition, it is probable that the afferent drivers coming from any

one of these cortical areas also represent several functionally distinct pathways. An important key to understanding the functional significance of this higher-order thalamic relay will depend on understanding how the several distinct corticopulvinar driver afferents relate to the pathways that go from the pulvinar region to multiple different cortical areas. We know almost nothing about this either in terms of the specific patterns of connectivity that are established or in terms of possible interactions within the thalamic relay. The parallel afferents may prove to show little or no interaction, comparable to the situation in the first-order geniculate relay, or there may be interaction among the several corticopulvinar afferent drivers, and this could strongly influence views of pulvinar functions.

The organization of the modulatory afferents to the pulvinar also merits closer study than it has received to date. We propose that in general terms, the functions of these afferents are comparable to the functions of the modulators in the lateral geniculate nucleus. That is, they serve to switch the relay between the burst and tonic modes. They can do this on a global basis from the brainstem and other sources, or in terms of local parts of the mapped projections from layer 6 of many distinct cortical areas cortex, or from the thalamic reticular nucleus.

36 The Visual Functions of the Pulvinar

CHRISTIAN CASANOVA

IN FLIPPING THROUGH a general textbook of neuroscience, very little information on the pulvinar is found. This is regrettable given that the pulvinar of higher mammals is the largest extrageniculate visual thalamic complex and is likely to play a key role in visual and visuomotor processing. This structure lies over the dorsolateral posterior thalamus and runs along the medial edge of the lateral geniculate nucleus (LGN). Through evolution, the primate pulvinar, in parallel with the expansion of the neocortex, has undergone a considerable increase in size and has established extensive reciprocal connections with most visual cortical areas (Fig. 36.1). The almost total omission of the pulvinar from textbooks may come from the fact that its function in normal vision has remained largely elusive. When compared to other subcortical areas such as the LGN or the superior colliculus (SC), few studies have investigated the response properties of neurons in the mammalian pulvinar complex. This may result partly from the difficulty of characterizing these neurons' visual receptive field properties. In addition, research may have been discouraged by a number of behavioral findings that revealed no strong impairment of visual function after destruction of the pulvinar (for a comprehensive review, see Chalupa, 1991). Despite such impediments, several investigators labored on and their work provided contemporary researchers with precious information on the functional organization of the pulvinar complex. This chapter reviews recent findings on the anatomy and physiology of the pulvinar. The information focuses on findings from the cat and monkey, as most of our knowledge of this thalamic region comes from work on these two species. Unraveling the function of the pulvinar is still a formidable challenge to researchers, but new findings have opened promising avenues in deciphering the role of this structure in vision.

Structural and visuotopic organization

The anatomical limits of the pulvinar and the nuclei comprising it are not readily defined. Work on the cat and monkey, using various experimental approaches, has shown this extrageniculate structure to be parceled into several nuclei. As discussed below, these subregions' boundaries vary across studies (especially in primates), and additional work is necessary to establish a clear structural organization that relates to function adequately.

In cats, the pulvinar is referred to as the *lateral posterior-pulvinar* (LP-pulvinar) *complex*. Internal subdivisions of the LP-pulvinar have been defined by connectivity patterns (Berson and Graybiel, 1978; Updyke, 1977, 1981), cyto- and chemoarchitectonics (Berson and Graybiel, 1980, 1983; Updyke, 1983), and functional properties (Chalupa and Abramson, 1988, 1989; Chalupa et al., 1983). Of note is the histochemical work by Graybiel and Berson (1980) and Berson and Graybiel (1983), who parceled the LP-pulvinar by revealing thalamic acetylcholinesterase (AChE) activity. Several laboratories currently use this method to reveal the three main LP-pulvinar subregions that are generally agreed upon: the lateral and medial parts of the LP nucleus (LP_l and LP_m) and the pulvinar. Each division contains a representation of the contralateral visual field that encompasses slightly the vertical meridian, and overrepresents the binocular part of the visual field. The overall visuotopic organization of the LP-pulvinar is rather complex because of multiple visual field representations (Raczkowski and Rosenquist, 1981; Updyke, 1983); up to five have been proposed by Hutchins and Updyke (1989). These multiple representations and the large extent of receptive fields contribute to an LP-pulvinar visuotopic organization that is less rigorous than that of the LGN.

The pulvinar of primates is relatively larger than that of cats; the structural boundaries of its subdivisions are more easily differentiated, though firm delimitations using Nissl and myelin stains remain difficult. Four nuclei have been identified on classical cytoarchitectonic grounds (Olszewski, 1952; Walker, 1938): the inferior, lateral, medial, and oral (or anterior) pulvinar. An LP nucleus also exists, but it is not well developed and does not seem to receive any prominent visual input (Jones, 1985). As work progressed, it became evident that there was no clear correspondence between the cytoarchitectonically defined structural organization and the functional and connectional subdivisions of the primate pulvinar (Robinson and Cowie, 1997). In recent years, pulvinar organization has been challenged by studies using a host of chemoarchitectonic techniques. In particular, Cusik and collaborators, with the use of calbindin, AChE, cytochrome oxidase (CO), and parvalbumin stains, have divided the inferior pulvinar into four to five subregions that encompass the entire ventral part of the original lateral pulvinar (Gray et al., 1999; Gutierrez et al., 1995; in humans, Cola et al., 1999). Comparable subdivisions have been described by

FIGURE 36.1. Schematic representation of the human brain showing the location of the pulvinar. The pulvinar is most fully developed in humans, and based on cat and primate studies, it establishes reciprocal connections with visual areas or visually

related areas of the neocortex. These cortico-thalamo-cortical loops may represent computational modules involved in analyzing specific features of complex visual scenes.

Stepniewska and Kaas (1997) and Adams et al. (2000) using Nissl, calbindin, myelin, CO, AChE, and Cat-301 stains. According to their proposals, however, the inferior pulvinar does not extend strongly over the lateral division. Clearly, the internal organization of the primate pulvinar remains vaguely defined. A solution to this anatomical puzzle is necessary to better understand the pulvinar's anatomic-functional organization and overall function. Nevertheless, the inferior and lateral subdivisions of the pulvinar are generally considered as the main visual nuclei. Both contain a complete topographic representation of the contralateral visual field where receptive field size increases with eccentricity (Bender, 1982; Petersen et al., 1985) and where the central visual field is overrepresented (Bender, 1981). A third area, located in the dorsomedial part of the lateral pulvinar (Pdm), has been described: it does not show a structured visuotopic organization, and the neurons comprising it have large receptive fields (Benevento and Miller, 1981; Petersen et al., 1985).

Afferent and efferent connectivity

The pulvinar receives visual input from a number of sub-cortical and cortical structures (Fig. 36.2). Only projections that are directly related to establishing the visual responsiveness of pulvinar cells are reviewed here. As discussed later, it is generally accepted that retinal projections are insufficient to account for the overall visual properties of pulvinar neurons in both cats and primates. Unlike its thalamic neighbor, the LGN, the pulvinar seems to receive its primary or driving visual afferents through descending

pathways from the cortex. For this reason, the pulvinar should be considered as a higher-order nucleus, as opposed to a first-order nucleus such as the LGN (Sherman and Guillery, 1998).

RETINAL INPUTS It was long believed that direct retinal projections to the LP-pulvinar complex only reach the lateral edge of the pulvinar in cats (Berman and Jones, 1977; Berson and Graybiel, 1978; Kawamura et al., 1979), and some authors (e.g., Guillery et al., 1980; Mason, 1981) considered this retino-recipient region as part of the geniculate complex (geniculate wing) rather than the pulvinar complex. However, vitreal injection of the B-fragment of the cholera toxin reveals the presence of direct retinal (bilateral, but predominantly contralateral) projections to the medial portion of the pulvinar as well as to the LPI and LPm subdivisions (Boire et al., in prep.). Most terminals exhibit small-caliber axons, and some are similar to the large endings of corticothalamic projections (R-type, see below). The functional properties of these retino-LP fibers are not yet known, though it is now necessary to consider that some receptive field properties in the LP nucleus may be modulated by, or even built from, direct retinal ganglion cell input. It is recognized, however, that ganglion cells reaching the retinorecipient zone of the pulvinar are electrophysiologically defined W cells (Mason, 1981), and subsequent anatomical work indicates that they are e cells (Pu et al., 1994).

In primates, bilateral retinal projections terminate in the inferior pulvinar (Itaya and Van Hoesen, 1983; Mizuno et al., 1982; O'Brien et al., 2001). In the macaque, Cowey

A. Cat

B. Primate

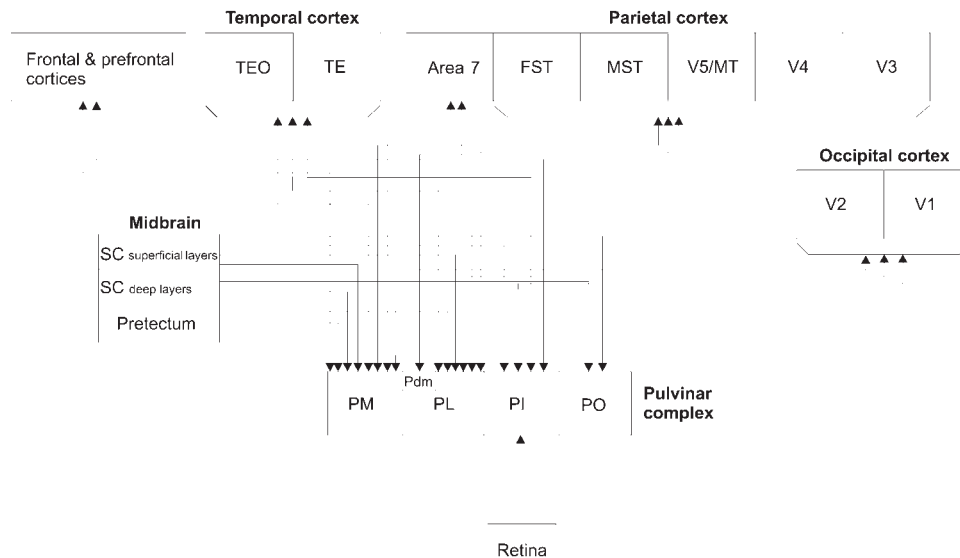

FIGURE 36.2. Schematic diagrams representing the main efferent and afferent connections of the cat's LP-pulvinar complex (*A*) and primate pulvinar (*B*). Abbreviations are defined throughout the text.

et al. (1994) reported that the injection of horseradish peroxidase in the inferior pulvinar labeled all three major ganglion cell classes (note, however, that the authors could not rule out the possible labeling of axons of passage). Some were located near the fovea, but the majority was in eccentric retinal regions. Gamma (γ) cells appeared to form most of the retinal afferents, but α and β cells were also present. Cowey and collaborators have long believed that the pulvinar is likely involved in blindsight (along with the SC and extrastriate areas (for a review, see Stoerig and Cowey, 1997) and that the presence of β retinopulvinar cells may con-

tribute to the postlesion (striate cortex) preservation of visual function.

MIDBRAIN INPUTS There is no doubt that the pathway from the SC to the pulvinar has been the most thoroughly studied, given the SC's key role in the control of fixation and saccadic eye movements. In cats, collicular fibers (also referred to as *tectal fibers*) reaching the LP-pulvinar originate predominantly from the lower part of the stratum griseum superficiale (SGSi) and terminate in the LPm; the latter is considered as the *tectorecipient* zone of the complex (Graybiel

and Berson, 1980; Kawamura et al., 1980). Some of these projection cells are substance P immunoreactive, suggesting that this neuropeptide plays a role in tecto-LP pathway function (Hutsler and Chalupa, 1991). Abramson and Chalupa (1988) have shown that a small contingent of SGS cells, distinct from the above cellular pool, projects to a restricted portion of the LPI adjacent to the pulvinar and identified as the LPI₂. These authors have also reported the existence of another pathway that originates from cells in the stratum opticum and terminates in a region just below the LPM, the ventral division of the LP. There are thus multiple pathways from the SC to the LP-pulvinar, and the exact role of each has yet to be established (the possibility that the pulvinar serves as a relay for collicular signals en route to the visual cortex is discussed later in this chapter). In addition, the tecto-LGN pathway originates from the upper part of the SGS and runs in parallel to the tecto-LP pathway; it would be of interest to determine how these two compare. Since SC cell properties vary according to their laminar position in the SGS, it is likely that these two anatomically defined tectothalamic pathways have distinct functions. Another midbrain region associated with visuomotor reflexes, the pretectum, projects bilaterally to the LP-pulvinar complex. Most terminals appear to use glutamate, to be excitatory, and to end in the pulvinar nucleus (Berson and Graybiel, 1978; Sudkamp and Schmidt, 1995; Weber et al., 1986).

Dense projections from the primate SC to the pulvinar have also been described. Neurons located in the inferior part of the collicular SGS send terminals to the inferior pulvinar and, to a lesser extent, to the lateral subdivision (Benevento and Standage, 1983; Harting et al., 1980; Huerta and Harting, 1983; Marrocco et al., 1981). These projections are mainly ipsilateral and topographically organized. Another pathway arises from the deep collicular layers and reaches the medial and oral pulvinar (Benevento and Fallon, 1975; Benevento and Standage, 1983), and terminals from the pretectum end in the lateral and medial pulvinar (Benevento and Standage, 1983).

CORTICAL INPUTS Cortical afferents appear to represent the main source of visual signals to all subdivisions of the pulvinar. Remarkably, in both species considered here, the pulvinar complex is connected to nearly all visual cortical areas that contain a complete or partial representation of the visual world. Moreover, these connections are reciprocal, allowing for a multitude of cortico-thalamo-cortical loops that may represent distinct computational modules to be established.

In cats, all subdivisions of the LP-pulvinar receive dense cortical projections from extrastriate cortical areas such as areas 19, 20, 21, and the suprasylvian cortex and, in turn, project back to these areas. The density of the projections may vary among subdivisions (Graybiel and Berson, 1980;

Raczkowski and Rosenquist, 1983; Updyke, 1977, 1981). There is one notable observation. The primary visual cortex (areas 17 and 18) projects only to the LPI, which is considered the *striatoprecedent* zone of the cat LP-pulvinar (Abramson and Chalupa, 1985; Graybiel and Berson, 1980). This input is mainly excitatory in nature (Casanova et al., 1997) and may be glutamate- and aspartate-ergic (Fosse et al., 1989). According to Benedek et al. (1983), striate and collicular projections overlap in the caudal part of the LP-pulvinar complex, allowing signals from the two main retinofugal pathways to be combined. It is not known whether there are intrinsic connections between the LPI and LPM, and the aforementioned overlap provides the substrate for a possible collicular modulation of striate input preceding transfer to higher-order areas.

Neuroanatomical studies have shown that most cortical neurons projecting to the LP-pulvinar are pyramidal cells located in layer V and, to a much lesser extent, in layer VI (Abramson and Chalupa, 1985; Norita et al., 1986; Ojima et al., 1996). Cortico-LPI neurons in area 17 are complex cells located in the upper part of layer V (Abramson and Chalupa, 1985; Casanova, 1993). According to Lund et al. (1979), a majority of striate terminals ending in the LPI are collaterals of corticotectal neurons, but this was confirmed only in part by an electrophysiological investigation (Casanova, 1993). This is an important issue, because it may indicate whether striate output signals to the SC and LP-pulvinar are similar or not. If they are similar, the key factor would be a contrast between target-cell processing of this input and that of other afferent signals.

LP-pulvinar cells project to extrastriate neurons in layer IV (and, to a lesser extent, layer I) (Abramson and Chalupa, 1985; Norita et al., 1986), whereas LPI neurons projecting to the primary visual cortex seem to end preferentially in layer I (Abramson and Chalupa, 1985), though projections to layer IV also have been described (Symonds et al., 1981). There is some evidence that individual LP-pulvinar neurons are double-labeled by injection of different tracers in separate cortical areas (Kaufman et al., 1984; Miceli et al., 1991). For instance, a subset of LPI neurons projects to the posteromedial part of the lateral suprasylvian cortex (PMLS) and the primary visual cortex, and some LPM neurons project to both the posterolateral part of the LS (PLLS) and the visual part of the anterior ectosylvian (AEV) cortex (Miceli et al., 1991).

In primates, striate, prestriate, parietal, temporal, and frontal visual or visually related areas project to all subdivisions of the pulvinar (Boussaoud et al., 1991; Ungerleider et al., 1983; Webster et al., 1993; see also Jones, 1985; Robinson and Cowie, 1997). These projections generally present a topographical organization (Campos-Ortega and Hayhow, 1972; Gutierrez and Cusick, 1997; Ungerleider et al., 1983) and are schematically represented in Figure

36.2. Note that a restricted zone of the medial pulvinar, which is not considered a purely visual nucleus, appears to be innervated by cells from areas 17 and 18 (Benevento and Davis, 1977). This region, however, is primarily connected to association cortices, such as the prefrontal cortex and area 7, involved in attentional processing (Baleydier and Mauguière, 1985; Hardy and Lynch, 1992).

The inferior and lateral pulvinar receive their cortical input through layer V neurons of the primary visual cortex and layer VI neurons of extrastriate cortical areas (Lund et al., 1975; Trojanowski and Jacobson, 1977). As shown in cats, these projections are reciprocal: pulvinar fibers end in layers I, II, and III of the striate cortex and in layers I, III, and IV of extrastriate areas (Benevento and Rezak, 1976; Ogren and Hendrickson, 1979; Rezak and Benevento, 1979).

A fundamental question regarding the pulvinar complex and its relationship with cortical areas is the nature of the afferent and efferent terminals. In other words, are the projections likely to drive (i.e., be necessary for establishing response properties in a targeted area) or modulate the activity of recipient cells? V1 and V2 neurons projecting to the cat and primate pulvinar complex exhibit E- and R-type (types 1 and 2, respectively) axon terminals, with a predominance of R-axons (Bickford et al., 1998; Guillery et al., 2001; Rockland, 1996, 1998). This would suggest that projections from the primary visual cortex are mainly driving cellular activity (rather than modulating it; see Sherman and Guillery, 1998, 2001), a concept in agreement with the ultrastructural analysis of terminals (Feig and Harting, 1998) and the electrophysiological findings of Bender (1983, 1988) and Casanova et al. (1997) described below. A different picture seems to emerge for higher-order cortical areas, as projections from primate area MT are predominantly of the E-type, that is, presumably of a modulatory nature (Rockland, 1998).

In primates, neurons projecting from the pulvinar to striate and extrastriate cortices are heterogeneous in their arbor size and terminal fields, suggesting that these projections do not have the same function in all cortical areas. It remains to be determined whether the pulvinocortical terminals are inhibitory or excitatory in nature. More important, perhaps, is to address a question whose answer may establish the relative strength between converging thalamocortical and feedforward corticocortical projections: do pulvinar terminals drive cortical units or is these terminals' action strictly modulatory? Data from Minville and Casanova (1998) have shown that the activity of only a few PMLS neurons is reduced by the deactivation of the LPI, suggesting that these projections are not predominantly of a driving type, despite the fact that they terminate in layer IV.

Another important task is to determine the visual response properties of cells projecting within the cortico- and thalamo-

mofugal systems (e.g., by antidromic activation methods). At this point, very little is known of the stimulus configurations that drive these neurons and trigger output from the cortico- and pulvinofugal systems.

Receptive field properties

Response properties of neurons in the pulvinar complex reflect the presence of prominent descending cortical input and therefore resemble those of cortical rather than subcortical neurons (such as those characterizing the neighboring LGN cells). Whether some of these properties are strictly imposed by the cortex or result from the intrinsic integration of cortical and subcortical inputs remains to be determined.

BASIC ORGANIZATION Most studies investigating the function of the cat's LP-pulvinar neurons were carried out in anesthetized animals. In such preparations, several cells cannot be driven by visual stimuli. Future studies in awake, behaving animals may reveal the function of these seemingly nonresponsive cells. Nevertheless, all studies have shown that receptive fields in the cat LP-pulvinar are generally large, with boundaries that cannot be delimited easily. It has been determined that neurons in the three main LP-pulvinar subdivisions have distinct visual properties.

Most receptive fields in the LPI or striatorecipient zone are orientation- and direction-selective (Casanova et al., 1989; Chalupa and Abramson, 1989; Mason, 1978, 1981; Fig. 36.3). They are binocular and exhibit binocular facilitation, and many are sensitive to relative retinal disparities (Casanova et al., 1989). Receptive fields are composed of superimposed ON and OFF subregions, surrounded by ON or OFF peripheral edges (Chalupa and Abramson, 1989), and are driven by low spatial frequency gratings (generally less than 0.5 c/deg) drifted at a relatively high temporal frequency, between 4 and 8 Hz (Casanova et al., 1989). As expected from their receptive field organization, they do not exhibit a strong response modulation to drifting gratings. The motion sensitivity of LPI neurons is better illustrated by two factors. LPI cells are highly sensitive to textured patterns or visual noise (Casanova and Savard, 1996a), and their responses to sine wave gratings are modulated by the presence of a visual noise background (Casanova and Savard, 1996b). This suggests that the LP-pulvinar complex may be involved in the analysis of the relative motion of an object in its surrounding environment. As a general rule, we have found that gratings and noise patterns are more efficient in driving LP neurons than moving bars or spots. Despite their multiple cortical inputs, LPI cells constitute a relatively homogeneous population with regard to their receptive field properties. This may indicate that striate and extrastriate cortical signals are somewhat integrated at this thalamic level. Overall, receptive field properties resemble those of

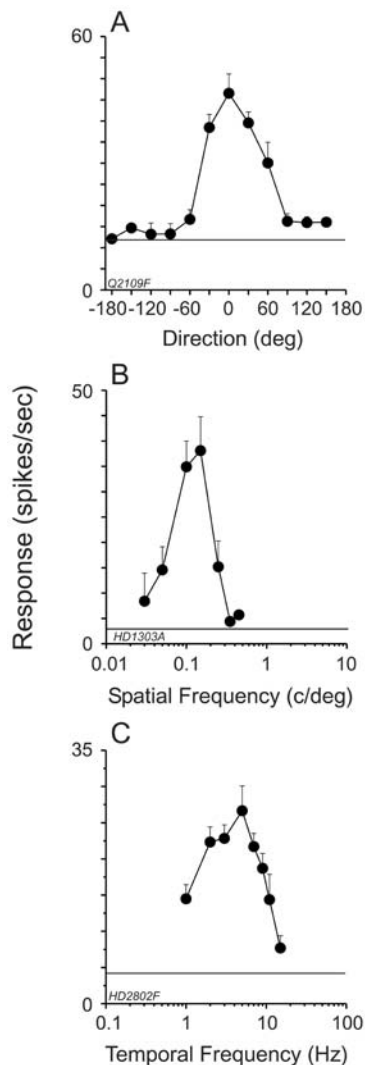

FIGURE 36.3. Examples of representative basic response properties of neurons in the cat's LP-pulvinar. *A*, The neurons respond optimally to an oriented grating drifting in the forward (0 degrees) but not the reverse (180 degrees) direction of motion. *B*, *C*, Spatial and temporal frequency tuning functions in LP-pulvinar. Note that in both cases, the bandpass pattern prevails.

complex cells in the visual cortex. This is in agreement with the fact that striate-LPI cells are complex or special-complex cells (Casanova, 1993) and neurons in extrastriate cortical areas exhibit, for the most part, complex-like properties (for a review, see Spear, 1991).

Three major differences exist between receptive field properties of neurons in the LPm and LPI (Chalupa and Abramson, 1988, 1989; Chalupa et al., 1983). Receptive fields in the LPm are approximately four times larger than those in the LPI, and some may cover the whole contralateral hemifield. They exhibit a more uniform internal organization, that is, they composed of a single ON, OFF, or ON-OFF region. Finally, fewer LPm neurons are orientation selective, and their tuning function is broader.

These differences are likely to reflect the presence of collicular input and the absence of striate projections to the LPm.

The pulvinar remains the least characterized nucleus of the cat LP-pulvinar complex, and additional investigation of its constituent neurons must be carried out. According to Mason (1981), visual properties of pulvinar cells are comparable to those he has described in the LP nucleus [note, however, that very few orientation-selective neurons were found by this author (Mason, 1978, 1981)]. A notable difference has been reported for cells located in the lateral part of the pulvinar (corresponding to Guillery's geniculate wing); neurons in this retinorecipient zone had concentric receptive fields and were mainly of the W type.

Unfortunately, when compared to the cat, there is a dearth of data regarding response properties in the primate pulvinar, and most relevant work was carried out at a time when this region was defined classically on cytoarchitectonic grounds. Most receptive fields in the inferior and medial pulvinar have a small diameter (1 to 5 degrees in the inferior pulvinar; Bender, 1982), but very large ones have been reported (Mathers and Rapisardi, 1973). The majority of cells are binocular and orientation selective, and a subset are direction selective. Color-sensitive cells have also been identified (Bender, 1982; Felsten et al., 1983).

HIGHER-ORDER MOTION SENSITIVITY There is clear evidence that a subset of neurons in the LP-pulvinar complex are capable of signaling the true direction of motion of a plaid pattern [i.e., they can integrate separate motion signals into a single coherently moving percept termed *pattern motion* (PM)]. This implies that these thalamic cells are involved in higher-order motion processing (Merabet et al., 1998; see Casanova et al., 2001; Fig. 36.4). LP-pulvinar neurons selective for PM are distinguished by large receptive fields (suitable for spatial integration) and are located mainly in the LPm. Thus far, this plaid-defined higher-level neuronal operation has been reported solely in higher-order visual areas: PM responses have been described in primate area MT (Movshon et al., 1985) and subsequently in the cat's AEV (Scannell et al., 1996)—two regions reciprocally connected to the pulvinar complex. The involvement of the cat LP-pulvinar complex in higher-order motion processing was further demonstrated by the finding that LP cells signal the direction of complex random dot kinematograms (RDKs), whose elements do not indicate locally the direction of motion (Dumbrava et al., 2001). It is not yet known whether the plaid pattern and complex RDK motion-sensitive neurons described in the cat also exist in the primate pulvinar. The cat model may very well extend to the primate, as reciprocal connections between the pulvinar and area MT exist (Cusick et al., 1993); MT cells are known to respond to similar or comparable higher-order stimuli (Movshon et al., 1985; Newsome and Pare, 1988; Rodman

FIGURE 36.4. Higher-order motion characteristics of LP-pulvinar neurons. Polar graph illustrating the responses of a pattern-motion selective LPm neuron to gratings (open symbols) and plaid patterns (filled symbols) drifted in 12 directions of motion. The response to gratings alone is considered the predicted profile for a truly pattern-direction selective unit. The dashed line represents the predicted response to plaids for a component-direction selective unit. The small central circle represents spontaneous activity level.

and Albright, 1989). In addition, there are strong similarities in the organization of cat and primate extrageniculate pathways (Creutzfeldt, 1988).

VISUAL SALIENCE AND ASSOCIATED VISUOMOTOR CHARACTERISTICS There is evidence that the activity of a subset of neurons in the pulvinar complex varies according to the animal's attentional state, to stimulus relevance, and to eye movements associated with scanning a visual scene.

Sudkamp and Schmidt (2000) have demonstrated the existence of three classes of neurons in the pulvinar of awake cats, which, by order of incidence, are purely visual neurons, saccadic visual neurons, and cells that respond solely during a saccade. These authors suggested that saccadic visual neurons could induce arousal in visual cortical areas after self-induced eye movements or external motion lead to changes of the visual scene.

In primates, the Pdm, which is reciprocally connected to the posterior parietal cortex (area 7a), contains neurons with large nonorientation-selective receptive fields whose discharges are enhanced during visual attention tasks. Specifically, Pdm neurons respond more strongly to stimuli relevant to active behavior (targets) than to stimuli not associated as such (Fig. 36.5; Petersen et al., 1985). This enhancement is spatially selective and independent of eye movements. Another subpopulation of Pdm cells characterized by larger receptive fields was found to discharge during and after saccadic eye movements (Petersen et al., 1985; Robinson et al., 1986). These cells may therefore

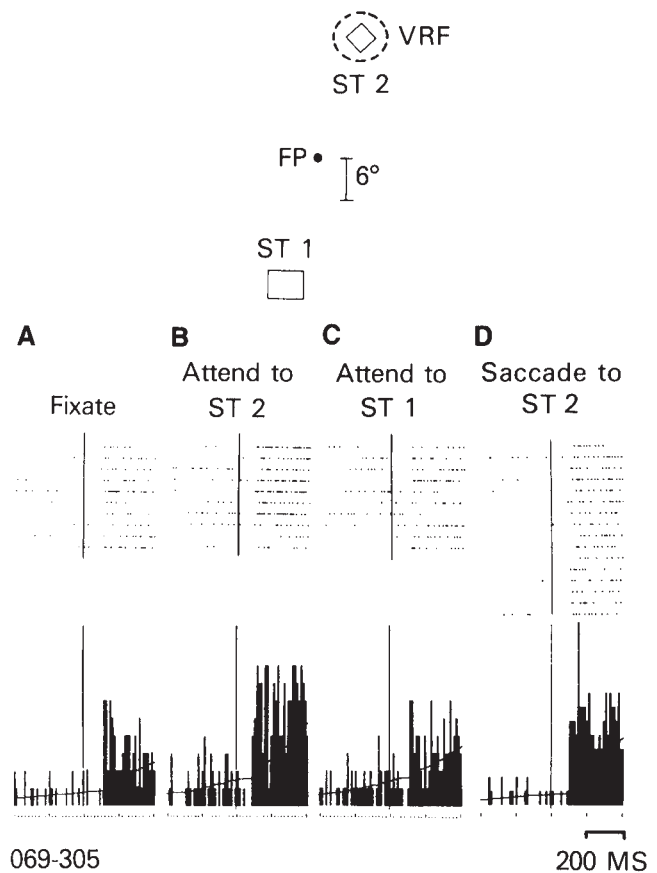

FIGURE 36.5. Responses of cells in the Pdm of primates are modulated by visual spatial attention. *A*, Response of the cell to the stimulation of its receptive field (RF) by the ST 2 stimulus (the animal is fixating FP). *B*, This response is enhanced when ST 2 is used as a target for saccadic eye movements. *C*, There is no increase in the cell's discharge when the animal attends to ST 1, which is located outside the RF. *D*, The response is still enhanced when the monkey attends to ST 2 in the receptive field (no saccade is made). (Modified from Petersen et al., 1985).

signal a change in the axis of gaze and indicate that a fixation period (i.e., an increase of attention) is to occur (Petersen et al., 1987). On the other hand, findings have shown the visual responses of neurons in the inferior and lateral pulvinar to be suppressed during eye movements (Robinson et al., 1991). Robinson's group has also reported that neuronal discharges in the inferior and lateral pulvinar of the behaving macaque vary as a function of orbital position (Robinson et al., 1990). Recent work by Bender and Youakim (2001) has confirmed the involvement of the pulvinar in visual attention: attention during a fixation task increases or reduces excitability (*push-pull* modulation) for about a quarter of inferior and lateral pulvinar cells. They reported, however, that the same attentional fixation task produces only a suppression of neuronal discharges in the Pdm. This last finding is counter to the observations of Petersen et al. (1985). This difference remains somewhat

intriguing and may arise from the nature of the attentional task in the two studies. Nevertheless, Bender and Youakim (2001) suggest that the push-pull form of modulation observed in the pulvinar is similar to that seen in extrastriate cortex associated with early, intermediate, and late stages of cortical processing. This cellular behavior is most likely related to the engagement and disengagement of attention during fixation. Finally, Acuna et al. (1986, 1990) and Cudeiro et al. (1989) have found *reaching cells* in the macaque LP nucleus and in the oral and lateral pulvinar. These neurons respond during intentional movement of the upper limbs that is visually triggered and guided.

What does the pulvinar do?

For many years, most physiologists have regarded thalamic nuclei as stations that passively relay sensory information to the cortex, dependent on the animal's state of arousal, and in which minimal subcortical processing takes place (Sherman and Guillery, 1996; Macchi et al., 1996). This conventional view does not hold when one considers the extensive reciprocal connectivity between the thalamus and the visual cortex and the complex intrinsic response properties described above. Both first- and higher-order thalamic nuclei are closely linked to the cortex through cortico-thalamo-cortical loops, and it has been proposed in recent years that thalamic nuclei may participate actively in the processing of specific information in conjunction with cortical areas (Grieve et al., 2000; Macchi et al., 1996; Miller and Schreiner, 2000; Mumford, 1991; Miller, 1996; Sherman and Guillery, 1996). This may be especially true for the pulvinar, given its remarkable connectivity with the neocortex. In fact, higher-order thalamic nuclei such as the pulvinar may represent a better model for the study of cortico-thalamo-cortical loops. The reason is that unlike first-order nuclei (such as the LGN), higher-order nuclei do not receive powerful retinal inputs that can mask the subtler role of cortical feedback projections and corresponding cortico-thalamic loops. In the next sections, some hypotheses as to the function of the pulvinar in vision are presented.

THE "NOT SO STRONG" RELAY HYPOTHESIS To some extent, the importance of the pulvinar complex was revealed when Diamond and colleagues (Diamond and Hall, 1969; Killackey and Diamond, 1971), Schneider (1967, 1969), and Trevarthen (1968) demonstrated the involvement of a second retinofugal visual system, the retino-collicular pathway, in orienting behavior (the where pathway as opposed to the what or retino-geniculo-cortical pathway). In order to reach the visual cortex, signals from the SC and the pretectum must be relayed via thalamic nuclei, and the pulvinar complex represented the best candidate. Despite the fact that the pulvinar may indeed provide a route along an ascending

tectocortical pathway or between cortical areas, almost all available evidence is against a simple¹ relay function.

In cats, there are major differences between the receptive field organization of collicular (including tecto-LP cells) and LPm neurons (e.g., receptive field size, orientation selectivity, binocular facilitation) that preclude the LPm from acting as a simple relay between the colliculus and visual cortex (Chalupa et al., 1983; Fish and Chalupa, 1979; McIlwain, 1978). It seems that tectal signals undergo substantial transformation within the LP-pulvinar. Subsequent experiments, confirming earlier work using evoked potential recordings by Chalupa et al. (1972), indicate that deactivating the SC by lidocaine injection or cooling fails to influence significantly the visual responsiveness of LPm neurons (Chalupa, 1991). In agreement with the last observation, Smith and Spear (1979) have reported that lesioning the SC has little effect on the response properties of most neurons in LS subregions that are known to receive a prominent input from the LP-pulvinar complex.

Support for the suggestion that the SC does not contribute substantially to establishing response properties in the LP-pulvinar comes from studies carried out in primates. Bender (1983, 1988) has shown that collicular lesions have no effect on receptive field properties in the inferior pulvinar.² The idea that the pulvinar is not simply relaying information to the cortex is further emphasized by the findings that SC and pulvinar lesions do not yield similar behavioral deficits (Bender and Butter, 1987). In addition, SC lesions do not abolish neuronal responses in area MT (Rodman et al., 1990), and the medial nucleus of the inferior pulvinar, the major projection zone to MT, does not receive significant SC input (Stepniewska et al., 1999): such an ascending pathway was often proposed to explain the persistence of activity in area MT after acute or chronic deactivation of the macaque primary visual cortex (Girard et al., 1992; Rodman et al., 1989; but see Kaas and Krubitzer, 1992; Maunsell et al., 1990). This pathway is also considered part

¹The term *simple* may not be adequate, as no such thing as a simple nucleus exists. For example, the LGN, often referred to as a *simple relay nucleus*, receives a number of projections from both the brainstem and primary visual cortex that modulate its visual responsiveness. Nevertheless, the basic structural organization of retinal ganglion cells and LGN neuron receptive fields is virtually the same. Such a close correspondence of properties between a region and its target is not seen at the level of the pulvinar.

²It is interesting to note that the colliculus appears to have a more significant impact on the LP-pulvinar of less telencephalized species (e.g., the rabbit; Casanova and Molotchnikoff, 1990). This may be related to the considerable development of the pulvinar, the neocortex, and of their interconnectivity throughout evolution. As a consequence, the impact of the cortex on LP and pulvinar cells may have increased to the detriment of collicular influence during that period.

of the neural substrate for blindsight (Stoerig and Cowey, 1997), despite a lack of clear evidence for pulvinar involvement in the persistence of visual function in brain-lesioned patients (see, however, Püto et al., 1999, for an interesting case of “spontaneous recovery” that involved a pathway comprising the pulvinar).

Supporting evidence accompanies the possibility that the pulvinar offers another route for primary visual cortex signals to reach extrastriate areas. In cats, cooling the primary visual cortex causes an overall decrease in visual responsiveness for about one-third of LPl neurons tested (Casanova et al., 1997). The persistence of visual responses during cortical deactivation has been confirmed by additional experiments in which area 17 was removed by aspiration (Casanova et al., 1997). In these brain-damaged animals, a few LPl receptive fields within the cortical scotoma remained sensitive to the orientation and/or direction of a moving stimulus. Despite the strong impact of area 17 projections, our data suggest that the extrastriate cortex might also play a role in establishing response properties in the cat's LPl. This is, to some extent, confirmed by the preliminary data of Chalupa (1991), who observed a complete loss of responsiveness in the LP-pulvinar after cryoblockade of a large cortical surface encompassing the striate cortex and most, if not all, extrastriate areas. Nevertheless, it is very likely that the striate cortex may be necessary to fully establish the basic retinotopic map in the LP-pulvinar complex, on which maps of other areas may be superimposed (Fig. 36.6). Primary visual cortex input appears more critical in primates than in cats because its removal yields an almost total loss of visual responses in the pulvinar (Bender, 1983). It would be somewhat erroneous to conclude at this point that the pulvinar is “relaying” information from striate to extrastriate cortex. In primates, the integrity of the primary visual cortex is necessary to maintain activity in most extrastriate areas. For example, the deactivation of area 17 causes complete elimination of cellular responses in areas V3 and V4 (Girard et al., 1991a, 1991b). Should we then consider these two cortical regions as “simple” relay areas? Surely not.

Results from Minville and Casanova (1998) further support the claim that the pulvinar does more than relay signals from the striate cortex. Spatial and temporal contrast properties of PMLS neurons were studied after the pharmacological deactivation of their main thalamic input, that is, the LPl (Grant and Shipp, 1991; Norita et al., 1996). Despite numerous large injections of lidocaine or GABA, deactivation of the LPl had little effect on the spatial and temporal frequency tuning of neurons in the PMLS cortex and on their direction selectivity. Less than 20% of PMLS cells were affected by the deactivation, and the observed effect consisted of a decrease in the cells' overall respon-

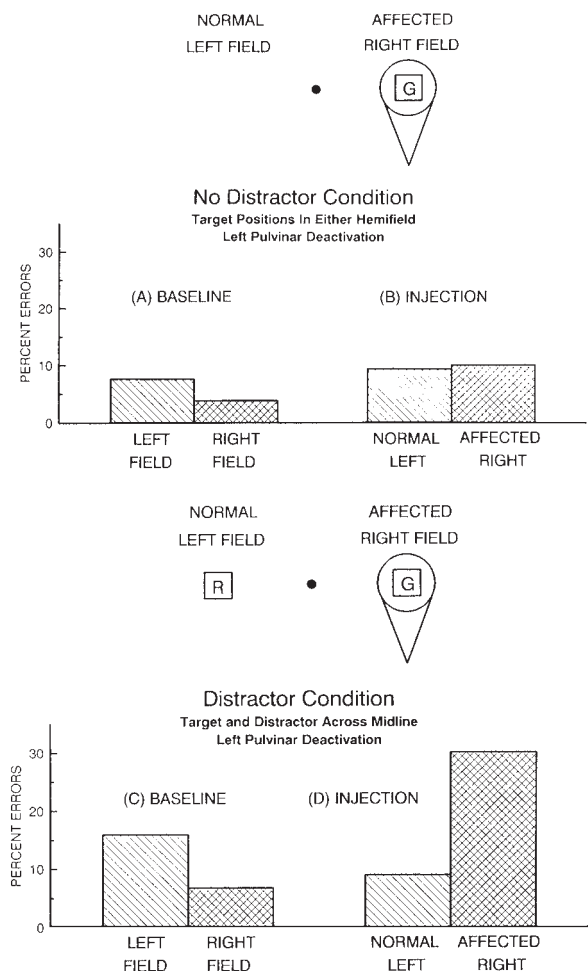

FIGURE 36.6. The pulvinar may participate in visual selection by filtering irrelevant information. After deactivating the inferior pulvinar, the trained monkey could still perform form and color discrimination tasks (*A* and *B*). The animal's performance was slightly reduced when distracting stimuli were added to the right hemifield (*C*) and was dramatically impaired when the pulvinar was deactivated in this condition (*D*). G, green; R, red. (From Desimone et al., 1990).

siveness. It was concluded that only a small fraction of the projections from LPl to PMLS are necessary to drive cortical neurons and that the signals from the remaining LPl projection cells may be used for more subtle functions (e.g., response modulation to the stimulation context). This last assumption was confirmed by some preliminary data obtained subsequently, which suggest that stimulus-background interactions observed in PMLS cortex (von Grunau and Frost, 1983) may depend on the integrity of the LPl (see Figure 9 in Casanova, 2002). In summary, while the pulvinar complex may be used to bypass corticocortical connections, it should not be regarded as a strict relay nucleus, but rather as an active partner of the visual cortex (see below).

EYE MOVEMENTS The implication of the LP-pulvinar in visuomotor processing was initially precipitated by two findings. LP-pulvinar electrical stimulation evoked conjugated saccades (Crommelinck et al., 1977), and its neurons were reportedly linked polysynaptically to the abducens nucleus (Wilson and Goldberg, 1980). Given its relationship to structures such as the SC, the pretectal and oculomotor nuclei, and cortical areas such as the frontal eye fields (Huerta et al., 1986), the pulvinar complex likely contributes to the visuomotor processing underlying eye movements (particularly saccadic eye movements). As discussed below, this may be closely linked to the identification of salient objects in a visual scene. As previously stated, neural discharges of primate and cat pulvinar cells are correlated with saccades and orbital position (in primates: Petersen et al., 1985, 1987; Robinson et al., 1986, 1990, 1991; in cats: Sudkamp and Schmidt, 2000). It has been proposed that these neurons may be used to enhance the level of attention during fixation and a change in the axis of gaze. Signals from these neurons may also lead to increased visual perception after the occurrence of an eye movement, to initiation or guidance of corrective saccades, and to spatial constancy (Petersen et al., 1987; Robinson and Petersen, 1992; Robinson et al., 1990). Some neurons may also be used to suppress vision during saccadic eye movements (Robinson et al., 1990). In partial support of these hypotheses, bilateral lesions of the macaque pulvinar have been shown to yield abnormally spontaneous and task-related scanning of visual stimuli and prolonged fixation times (Ungerleider and Christensen, 1977, 1979). Similar deficits have been observed in a human patient with a unilateral lesion of the posterior portion of the pulvinar (Ogren et al., 1984).

All primate studies investigating eye movement-related activity were conducted in awake animals that could not move their heads. It is still unknown whether pulvinar cells, like parietal cortex neurons, can encode any changes in head- or body-centered reference frames that accompany head movements (see Grieve et al., 2000).

VISUAL ATTENTION AND SALIENCE Neurophysiological findings that the Pdm, and the inferior and lateral pulvinar of primates, contain neurons exhibiting attention-related discharge modulation (Bender and Youakim, 2001; Petersen et al., 1985; Salzman, 1995) are supported by an elegant series of behavioral experiments. Petersen et al. (1987) showed that injections of muscimol (a potent GABA_A receptor agonist) in the Pdm reduced reaction times during a cued spatial attention task. Conversely, the administration of bicuculline (a GABA antagonist) in the same region had the opposite effect: the monkey's ability to shift its attention from ipsilateral to contralateral visual fields was enhanced. The pulvinar has also been shown to be involved in visual

target selection. Desimone et al. (1990) showed that muscimol deactivation of the lateral pulvinar (more specifically, in the part connected to area V4 and the inferior temporal cortex) impaired the monkey's ability to perform a color discrimination task only when a distractor was present (Fig. 36.6). The pulvinar therefore seems to play a critical role in the filtering of irrelevant visual information, as its deactivation affects the animal's performance only when attention is to be directed to a target presented with a distractor. Overall, the pulvinar may participate in visual selection either by enhancing relevant information (Petersen et al., 1987) or by filtering irrelevant information (Desimone et al., 1990).

Further support for the pulvinar's involvement in mechanisms of attention comes from the work of Acuna's group on the responses associated with intentional, visually guided limb movements (Acuna et al., 1986, 1990; Cudeiro et al., 1989). These authors proposed that the monkey LP-pulvinar would integrate subcortical and cortical signals, allowing for the execution and programming of intentional visually guided movement, and would participate in the maintenance of attention during those movements. Their hypothesis is in agreement with the observation that the destruction of the LP nucleus (but not the pulvinar) leads to a marked impairment in visual guidance in the cat (Fabre-Thorpe et al., 1986).

Human studies have also provided clues to the implication of the pulvinar in visual salience. Rafal and Posner (1987) reported that patients with hemorrhages in the thalamus (clearly, though not exclusively, involving the pulvinar in two out of three patients) exhibited deficiencies in performing the same cued-reaction time task used by Petersen et al. (1987). While these patients exhibited neither visual neglect nor visual field defects, they were slow at engaging attention for a new target location in the visual field contralateral to the lesion. Michael et al. (2001) presented evidence that the efficiency of attentional shifts for the exploration of new relevant stimuli is reduced in patients with thalamic lesions involving the pulvinar. Accordingly, positron emission tomography (PET) work has revealed increases in pulvinar-specific activity when subjects are asked to perform an object-identification task (which requires attentional selection) in the contralateral field (LaBerge and Buchsbaum, 1990). As one of the tests required the selection of a single letter among others (*filtering task*), these data strongly support the concept that the pulvinar is involved in separating relevant from irrelevant visual information. Using the same brain imaging technique, Corbetta et al. (1991) subsequently observed that the pulvinar was activated during a feature discrimination task necessitating selective (as opposed to divided) attention. The contribution of the pulvinar in the selective processing of stimuli was further

demonstrated by Morris et al. (1997). Using a simple visual reaction time task, a recent PET-activation study by Sturm et al. (1999) has shown the pulvinar to be part of a large network, comprising cortical and brainstem areas, involved in intrinsic alertness and defined as an internal control of wakefulness and arousal. Throughout these studies, the importance of corticopulvinar relationships is emphasized, and these relationships may be the key to understanding pulvinar function.

OTHER FUNCTIONAL CLUES REVEALED BY HUMAN STUDIES
Aside from the studies described above associating the pulvinar with visual salience, this structure has been linked to other normal visual functions and to visual deficits observed in neurodegenerative pathologies. Takayama et al. (1994) studied the visual function of a patient with a unilaterally restricted lesion of the pulvinar. Only deficits in the patient's stereoacuity were observed; this is in accord with the finding that binocular LP-pulvinar neurons are sensitive to relative retinal disparity (Casanova et al., 1989). Surprisingly, no impairment of visual spatial attention was seen—a discrepancy that may have resulted from the nature of the task or from the limited extent of the lesion, both of which differed from those mentioned above.

Kuljis (1994) presented evidence that all subdivisions of the pulvinar of Alzheimer's disease (AD) patients exhibit extensive lesions (e.g., amyloid and neuritic plaques). This observation is of interest, as it suggests that some of the visual deficits observed in AD patients [e.g., abnormal eye movements (Fletcher and Sharpe, 1986), reduced global motion sensitivity (Matsumoto et al., 2000), impaired visual attention (Baddeley et al., 2001)] may be due to pulvinar dysfunction and/or to the disruption of associated cortico-thalamo-cortical loops. A recent study using single-photon emission computed tomography (SPECT) also revealed a dysfunction (reduced blood perfusion) of the pulvinar in AD patients displaying psychoses such as visual hallucinations (Mega et al., 2000).

Pulvinar dysfunction has also been reported in schizophrenia. Heckers et al. (2000) have shown that schizophrenic patients (compared to controls) exhibit reduced activation of the right pulvinar (revealed by PET) during tasks that required them to pay attention to or recognize novel visual stimuli. This may be linked to the diminished metabolic rate seen in the thalamus (including the pulvinar) of schizophrenic patients (Buchsbaum et al., 1996; Hazlett et al., 1999) or to an impairment of the connections between thalamic nuclei and prefrontal cortical areas (Portas et al., 1998), which may lead to inefficient filtering of visual information. Again, the disruption of normal activity along the cortico-thalamo-cortical loops may be responsible for the sensory deficits observed in neurodegenerative diseases.

SEEING THE PULVINAR COMPLEX AS AN ACTIVE PARTNER OF CORTICAL AREAS The original statement by Le Gros Clark (1932) on the possible associative or integrative function of the pulvinar is as timely as ever. Given that the pulvinar receives prominent signals from the mesencephalon and the primary visual cortex, it represents a strategic thalamic structure and a unique platform for the integration of neural signals from the two main retinofugal pathways (i.e., retino-tectal and retino-geniculo-striate). In addition, the pulvinar establishes reciprocal connections with most visual cortical areas. It thus finds itself in an exceptional position to influence and/or inform multiple cortical regions of processing in lower- and higher-level areas or to increase the effectiveness (e.g., stimulus salience) of analysis in a given cortical area (Fig. 36.7). Another hypothesis, which does not exclude the others, is to consider the pulvinar complex as the basis for multiple extrageniculate cortico-thalamo-cortical loops that may be implicated in various complex neuronal opera-

FIGURE 36.7. Hypothetical schematic for visual integration with the pulvinar complex taken into account. Local visual signals are processed in the primary visual cortex and later integrated at second and third cortical levels (increased level of integration is illustrated by an increase in receptive field size). The pulvinar is reciprocally connected to these three cortical levels and contains cell types that were characterized in those areas. One fundamental question is whether pulvinar cells are preferentially connected to neurons with similar properties (yielding specific cortico-thalamic loops; see the *continuous lines* and *filled arrows*) and/or linked to cells with lower- or higher-order motion properties (for an example, see the *dotted line*). In the latter case, activity within a loop could be compared with incoming and outgoing signals and modified accordingly. In addition, such a pathway may be used to short-circuit corticocortical connections (*open arrows*). Besides, it is possible that some integration of cortical signaling levels occurs in the pulvinar through intrinsic connections (*dashed lines*).

tions. In accordance with this hypothesis are the reports of cells in the cat LP-pulvinar responding to moving plaids with pattern-motion responses and of cells coding for the displacement of complex RDKs (Dumbrava et al. 2001; Merabet et al., 1998). It is possible to propose the existence of one loop (e.g., AEV-LPm in the cat) involved in higher-order motion analysis, while another loop (e.g., Pdm and area 7 in monkeys) is implicated in visual attentional processing, and so on. In cats, disrupting the loop by deactivating the cortex has been shown to impair processing in the LPm (Merabet et al., 1998). The effect of pulvinar-complex deactivation on cortical function remains unknown. Mumford (1991) has proposed that the thalamus may act as an active blackboard, through which each cortical area would be informed of the processing taking place in another area and would modify its activity accordingly. The pulvinar may play such a role by maintaining an “up-to-date” copy of the reconstructed visual world, thus allowing cortical areas to be informed of any relevant change in the visual scene that would need new neuronal computations for planning action strategies (see also Jones, 2001; Mumford, 1995). Along the same line, Olshausen et al. (1993) have suggested that the pulvinar may be involved not only in attentional processing but also in pattern recognition, a suggestion supported by the PET activation maps described by Barrett et al. (2001). In addition, some evidence suggests that the cat LP-pulvinar may participate in the synchronization of cortical cell discharges in area 17 (Shumikhina and Molotchnikoff, 1999), a phenomenon that would amplify the effectiveness of synaptic transfer between processing stages and further the resolution of the neuronal assembly engaged by a stimulus (Singer, 1999). Recently, the investigation of the visual function of a patient with unilateral damage of the pulvinar suggest that this nucleus may indeed be involved in feature binding (Ward et al., 2002).

Future research avenues on the pulvinar

Paraphrasing Sillito and Jones (1997), pulvinar and cortical levels of visual processing cannot be separated easily: they form a circuit, not a sequence. As such, the understanding of pulvinar function may depend largely on the researcher's ability to clearly establish the functional significance of the bidirectional connections between this large extrageniculate nucleus and the visual cortex. Uncovering the nature and function of the signals transferred along the cortico-thalamo-cortical loops will prove to be a challenging task, given the number of connections between the neocortex and the thalamus. Throughout the text, some specific questions have been pinpointed. Here are some general issues that need to be addressed.

Is the pulvinar made up of distinct functional modules? Despite the neuroanatomical finding that the pulvinar complex can

be parceled into distinct modules, it is not clear whether these modules have a distinct function in vision. In other words, should the pulvinar be seen as a single entity when it comes to function? While the available electrophysiological data in cat favor functional parcellation (e.g., pattern-motion selectivity was found almost exclusively in the medial part of the LP nucleus), additional studies should be conducted to determine the specificity of each nucleus comprising the pulvinar. This is especially true for primates, in which relatively little is known of pulvinar receptive properties. Once the parcellation of the primate pulvinar is clearly assessed, efforts should be made to reevaluate the characteristics of each module. In particular, higher-order neuronal functions should be assessed, as the pulvinar is likely to be involved in higher-order processing. Specific visual tasks could then be developed to further the study of pulvinar module function through brain imaging or selective pharmacological deactivations.

To what extent are these modules and their cortical counterparts interconnected? Another fundamental issue is to determine whether or not a given pulvinar module is preferentially linked to a specific cortical area; that is, are specific cortico-thalamo-cortical loops involved in particular functions? In order to answer this question, the arbor size, the overall configuration, and the branching of individual axons from projecting neurons must be established. The outcome of these studies is important not only to determine the functional nature of the inputs (e.g., driving vs. modulatory), but also to reveal the level of axonal divergence and convergence onto individual neurons or a pool. Pulvinar neurons projecting to multiple areas via axonal collaterals permit computations along a given loop. These projections also provide a route by which cortical areas are informed of ongoing computations and, by extension, of processes in other cortices connected to the loop. Such a system makes comparisons between different levels of visual analysis possible.

A related research goal is to determine the extent of communications between pulvinar modules that occur via intrinsic connections. As in other thalamic nuclei, pulvinar nuclei comprise projection neurons and intrinsic interneurons (Jones, 1985; Ma et al., 1998). Thalamic nuclei are generally considered to be independent of one another. To my knowledge, however, this issue has not been addressed in the pulvinar, and it may well be that dendritic or axon terminals in one module extend and reach cells located in neighboring subdivisions.

Who's driving whom? Finally, the relative weight of ascending and descending projections must be assessed. At this point, the primary visual cortex seems crucial for establishing an organized visuotopic map in the pulvinar complex. The contribution of extrastriate cortical areas to pulvinar function is not yet known. Another point of interest is that the activity of pulvinar neurons appears to be modulated by

stimulus relevance, but the impact of these “salience” signals (as well as any other signals from the pulvinar) onto cortical receptive fields remains virtually unknown.

Acknowledgments

I am grateful to Karine Minville, research assistant, for her help in the preparation of this chapter and to M. Ptito and D. Boire for constructive comments. I would also like to thank the members of my laboratory who worked on pulvinar-related projects, especially Karine Minville, Lotfi Merabet, Daniela Dumbrava, Alex Desautels, and Tony Savard, as well as the agencies that funded the projects: Canadian Institutes of Health Research, Fonds de la recherche en Santé du Québec, Fonds pour la Formation de chercheurs et l'aide à la recherche.

37 Feedback Systems in Visual Processing

ADAM M. SILLITO AND HELEN E. JONES

ONE OF THE ABIDING challenges in vision is the role of the extensive feedback systems that parallel the ascending feed-forward pathways. In some senses, the way we conceptualize these feedback systems may be misleading because it follows from a view that the process of vision proceeds upward in a series of divergent steps and hence the return connections have to be judged as feedback. Indeed, for a visual world in motion, and taking note of the rapid responses seen in some of the higher visual areas, the feedback connections have the capacity to influence the earliest central processing steps. Thus, they become more a part of a complex and integrated circuit rather than a reflected regulatory influence down a hierarchy.

From some viewpoints, an understanding of the organization of the visual system seems to be best encapsulated by descriptions that invoke a stepwise processing of the retinal input through a hierarchy of areas that build increasingly complex abstractions of the visual world. At higher levels these areas, in turn, could broadly be described as falling into two streams, one concerned with form and the other with motion and location. The earlier levels of the system can also be subdivided into channels subserving the differing “objectives” of the higher-level areas. Aspects of the segregation and the hierarchical nature of the processing in the sequence of cortical steps are, for example, supported by data from imaging studies. On the other hand, an extensive body of anatomical and neurophysiological data suggests a more complex and subtle organization of the central visual mechanism. Firstly, there are substantial interconnections enabling transfer of information between the processing streams at the level of the primary visual cortex (V1) and between higher cortical visual areas. Secondly, feedback connections provide an extensive and potentially very fast influence that can rephrase the local processing mechanisms at earlier levels in the system. Because of the interconnections between many of the higher areas, this also blurs the absolute segregation of the processing streams. Although it has been argued that such influences have a minor effect on visual processing, the evidence now available suggests the potential for a much more significant role. Thus, for example, the feedback from cortex to lateral geniculate nucleus (LGN) has been shown from several lines of evidence to influence both the temporal and spatial characteristics of the way visual information is translated through the LGN. In the cortex, feedback from area MT, associated with

higher-level motion processing, has been shown by a range of techniques to exert a strong influence on many aspects of visual processing in V1. Indeed, the strength and potential speed of MT feedback influences bring into question some of the associations that link to the concept of *feedback systems* and suggest that it might be more appropriate to consider them as components of a circuit. In this chapter, we shall review some of the evidence regarding the function of feedback in the visual system of the cat and primate, with particular, although not exclusive, reference to feedback from the visual cortex to the LGN and area MT to V1.

The geniculo-cortical loop

ANATOMICAL CONSIDERATIONS A common feature of the projections transferring retinal information to higher levels is that numerically the feedforward synapses constitute a relatively small component of the total excitatory synaptic input converging on the cells that relay the input to the next level. Thus, at each level in the system, the transfer of information is potentially subject to influences from both lateral interactions in the local horizontal network and feedback from higher levels in the system. In the LGN of cat and primates the retinal afferents comprise about 10% of the input to relay cells, while the corticofugal feedback connections to the relay cells represent 30% of the input (Sherman, 2001; Wilson, 1993). As well as the relay cells, the cortical feedback connections target intrinsic inhibitory interneurons in the LGN and inhibitory neurons in the thalamic reticular nucleus/perigeniculate nucleus. The main details of the circuitry in the LGN are summarized in Figure 37.1. In the cat the projection to the LGN, which derives primarily from areas 17 and 18, is dense, and individual corticofugal axons’ arborizations have a central core projection of approximately 180–1080 μ with a sparse scattering of long-range axons which spread over 500–2000 μ (Murphy et al., 2000; Murphy and Sillito, 1996; Robson, 1984). This needs to be placed in the perspective of the fact that the average spread of the retinal X axonal arborizations is 150 μ and that of the Y axons is 375 μ (Bowling and Michael, 1984). Thus, even within their central core, individual corticofugal axons innervate an area of the LGN that extends significantly beyond their own location in retinotopic space. These points and the circuitry in the LGN are summarized in Figure 37.1. This, together with their longer-range connections, means they

FIGURE 37.1. Schematic summary of the geniculo-cortical loop. Shaded ovals denote the typical retinotopic extent (at 5 degrees of eccentricity from the area centralis) of the axonal arborizations of X and Y retinal ganglion cell axons and corticofugal axons. Two dimensions are given for feedback axons: the smaller dimension depicts the typical spread for the dense central core projection, while the larger dimension depicts the overall coverage of the

axonal arborization. Percentages to the right of the drawing summarize the contribution of synaptic contacts from retinal axons, corticofugal feedback axons, and inhibitory interneurons synapsing on LGN relay cells, as well as the contributions from geniculate axons, layer 6 collaterals, and layer 4 connections synapsing on spiny stellate cells in layer 4 of the cortex.

can influence inputs that may lie outside their own classical receptive field. There is also good evidence favoring the view that the projection comprises axons with several diameters and conduction velocities. Individual axons, both coarse and fine, seem to innervate both perigeniculate nucleus (PGN) and LGN (Murphy and Sillito, 1996; Murphy et al., 2000). Similarly, estimates of the conduction velocity from latency measurements provide support for two groups of corticofugal afferents (Grieve and Sillito, 1995b; Tsumoto et al., 1978) projecting to the LGN and PGN. The fastest pathway allows for a very rapid influence of the corticofugal system on the developing response and would enable the loop from LGN

cell response to cortex and back within approximately 3–5 msec. Even the slower group would enable a loop within 4–10 msec. The organization of layer 6 and its interactions with the LGN in the primate are particularly interesting because there is a clear segregation of cells in relation to the incoming channels. Cells projecting to the parvocellular layers of the LGN lie in the upper part of layer 6, while the lower part contains cells projecting to both magnocellular and parvocellular laminae (Fitzpatrick et al., 1994). Additionally, the intercalated cells in the LGN that send axons to layer 1 and the cytochrome oxidase-rich blobs (Hendry and Yoshioka, 1994) seem to receive feedback from a distinct

group of cells in the deepest part of layer 6 (Fitzpatrick et al., 1994). Cells in the middle of layer 6 do not project to the LGN but may project to the claustrum.

An interesting feature of the organization of feedback connections from the visual cortex to the LGN in the cat is that the most dense component of the terminal arborizations of the corticofugal axons in the LGN exhibits marked asymmetry. These arborizations are extended either parallel or perpendicular to the axis of the orientation preference of the parent cell in layer 6 of the visual cortex (Murphy et al., 1999), as shown in Figure 37.2. This anatomical asymmetry strongly suggests that the feedback might be organized to influence the processing of information relevant to the extraction of the orientation of contours in the visual cortex. We discuss this further in relation to functional data below.

FIRING PATTERNS A key question is whether under normal circumstances layer 6 cells in the visual cortex directly drive LGN relay cells or whether they simply modulate their response to the retinal input. The synaptic input from the corticofugal axons, although extensive, as discussed above, targets the distal portion of the relay cell dendrites via ionotropic and metabotropic receptors (Sherman, 2001; Von Krosigk et al., 1999) while the retinal axons target the proximal dendrites via ionotropic receptors. While it is clear that under certain nonphysiological circumstances (e.g., electrical stimulation of layer 6 cells at 30–50 Hz) the feedback pathway effects are optimized and can drive relay cells directly (Lindstrom and Wróbel, 1990), the balance of the evidence favors a feedback-driven modulation of the probability that relay cells will respond to their retinal input (Sherman and Guillery, 1998). Certainly for visual

FIGURE 37.2. Asymmetric termination pattern of corticofugal axons links to parent cell response properties. *A–E*, Experimental paradigm. Receptive field properties of layer 6 cortical cells were mapped prior to labeling with biocytin (*A*). The receptive fields (*B*) were superimposed on the geniculate retinotopic map (*C*). Single axons were reconstructed from serial sections and the bouton distribution was quantified in three dimensions, then analyzed with

respect to their relation to the geniculate representation of visual space (*D*, *E*). *F*, *G*, Two main patterns of connectivity were observed. Feedback axons either innervated LGN cells lying along a line corresponding to the preferred orientation of the parent layer 6 cell (*F*) or orthogonal to (hence lying along the preferred axis of stimulus movement) the parent cell orientation preference (*G*). (Data taken from Murphy et al., 1999.)

stimulation, several investigations support the view that virtually all the spikes fired by X- and Y-type relay cells in the cat can be linked to spikes in the retinal ganglion cells providing the input (Cleland and Lee, 1985; Mastronarde, 1987). This point needs further experimental verification with stimuli that will strongly activate layer 6 cells in the visual cortex. Additionally, the suggestion that burst mode firing in relay cells, originally associated with synchronized firing of relay cells and slow-wave sleep, also occurs in the waking state (Guido and Weyand, 1995; Sherman, 2001) adds another dimension of complexity (Rowe and Fischer, 2001). Burst mode firing occurs when relay cells have been hyperpolarized for periods of 100 msec or more and follows the deinactivation of a voltage- and time-dependent calcium current (I_T). Under these conditions, when the cell receives a suprathreshold depolarizing input, there is a calcium influx generating a low-threshold depolarizing spike that then activates a burst of conventional spikes. The size of the low-threshold depolarizing spike and the number of conventional spikes in the burst depend on the degree of hyperpolarization of the membrane, not the magnitude of the suprathreshold activating input. A sustained depolarization of relay cells for 100 msec or more inactivates I_T , and the cell switches to tonic mode firing associated with a linear transmission of sensory information and in this sense associated more conventionally with the waking state.

We suggest that the key to the reported presence of burst firing mode in the waking state is the strength of the hyperpolarization that can follow from the visual input. An example could be a group of OFF-center X cells with receptive fields lying within a bright, featureless, and thus uniform field. This would produce a visually driven hyperpolarization of their membrane potential. The salient components of an image are the loci where a change occurs; thus, in this sense, the hypothetical group of cells would have nothing to signal. On the other hand, the appearance of a moving dark contour over their receptive field would provoke a depolarizing input and a low-threshold calcium spike driving a burst of action potentials.

It has been suggested that burst firing in thalamic cells in the waking state serves as a “wake-up” call to the cortical cells receiving the input (Sherman, 2001). However, in the sense that the cortex is already in the waking state, this may be a slightly misleading description. Rather, the burst of action potentials in the input to the cortex would provide a high-security signal to focus the circuitry on the new feature driving attention in the cortical mechanism. One suggested role for the corticofugal feedback system is that it may contribute to selective attention via its influence on geniculate firing patterns. Because the feedback axons influence LGN relay cells both directly via synapses involving ionotropic and metabotropic receptors (Sherman, 2001; Von Krosigk et al., 1999), and indirectly via an input to inhibitory interneurons,

they have the capacity to exert a complex pattern of control over relay cells that could switch the behavior of LGN cells between tonic and burst modes. Recent work has questioned whether the patterned activity that occurs normally in the visual cortex during visual stimulation might switch the behavior of LGN cells via the feedback system (Wang et al., submitted). While recording simultaneously in cortex and LGN, focal iontophoretic application of a GABA_B receptor antagonist, CGP 55845 (see below), was used to produce local relief of the GABA_B inhibition of layer 6 cells (Fig. 37.3A). This reversibly enhanced the gain of their visually driven responses without affecting their spontaneous firing rate, making it possible to isolate the effects of this change in a controlled fashion. This change in cortical visual responses led to a statistically significant shift in the ratio of burst to tonic firing for 68% of LGN cells tested. Of these, 43% showed a shift from tonic to bursting (e.g., Fig. 37.3B) and 25% from bursting to tonic firing (Fig. 37.3C). These effects did not follow from the drug’s application causing a state-dependent shift in the state of the cortex because simultaneously recorded LGN cells showed opposite direction shifts in firing. Thus, the data indicate that a focal change in the visual response magnitude of layer 6 cells can produce a clear switch in the firing pattern of LGN cells. In some cases, it moves them toward the tonic firing pattern and the faithful relay of their visual input; in others, it moves them to burst firing and a response mode suggested to underlie early signal detection (Sherman, 2001). With the complex input derived from stimuli in the natural visual world, the selective adjustment of the transfer properties of the LGN provides a means of alerting the system to salient change, while at the same time optimizing its capacity to relay accurate information about what has already engaged the system.

SPATIAL INTERACTIONS The corticofugal system also exerts a subtle but clear influence on the spatial properties of the LGN relay cell field. The fundamental effect seems to be an enhancement of the strength of the inhibitory surround in the presence of moving stimuli, so cells are more strongly patch-suppressed (and end-stopped) and the excitatory discharge zone for a moving stimulus is more focused (Cudeiro and Sillito, 1996; Jones et al., 2000; Murphy and Sillito, 1987; Sillito et al., 1993). Thus, the records in Figure 37.4A give an example of the length tuning of simultaneously recorded LGN cells, one with corticofugal feedback and one without. The loss of surround suppression in the absence of feedback is clear. The effect over the group of LGN cells tested is summarized by the block histogram in Figure 37.4B. These effects occurred without changing the degree of suppression associated with a stationary flashing stimulus of varying diameter. The enhancement of the inhibitory surround for moving stimuli also seems to lead to an increased sensitivity to orientation contrast, direction contrast, and

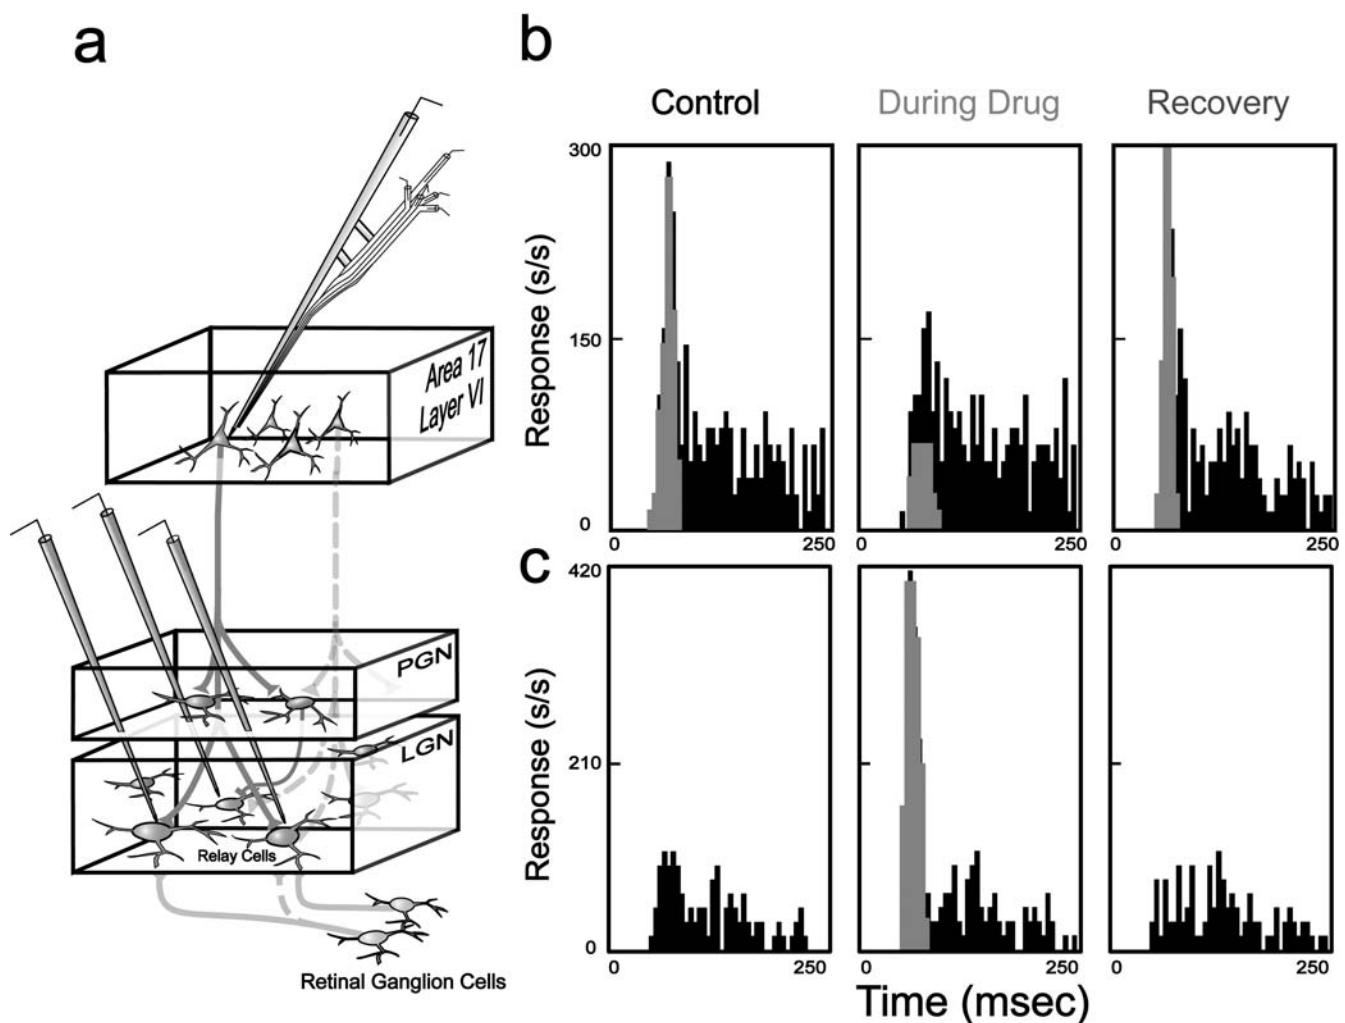

FIGURE 37.3. Effect of corticofugal feedback on LGN cell firing patterns. *A*, Experimental paradigm. Simultaneous recordings were obtained from a layer 6 cell and an LGN cell. Responses to visual stimulation were compared before, during, and after focal iontophoretic application of the GABA_B antagonist CGP in layer 6. Spike trains of LGN cell responses during periods of visual stimulation were divided into periods of burst and tonic activity. The first action potential in a burst showed a preceding silent period of at least 100 msec followed by a second spike with an interspike interval ≤ 4 msec. Any subsequent action potentials with preceding inter-

spike intervals ≤ 4 msec were also considered to be part of a burst. All other spikes were regarded as tonic. *B, C*, The peristimulus time histograms (PSTHs) show the responses of two LGN cells to an optimal diameter flashing spot located over the classical receptive field (CRF) before, during, and after focal enhancement of layer 6. For both cells, there was a clear change in firing pattern during focal enhancement of layer 6. Burst spikes are colored red; tonic spikes are colored black. PSTHs are plotted with 5 msec bins. (Data summarized from Wang et al., submitted.) (See color plate 20.)

temporal/phase contrast between center and surround mechanisms (Cudeiro and Sillito, 1996; Sillito and Jones, 1997; Sillito et al., 1993, 1999). The examples in Figure 37.5*A–D* illustrate the way LGN cells are influenced by direction (*A*), orientation (*B, F*), and temporal frequency (*D*) contrast in the presence of feedback, while the examples in Figure 37.5*C* and 37.5*G* show how the sensitivity to orientation contrast between a central and a surround stimulus is influenced by corticofugal feedback. In the absence of feedback, the sensitivity to the difference in orientation is greatly reduced, as summarized by the population histograms in Figure 37.5*E*. We stress that this reflects a sensitivity to

orientation contrast and is not influenced by the absolute orientation of the stimulus. This point is underlined by the surface plot in Figure 37.5*F*, which shows the response of an LGN cell when the orientations of a central and a surrounding stimulus are varied independently in a random and interleaved fashion. Those instances in which the orientations of the inner and outer stimuli are the same lie along a diagonal from top right to bottom left. This diagonal is marked by a trough of low response levels. Thus, the cell signals orientation contrast. These effects all seem to follow from an increased resolution of the receptive field center-surround mechanism for a discontinuity in moving

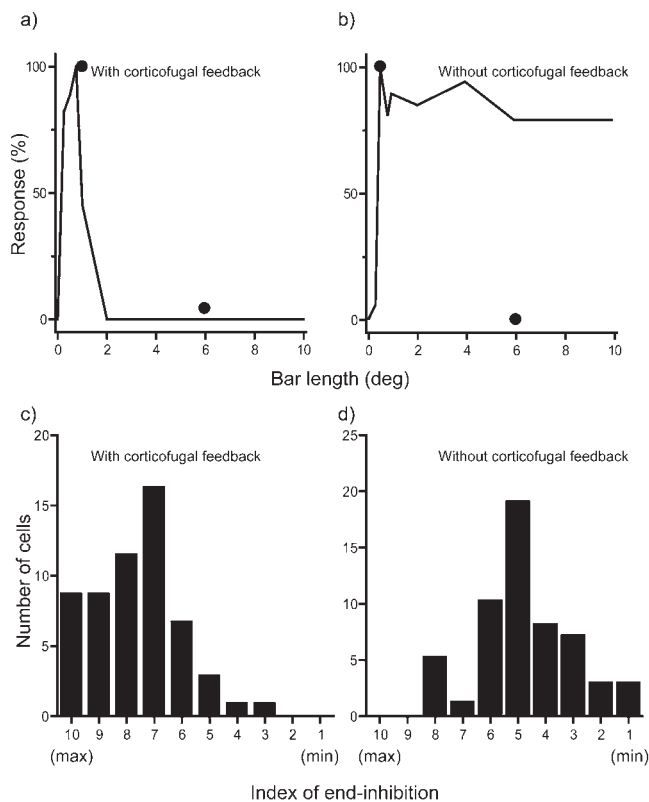

FIGURE 37.4. Effect of corticofugal feedback on LGN cell length tuning. *A,B*, Length tuning curves for two simultaneously recorded LGN cells. One was recorded from an LGN with corticofugal feedback (*A*), the other (*B*) from the other side of the brain from an LGN without feedback. The responses evoked by optimal and larger than optimal stationary spots of light flashed over the receptive field are superimposed on each graph (denoted by the filled spots). *C,D*, Bar histograms summarizing the distribution of end-inhibition with (*C*) and without (*D*) feedback. Cells are grouped into 10 categories for degree of end-inhibition. Category 10 contains cells showing total suppression of response at longer bar lengths, while those in category 1 show no suppression. (Observations summarized from Murphy and Sillito, 1987.)

stimuli and serve to highlight the points of change in the input to the cortex. The influence of the feedback in this sense might broadly be described as enhancing fine-scale segmentation.

The other side of the coin to segmentation is integration. The input from common elements belonging to, say, a moving contour needs to be integrated by a mechanism detecting the presence of the contour. At the most basic level, simple cells in the visual cortex integrate the inputs from LGN cells to detect the presence of contours with a particular orientation (Fig. 37.6). An appropriately oriented bar would coactivate the converging inputs illustrated in Figure 37.6 and synchronize their firing. The degree of synchronization of the inputs has a strong bearing on their ability to influence the simple cell. Indeed, evidence shows supralinear enhancement of transmission from hetero-

synaptic geniculate inputs to layer 4 simple cells in the visual cortex for spikes occurring within ~ 5 msec of each other (Usrey et al., 2000). It is thus very interesting that the feedback-enhanced center-surround antagonism influences the stimulus-driven synchronization (Andolina et al., submitted) of the discharges of LGN cells when they are precisely coactivated by a moving contour. We suggest in Figure 37.7 that the enhanced surround antagonism “focuses” the effective spatial extent of the receptive field center of LGN cells, leading to greater precision in firing when the two inputs are precisely coactivated. The evidence for this is summarized in Figure 37.6*A–D*. The experiments involved recordings in the cat LGN A laminae, using electrode assemblies configured to sample three cells of varying separation (Fig. 37.6*A*) in the presence and absence of feedback (Andolina et al., submitted). A grating patch was centered over one of the fields and was used to record the responses of the three cells at a range of orientations that included the angles linking each cell pair. Raw cross-correlograms (which show the stimulus-linked information that the second-order neuron sees) were then computed. These reflect the synchronicity of the inputs as “seen” by a theoretical simple cell for each pair at each orientation. Figure 37.6*B* shows representative results for a pair of X cells. A 5 msec window centered at zero lag (red) indicates those spikes that might generate supralinear enhancement of transmission. Note that shifts in orientation as small as 2° to either side of the angle linking the fields changed the count in this integration window. Converting the data to a surface representation of cross-correlogram time against grating orientation (Fig. 37.6*C*) reveals that the peak of the cross-correlogram shifted systematically throughout the time domain as orientation was varied. Interestingly, in the absence of feedback, this shift was less pronounced (Fig. 37.6*D*). As would be expected from this result, orientation tuning curves constructed from the synchronized spikes within the 5 msec window were much broader in the absence of feedback (see Fig. 37.6*E, F*, mean half width at half height 4.4 degrees with feedback and 13.17 degrees without feedback). Essentially this means that feedback greatly enhances the sensitivity to orientation in the stimulus-driven synchronization of the firing of LGN cells and thus the input to simple cells. In this sense, the organization is linked to contour and possibly motion integration.

Transfer of visual information through V1 and feedback from MT

SYNAPTIC ORGANIZATION, AND CIRCUITRY AND LAYER 6 CELL FUNCTION IN V1 In both cat and primate V1, the projections from the LGN provide a surprisingly small component of the excitatory (asymmetric) synaptic input to the main geniculo-recipient cells in layer 4. In the cat, input from the

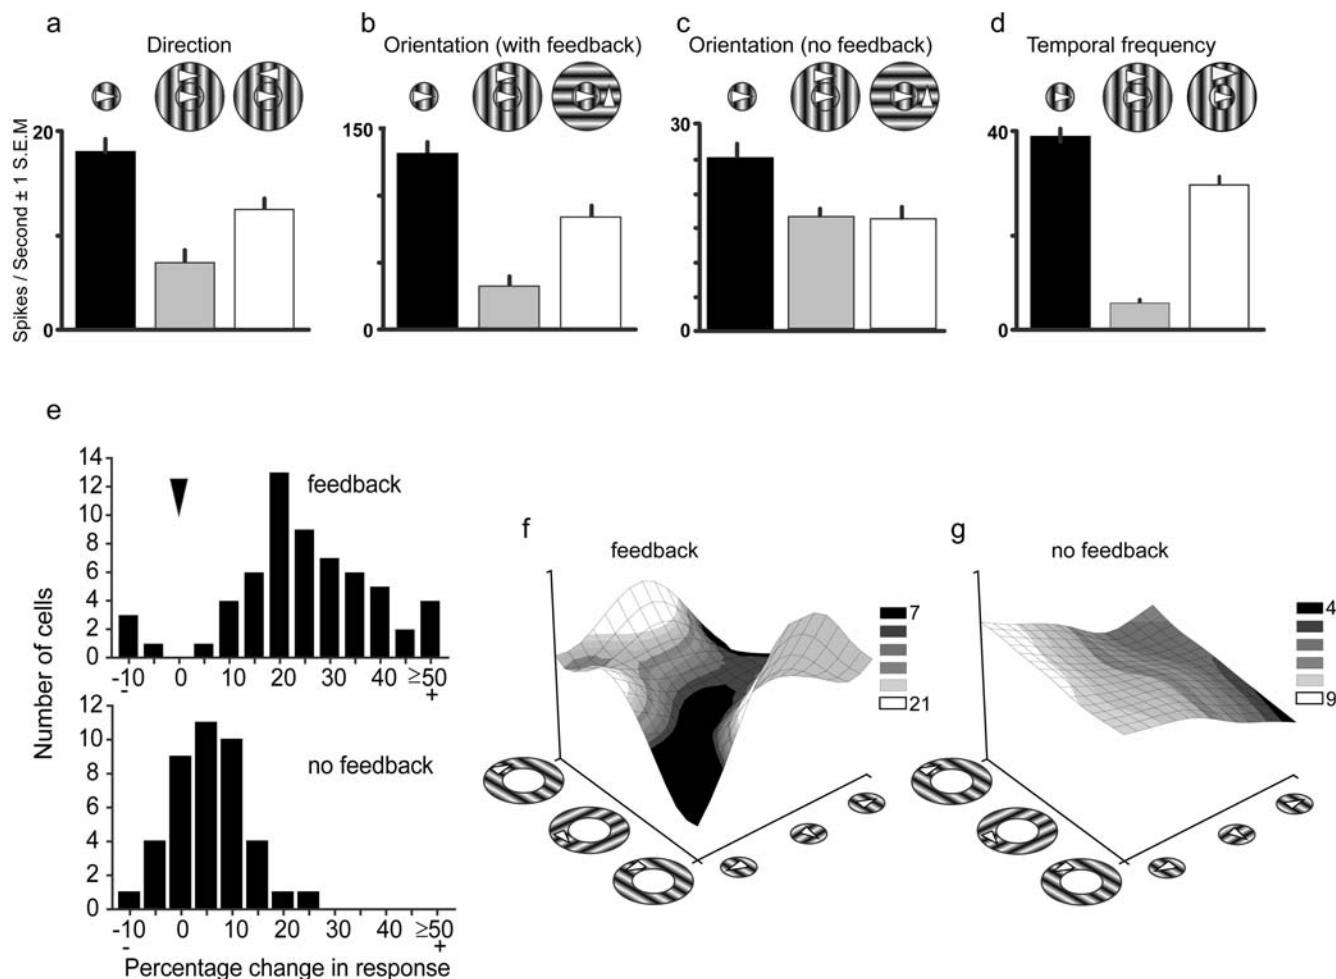

FIGURE 37.5. Corticofugal feedback enhances local segmentation effects in LGN cells. *A*, LGN cell response to direction contrast. The bar histogram shows the cell's response (spikes/second \pm 1 S.E.) to three stimulus conditions (shown diagrammatically by the stimulus icons above). These comprised a circular patch of grating overlying the receptive field (RF) center, the introduction of a surrounding field of identical grating drifting in the same direction of motion, and the presence of a surrounding grating with its direction of drift reversed. Drift direction is denoted by white arrowheads. *B*, LGN cell response to orientation contrast. Stimulus details as for *A*, but the last record shows the effect of changing the orientation of the surround grating. *C*, LGN cell response to orientation contrast in the absence of feedback. Stimulus details as for *B*. *D*, LGN cell response to temporal/phase contrast. Stimulus details as for *A*, but the last record shows the effect of changing the drift rate of the surrounding grating. *E*, Influence of feedback on orientation contrast. The histograms plot the percentage change in response observed between iso-oriented and orthogonally oriented

surround configurations (normalized with respect to the center-only response) in the presence (upper panel) and absence (lower panel) of corticofugal feedback. The mean increase in response magnitude for the switch from iso- to cross-oriented surround was 24.3% in the presence of feedback, which was reduced to 5.6% without feedback. *F*, LGN cells are sensitive to orientation contrast. The surface plot shows the response of an LGN cell (in the presence of feedback) to varying the orientation of an inner patch of grating in the presence of an outer patch of grating also of varying orientation. The diagonal running from bottom left to top right represents all those points where the orientation of the center and surround stimuli were the same over a complete sequence of absolute orientations. Response magnitude is shown by the height and shading of the contour. *G*, Reduction in orientation contrast in the absence of feedback. Stimulus details as for *F*. Note the absence of the pronounced diagonal trough. (Observations summarized from Cudeiro and Sillito, 1996; Sillito and Jones, 1997; Sillito et al., 1993, 1999.)

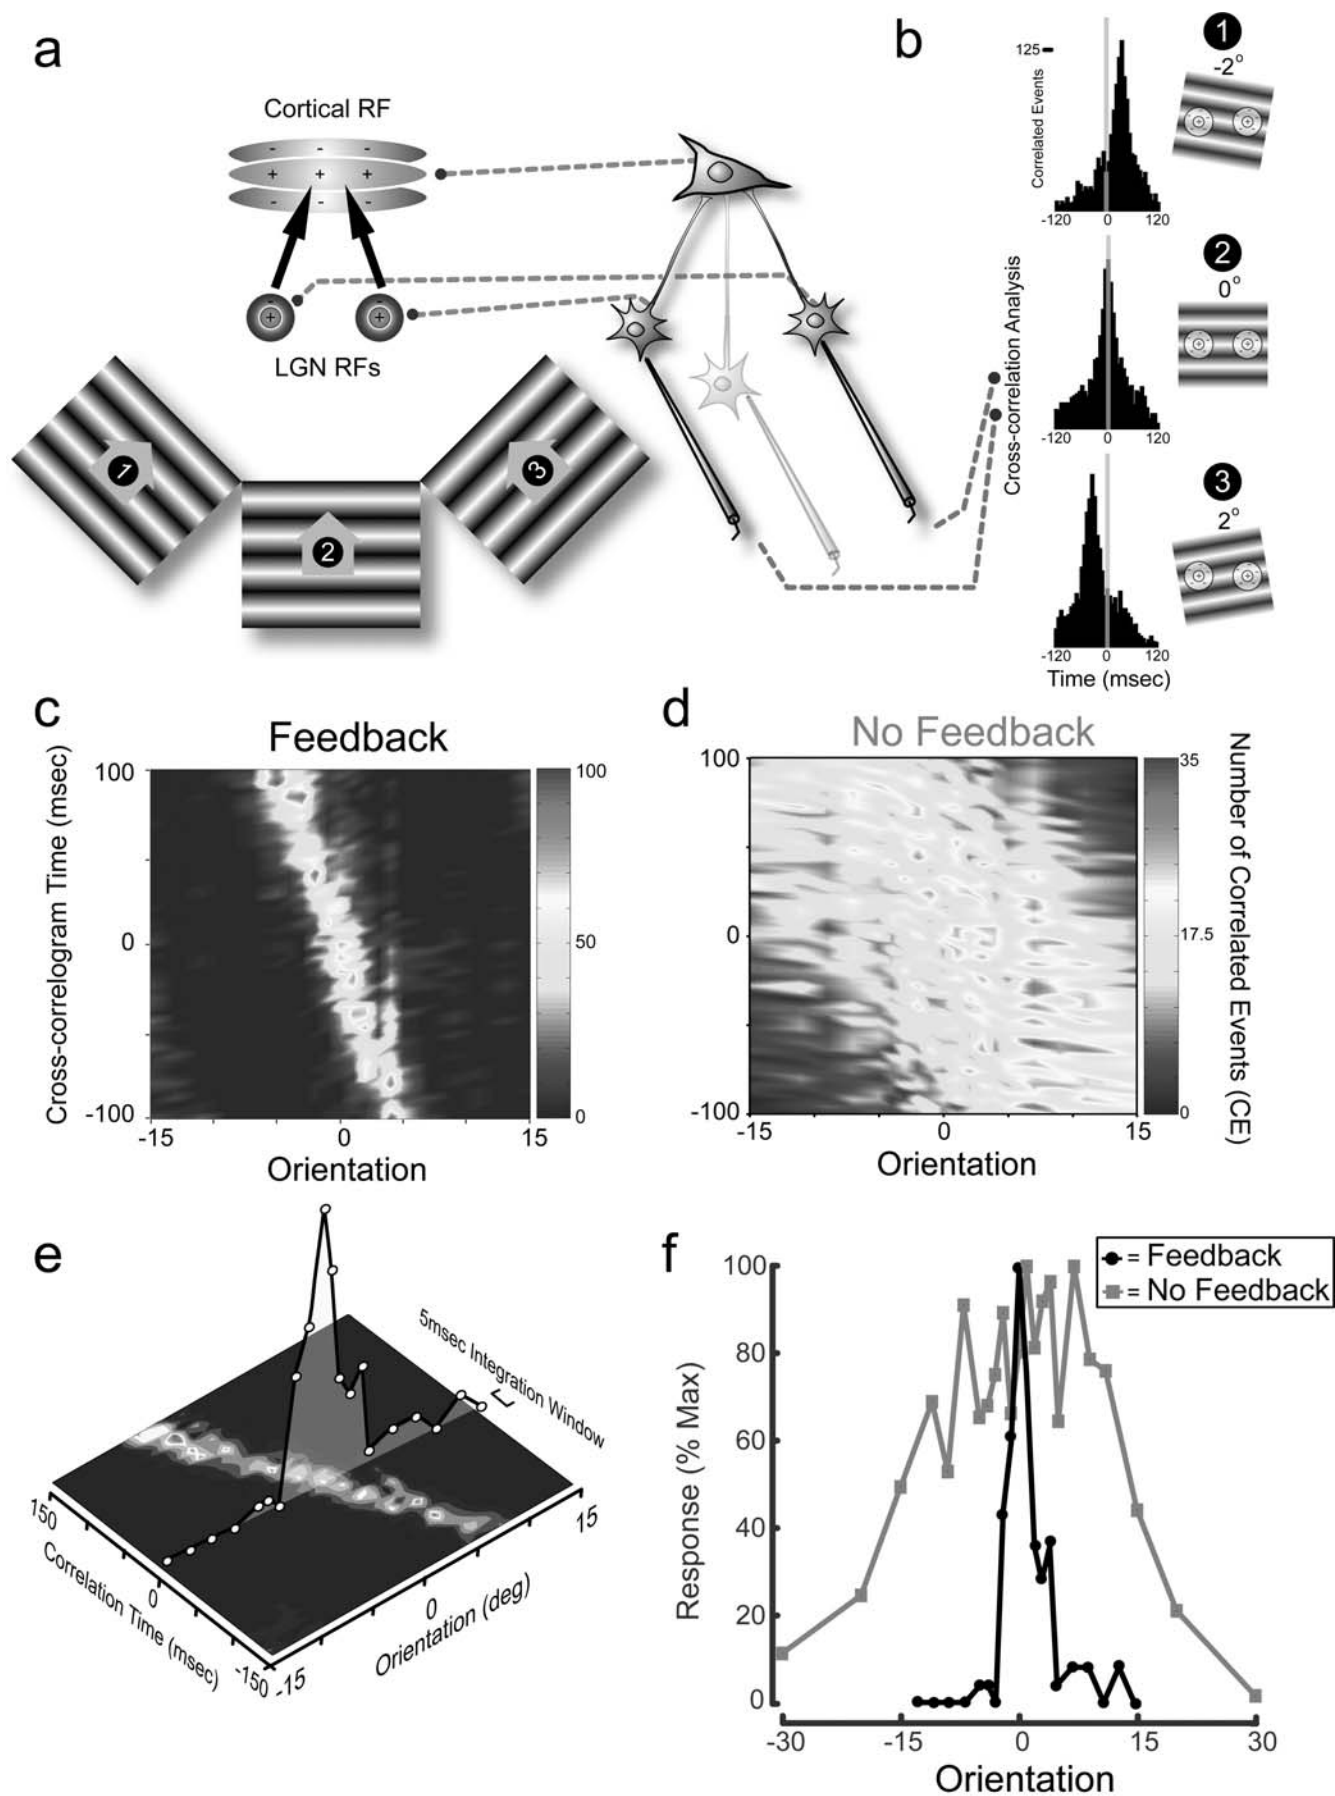

FIGURE 37.6. Corticofugal feedback influences stimulus-linked synchronization between LGN cell pairs. *A*, Experimental paradigm. The responses of pairs of LGN cells to drifting gratings of varying orientation were recorded, and raw cross-correlograms were constructed for each stimulus orientation. *B*, Raw cross-correlograms recorded from a pair of LGN cells for three stimulus orientations. The shaded bar centered at time 0 indicates a 5 msec time span and highlights the correlated events occurring within the supralinear integration window of a cortical layer 4 cell. *C, D*, Surface representation showing the cross-correlation data (y -axis)

versus orientation (x -axis) for LGN cells recorded in the presence (*C*) and absence (*D*) of feedback. The color scale represents the number of correlated events from low (dark blue) to high (dark red). *E*, Schematic example of an orientation tuning curve derived from the number of correlated events occurring in a 5 msec integration window. *F*, Orientation tuning curves for two LGN cells plotting the number of events in a 5 msec integration window recorded in the presence (black line) and absence (red line) of feedback. (Observations summarized from Andolina et al., submitted.) (See color plate 21.)

LGN provides only 6% of excitatory input to layer 4 cells, whereas neighboring spiny stellate cells provide 28% of the input and 45% of the inputs derive from layer 6 cell collaterals (from the same layer 6 cells that project to the LGN) (Ahmed et al., 1994). In the primate, the magnocellular input to layer 4C α comprises 8.7% of the asymmetric synapses and the parvocellular input to 4C β just 6.9% of the asymmetric synapses. The remaining asymmetric synaptic inputs to cells in 4C α and 4C β may be presumed to follow the same overall balance of the pattern reported in the cat, with strong inputs from layer 6 and surrounding spiny stellates (Latawiec et al., 2000). An issue that stands out from this is the role of the layer 6 cells that provide the feedback to the LGN. They sit in a unique position in relation to the transfer of the visual input, contributing numerically the majority of the connections to LGN relay cells and to the spiny stellate cells receiving the input from the relay cells. One cannot truly consider the role of the feedback to the LGN in isolation from that of the collateral projection to layer 4. Indeed, it is interesting to see that Callaway (1998) refers to these collateral connections to layer 4 as *feedback connections* in his analysis of the elements of local circuitry in V1. We have already discussed the functional segregation of the feedback neurons in the primate with respect to three input channels. The connections of these cells in V1 are equally discrete, showing dendritic and axonal configurations that are extremely laminar specific, so that some parvocellular projecting layer 6 cells may have dendritic and axonal arborizations that are, for example, almost exclusively focused on layer 4C β or layers 4C β and 4A. Magnocellular projecting cells, on the other hand, may have axonal and dendritic arborizations that distribute through layer 4C α , while others may distribute through 4C and enter 4A (or above). Cells in the middle of layer 6 do not project to the LGN, although some project to the claustrum, but they have very specific patterns of axonal distribution within 4C and include some that seem to sample both parvocellular and magnocellular sections of 4C (Callaway, 1998). In the cat, there is less apparent specificity amongst corticogeniculate cells in V1 but a very clear difference between LGN and claustrally projecting cells. The LGN projecting cells have extensive dendritic and axonal arborizations in

layer 4 but almost no horizontal arborization in layer 6, and their apical dendrites do not extend beyond layer 3. The claustral projecting cells have axon collaterals arborizing extensively in layer 6 and apical dendrites that reach layer 1 (Katz, 1987).

The detail of the visual response properties of identified corticofugally projecting cells is of considerable interest because it indicates the type of stimuli that might influence the transfer of visual information in the geniculate and layer 4. In the cat, feedback projections originate from both simple and complex cells, with simple cells predominating (Grieve and Sillito, 1995b; Tsumoto et al., 1978). The complex cells are spontaneously active and are strongly binocular, directional, broadly orientation tuned, and capable of responding at high stimulus velocities. The simple cells, on the other hand, have little or no spontaneous activity, are sharply orientation tuned, and include cells strongly or exclusively dominated by one eye. Although it was suggested that the corticofugal projection originates from cells with very long fields (generally 8 degrees or more; Bolz and Gilbert, 1986), the group that projects back to the LGN actually originates from cells with much shorter receptive fields, while the longer field cells project to the claustrum (Grieve and Sillito, 1995b). Indeed, in layer 6 as a whole, short field cells predominate (Grieve and Sillito, 1991b, 1995b). One fact stands out from all the available evidence: both the simple and complex cells projecting to the LGN tend to be strongly directionally sensitive. While there is no direct evidence regarding the properties of corticogeniculate cells in the primate, there is a wide consensus for a preponderance of directionally selective cells in layer 6 (Orban, 1994) along with layer 4 (A, B, and C α). Moreover, directionally selective simple cells have been reported to be the dominant cell type in layer 6, although there is substantive variance among investigators regarding this issue.

All this raises the intriguing question of what the collaterals of the corticogeniculate cells arborizing in layer 4 are doing. Intracellular work in vivo and in vitro (Ferster and Lindstrom, 1985; Tarczy-Hornoch et al., 1999) provides a consistent line of evidence for the layer 6 input to layer 4 cells driving many small excitatory postsynaptic potentials

FIGURE 37.7. Diagram summarizing the view that feedback-linked enhanced surround antagonism leads to greater synchronization of LGN cell firing to coherent contours and thus increases the probability of firing in cortical layer 4 cells.

(EPSPs) that show facilitation. This might serve to enhance the responsiveness of layer 4 cells as the visual response evolves. It is interesting to consider the possibility that were the cortex to receive a “burst” from a component of its thalamic input (see the discussion above) highlighting the appearance of a feature in a previously uniform sector of the visual input, the layer 6 input might serve to sustain the excitability of the layer 4 cells to the input as the relay cells switched to tonic mode firing. We know a little about the functional effects of layer 6 cells on layer 4 cell responses. Focal blockade of layer 6 reveals a loss of facilitatory drive to cells in overlying layer 4 (Grieve and Sillito, 1991a, 1995a). For a small proportion of non-end-stopped cells it seems to reduce an inhibitory input. This could follow from the loss of an influence mediated via inhibitory interneurons in layer 4 or a loss of direct inhibitory input from some GABAergic cells that have axon collaterals extending from layer 6 to layer 4 (Grieve and Sillito, 1995a). Overall, though, the predominant influence of layer 6 on layer 4 visual responses seems to be facilitatory (Grieve and Sillito, 1991a, 1995a). This is in accord with the distribution of layer 6 cell synapses to spiny stellate cells (Ahmed et al., 1994) and the electrophysiological data discussed above. The often expressed view that layer 6 cells with long receptive fields provide input to layer 4 inhibitory interneurons and generate end-stopped fields (Bolz and Gilbert, 1986) does not seem to be tenable (for a discussion, see Grieve and Sillito, 1991a, 1995a). Clearly, further work is needed here, but the balance of the evidence seems to favor a predominantly modulatory and facilitatory input. In a global sense, we wonder whether there may not be some mirror-image differentiation in the pattern of influence on visual responses, with the corticofugal connections on balance enhancing inhibitory mechanisms and the layer 4 collaterals enhancing facilitatory mechanisms.

LINKS BETWEEN V1 AND MT A consideration of the interactions between MT and V1 highlights many of the issues that are central to this discussion of the role of feedback. Area MT is associated with motion processing, and most of the cells are highly directionally selective (Orban, 1997). Area MT is particularly interesting in the context of feedback systems because, as discussed below, it uniquely sends feedback connections to V1 that target layer 4B and the depth of layer 6. It thus has the capacity to influence the layer 6 cells sitting at the interface of the input for all three streams of information translating through the thalamus. The output from V1 to MT derives from layers 4B and 6 (Shipp and Zeki, 1989). Layer 4B contains spiny stellates and pyramidal cells and receives input from both layer 4C α and 4C β (Callaway, 1998). The spiny stellate cells project directly to MT and receive input predominantly from layer 4C α together with a component from layer 5 and 6 cells. They

thus provide a strong magnocellular-dominated input to MT. The pyramidal cells in 4B also receive strong input from 4C α but gain a significant component from 4C β as well as a component from layer 5 and 6 cells. Pyramidal cells in layer 4B project directly to MT (Elston and Rosa, 1997), as well as to the thick stripes in V2, and there is a projection from the pyramidal cells in layer 3B of the V2 thick stripes to layer 4 in MT with some terminals in layers 1–3.

The information extracted by MT cells is fed back down the visual system to influence processing at the earlier levels. Feedback connections from layers 3 and 6 of MT target layers 1, 4B, and 6 in V1 (Orban, 1997; Rockland and Knutson, 2000; Shipp and Zeki, 1989); however, this varies with eccentricity. In the central 10 degrees the projection targets layers 4B and 6, while at greater eccentricities the projection focuses on layer 1. There is an interesting blurring in the reciprocal connections between MT and V1. The layer 4B and layer 6 cells projecting to MT from V1 are not uniformly distributed (Shipp and Zeki, 1989), the layer 4B cells are generally clustered together, and the layer 6 cells are restricted to the top of layer 6 (and avoid registration with the centers of blobs). The feedback connections from MT, on the other hand, project to wider patches of layer 4B and the whole of layer 6. Given the divergent connections of the various types of layer 6 cells (Callaway, 1998), including the feedback projections to the LGN, it seems fair to assume that the MT projection has the capacity to exert widespread influence over both magnocellular and parvocellular streams. Indeed, it is pertinent to note that the speed of transmission through the magnocellular pathway to MT is such that feedback from MT can potentially influence the feedforward relay of retinal information through the more slowly conducting parvocellular-dominated pathways of both the LGN and V1 (Orban, 1997).

EFFECTS OF FEEDBACK FROM MT ON RESPONSES IN V1 In considering the functional significance of these connections, one possibility is that the corticocortical feedback projections play a broad and nonspecific role centered on global gain control and that the detail of the connections is largely irrelevant from the viewpoint of processing mechanisms. On the other hand, the very early visual responses seen in MT cells and their pattern of termination in layers 4B and 6 in V1 suggest that MT is in a position to exert substantial influence on the early processing of the input in V1. Indeed, given the feedback from V1 layer 6 to the LGN, MT may additionally influence the responses of LGN cells. Thus, feedback containing information relevant to the high-level processing of motion in the visual world could influence visual processing in V1 for moving stimuli at a very early stage in the development of visual responses. Indeed, the available evidence does suggest a strong influence of MT on processing in V1. Firstly, studies that have either lesioned or reversibly

cooled MT show marked changes in the responses of V1 cells (Hupe et al., 2001; Lamme et al., 1997) including an effect on the earliest component of the responses to both stationary flashing and moving stimuli. However, the effects of cooling can be complex and difficult to control (Volgushev et al., 2000), and the gradient of cooling that logically has to occur will cause cells at a certain distance from the cooling focus to fire at higher levels than normal. Consequently, these procedures may well have influenced more than MT and may not have influenced MT uniformly. Even by removing all the influence of MT, it is not certain that the changes in V1 necessarily reflect the loss of a specific influence from MT on processing in V1. Blockade of MT may have eliminated static biasing influences, resulting in a shift in the balance of the V1 circuitry, which in turn shifted the way the circuitry processed visual stimuli. Thus, although the data from cooling studies provide a strong indication of the potential influence of the feedback from MT, they leave many unanswered questions.

In attempting to unravel the effects of feedback from MT, it is crucial to recognize that MT feedback will provoke the primary change in V1 processing when the stimulus contains features that best activate MT cells. Moreover, these stimuli, by virtue of their spatial focus and specific trigger features such as direction of motion, will provoke differential activation of MT, and the “high spots” of enhanced activity in MT will in turn provide highlights in the pattern of feedback to V1. Although it is clearly possible to generate stimuli that should cause a differential pattern of activation of MT, it is very difficult to dissociate any consequent reflected influence on V1 via feedback from potential direct effects of the stimulus on circuitry in V1. One way of tackling this problem is to use stimuli that will activate MT cells but, in addition, via a drug and recording electrode assembly inserted in area MT, produce very focal and reversible changes in the gain of the response of the recorded MT cells to these stimuli. In many ways, this could be argued to simply increase or decrease the salience of the stimuli to the cell

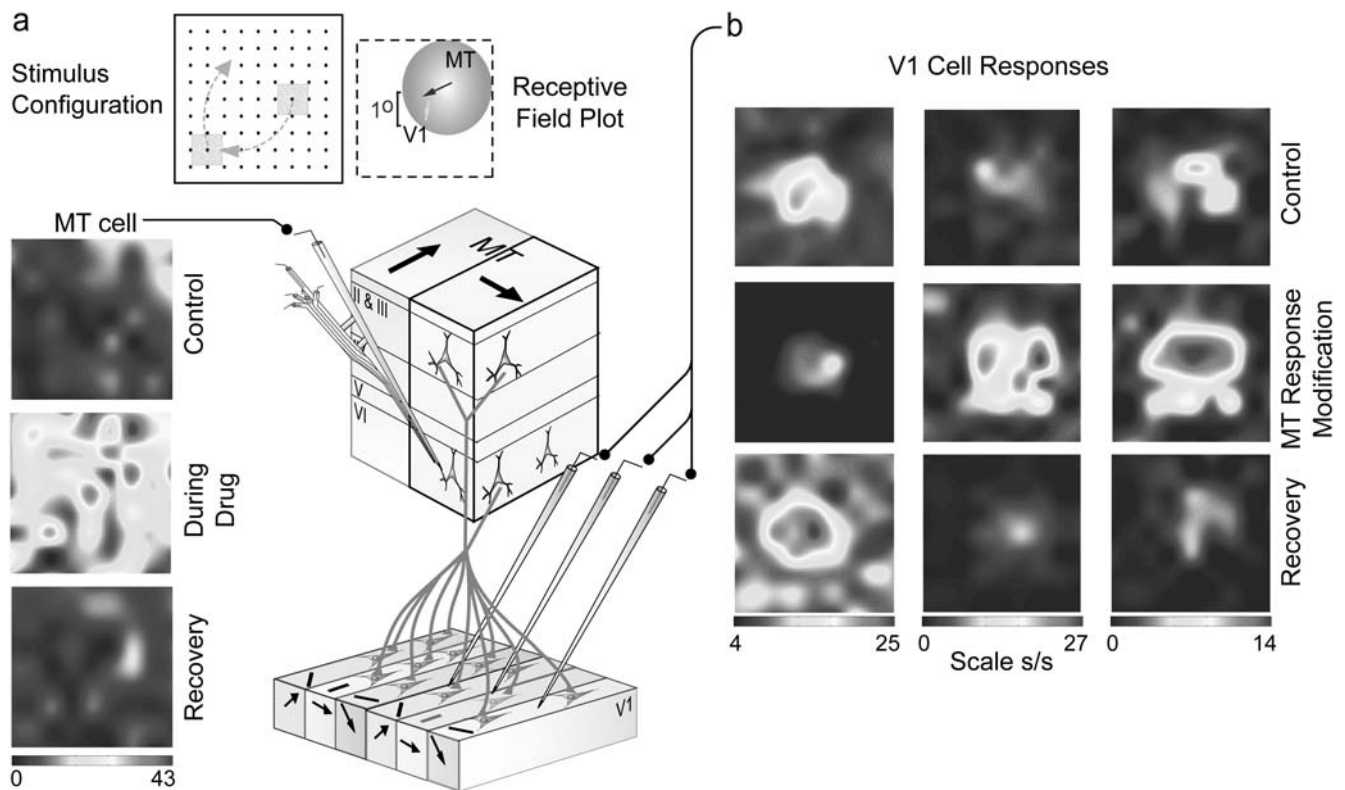

FIGURE 37.8. Effect of MT feedback on V1 cell responses to drifting stimuli. *A*, Experimental protocol. Simultaneous recordings were obtained from one or more V1 cells and an MT cell. Responses to visual stimuli were assessed before, during, and after focal iontophoretic application of the GABA_B antagonist CGP in MT. The stimulus was a patch of drifting texture displaced (in a randomized interleaved sequence) to cover a range of XY locations. The grid was centered over the receptive fields of the V1 cells, as shown by the example diagrammatic icon of the relative

locations of an MT (orange) and a V1 (green) cell receptive field (where the dotted rectangle depicts the total area of visual space covered by the grid). The contour maps show the response of an MT cell before, during, and after CGP iontophoresis. Response magnitude (s/s) is represented by color, from low (dark blue) to high (dark red). *B*, Effects in V1. The contour maps plot the responses of three V1 cells tested in the presence of the type of change in MT shown in *B*. (Observations summarized from Jones et al., submitted.) (See color plate 22.)

recorded by the MT electrode. Because one can reverse this and repeat it, there is a potential for unmasking influence of the MT feedback on V1 cell responses. A diagram summarizing this approach is shown in Figure 37.8A. The experiment involved iontophoretic application of the GABA_B antagonist CGP 55485 to produce a focal change in gain in the visually evoked response of a recorded MT cell without affecting either its background discharge or its response selectivity. The key here is that synaptically released GABA acting via the GABA_B receptor produces a long-lasting hyperpolarization of the cell membrane, moving it away from the depolarization threshold for initiating action potentials. This contrasts with the fast time course of action via GABA_A receptors which is linked to the dynamics of visual processing determining selectivity to the visual stimulus (Borg-Graham et al., 1998; Sillito, 1975). Thus, blockade of the GABA_B receptor, by decreasing the long-lasting hyperpolarization, renders the cells more responsive to their input. An example of the data obtained from the blockade of GABA_B receptors is shown in Figure 37.8. The visual stimulus used was a patch of drifting visual texture (Fig. 37.8A) presented through a series of XY coordinates within the rectangle to encompass the locations of the MT and V1 cell fields. The direction of drift of the stimulus matched the preferred direction of the MT cell, and the stimulus activated it. The responses of the cells are shown in the colored surface plots, and the different locations in the surface plot reflect the effect of the stimulus at each of the points shown in the stimulus icon rectangle. In the surface plots, the color scale denoting response magnitude (in spikes per second) moves from red (highest firing rates) to blue (lowest firing rates). An example of the effect on the responses of an MT cell is shown in Figure 37.8A. The strong increase in response during the GABA_B blockade is clear. The responses of three V1 cells, in the presence of the type of focal change in MT seen in Figure 37.8A, are shown in Figure 37.8B. Two of these examples (middle and right columns) showed enhanced responses when MT responses were enhanced, and one showed a diminished response (left column). These different patterns of effect were seen among simultaneously recorded V1 cells with overlapping fields.

Changes in response magnitude were seen in 76% of the V1 cells tested in this way. At the same time, there were changes in the spatial organization of the area from which the responses to patches of drifting visual texture could be elicited and changes in the response to motion contrast. The types of effects seen could be grouped in several ways. Firstly, most nonoriented cells showed a reciprocal relationship to the response level of the MT cell: when MT cell responses increased, those of the nonoriented cells decreased, while decreasing MT responses (by iontophoresing GABA, for example, with a very low current) led to an increase in the nonoriented cell response. Most simple cell responses, on the

other hand, increased when MT cells responses increased and decreased when they decreased. Complex cells were evenly distributed between the two patterns of linkage to MT cells. Functionally this suggests that MT differentially influences the processes in V1 that are represented by the receptive field characteristics associated with nonoriented and simple cells. A particular issue is that when the gain of the visual response of recorded MT cells was decreased (using GABA), changes in the V1 responses were also seen, with a reciprocal pattern to that for the MT increases in the nonorientation tuned and simple cells. Thus, the normal responses of MT cells seem to provide the basis for the “control” responses of V1 cells, as one might expect. It is also clear that MT influences the way V1 cells process stimulus features extending across visual space that may link together or highlight a focus of change. Thus, applying a second motion field around a central one overlying the V1 fields (Fig. 37.9A, B) and varying the direction of drift of the two reveals different patterns of response in V1 cells and a strong influence from MT on these patterns of response.

FIGURE 37.9. MT feedback influences responses of V1 cells to direction contrast stimuli. A,B, The tuning curves show the responses (in s/s) of two V1 cells before (solid line) and during (dotted line) MT response enhancement. Each tuning curve plots the effect of varying the outer texture direction (in degrees along the x-axis) while the direction of the inner texture stimulus was held constant (0 degrees—marked on each plot by the gray shading). (Observations summarized from Jones et al., submitted.)

The influence of MT on these cells fell into two categories, either enhancing contour/motion integration (Fig. 37.9A) or enhancing segmentation (Fig. 37.9B) produced by direction contrast. On a larger scale, this has many similarities to the types of effects seen with feedback in the LGN.

Conclusions

On the basis of both the anatomical and functional data, it is clear that the feedback systems highlighted in this account are structured to provide specific patterns of effect that can be linked to the organization of the processing of visual information. In different ways and on varying retinotopic scales, a major role seems to be the enhancement of the respective mechanisms linking to local and global segmentation and integration. The logic underlying this would be that the next stage in the processing stream starts to extract or detect the information that provides the basis for recognizing the common components of a feature or change in components defining different features. This information, reflected back to the earlier stages, seems to be able to enhance the finer resolution of the earlier level to the patterns isolated by the higher level. It would be incorrect to see this as a slow process or a process separate from the sequential processing of the input. For the visual world in motion, the “hand” of MT is present in the responses of V1 cells all the time. We also know that, via its influences in V1, it exerts clear effects in the LGN (H.E. Jones et al., unpublished observations). Feedback influences do not imply long latency. The size of MT cell receptive fields (10 times those of V1 cells; Orban, 1997), and spatial organization of the feedback connections which contact a retinotopic area in V1 that matches or exceeds that driving the input to a particular MT cell, mean that a moving stimulus can exert feedback effects on V1 circuitry that influence the response in V1 to its successive positions with zero latency. Indeed, effects could occur in advance of the arrival of a stimulus at a particular location. Reflected through the feedback projection from V1 to the LGN, this same logic applies to the LGN. The anatomical organization of the feedback to the LGN, which suggests a particular role in direction and orientation processing underlying segmentation and integration, argues for the ability of the feedback, reflected via layer 6 of V1 from higher levels, to exert rapid and structured patterns of effect. Embedded in the influences, and part of the mechanism driving the effects, is a regulation of the patterns of firing of the cells. In the LGN this is clear both in terms of the influence of feedback on the synchronization of the firing of LGN cells commonly activated by a contour and in the switch between burst and tonic firing modes. A key point for the burst versus tonic firing modes is that the cortex via the visually driven feedback can shift the response modes of LGN cells in a way that reflects the optimization best suited

to the visual image. As the image of the visual world contains features differentiated across retinotopic space and time, these in turn selectively activate different foci in the higher visual areas and produce a changing pattern of feedback reflected to the earlier levels. This drives a visually cued mechanism for selective attention to salient features and shifts in the local circuitry to optimize the system's hold on these at all levels. Finally, the question to repeat is whether the term *feedback* for these interconnections in the processing streams is not somewhat misleading. It might be better to consider the organization of the central visual system in terms of local and multilevel circuits.

A crucial step in the next phase of work on the central visual system is the recognition that these multilevel circuits underpin the evolution of the visual response to even simple stimuli, and that we need to unravel the way the feedback adjustments of the lower-level response properties contribute to the abstraction carried out by the higher level. Clearly, the way feedback from MT targets layer 6 in V1 within the central 10 degrees of the visual field suggests that the feedback of information linked to motion cues to layer 6 cells that sit at the “gate” of all the processing streams is important to the translation of the visual input through V1. The reasons for this need to be assessed in models and experiments designed to examine the interactions between different cues in the early visual system with and without manipulation of the feedback. Focusing on the special role of layer 6 cells, another interesting issue is that the majority of the feedback cells are simple cells (Grieve and Sillito, 1995b), and these contact cells in the LGN that are concentric and cells in layer 4 of V1 that are also simple (or concentric, as in primate 4C). The question is, does a particular layer 6 simple cell contact cells in the LGN in a fashion that reflects the spatial phase of the layer 6 cell, that is, does a layer 6 cell with a central ON zone in its receptive field contact ON-center LGN cells that are spatially aligned to the ON zone of the layer 6 cell? Are there direct connections in such an arrangement to OFF-center cells that lie under the OFF surround of the layer 6 cell or do these relay via an inhibitory interneuron? Alternatively, are the connections phase reversed or are phase relationships lost? Similar questions apply to the connections from layer 6 cells to layer 4. A further dimension here is the question of the potential phase relationships between layer 6 and LGN fields and those of the layer 6 collaterals with layer 4 cells. For example, it could be that the connections from layer 6 to the LGN are phased reversed with respect to those to layer 4. The net effect is positive feedback at one location in the circuit translating the retinal input to the cortex and negative feedback at the other. The specificity of such connections would have great significance for the way we interpret what might appear to be putative excitatory connections but would have essentially the opposite action if phase reversed.

These issues need to be resolved experimentally and modeled. Considering other feedback systems to V1, it is relevant to question the significance of the fact that with the exception of the feedback from MT (for the central 10 degrees and that from V3), the bulk of the connections target layer 1. We have no idea how these connections are ordered with respect to function or of the detailed synaptic organization. Possibly the most surprising thing about the organization of feedback systems is how little we know about them. On the other hand, we do know enough from the work over the past decade to know that they have strong effects and that we need to know more if we are to understand the visual system better.

38 Light Responsiveness and Photic Entrainment of the Mammalian Circadian Clock

JOHANNA H. MEIJER AND JOSEPH S. TAKAHASHI

THE ROTATION OF the Earth around its axis causes 24-hour rhythms in many aspects of the physical environment, while the Earth's revolution around the sun causes seasonal changes. As an adaptation to daily environmental changes, virtually all living systems have developed endogenous circadian clocks with periods of about 24 hours to anticipate changes in the solar day. Anticipation of, rather than passive responsiveness to, the daily cycle is deeply embedded in biology and perhaps first evolved in cyanobacteria 3–4 billion years ago (Johnson and Golden, 1999). The photic environment was likely the selective agent for optimization of photosynthesis as well as escape from the mutagenic effects of ultraviolet irradiation. In animals, this evolutionary history persists in the circadian rhythms that can be observed at the level of gene expression, cellular metabolism, endocrine function, physiology, and behavior (Takahashi et al., 2001).

For proper functioning, circadian rhythms have to be synchronized, or entrained, to the day-night cycle. The major synchronizing stimulus in the environment is light. Light, rather than temperature variation or other environmental features, is a reliable signal to indicate whether it is day or night, while changes in day length are a reliable signal to indicate the time of the year. Not surprisingly, circadian clocks are responsive to light to subserve entrainment to the daily and annual cycle. In mammals, the circadian clock is located in the suprachiasmatic nuclei (SCN) at the base of the anterior hypothalamus. Light information reaches the SCN via specialized neuronal projections, of which the retinohypothalamic tract appears sufficient for photic entrainment.

Circadian rhythms are generated at the cellular level, and in mammals individual neurons in the SCN are cell autonomous circadian oscillators (Welsh et al., 1995). In the past decade, progress has been made in the identification of “clock” genes that play a role in the generation of circadian rhythms. An autoregulatory transcriptional-translational feedback loop forms the core mechanism of the circadian clock in animals. The positive elements of the oscillator are

Clock and *BMAL1*, whose gene products (CLOCK and BMAL1) form a heterodimeric transcription factor to activate the mammalian *Period* and *Cryptochrome* genes. The negative elements of the oscillator are *Period* and *Cryptochrome*, whose gene products (PERIOD and CRYPTOCHROME) accumulate, associate with each other, and translocate into the nucleus to inhibit the CLOCK/BMAL1 activation of their own transcription. As the negative elements turn over, CLOCK and BMAL1 then become active again to begin a new cycle of transcription of the *Period* and *Cryptochrome* genes (for recent reviews, see King and Takahashi, 2000; Lowrey and Takahashi, 2000; Reppert and Weaver, 2001; Young and Kay, 2001).

This chapter will focus on the light responsiveness of the mammalian circadian pacemaker and will start with an overview of the behavioral responsiveness of circadian rhythms to light as it is measured in the behaving animal. This will be followed by a discussion of light input pathways to the SCN, the neurotransmitters involved, and the light response properties of SCN neurons. The last part of the chapter will deal with intracellular responsiveness of SCN neurons to light, including the effects of light on clock gene expression.

Responsiveness of behavioral circadian rhythms to light

Physiological and molecular experiments eventually intend to offer an explanation for the attributes of the system as they appear in the phenotype. For that reason, a description of the system's behavior can guide the design of experiments at other research levels. Complex attributes of the system that are not directly explainable in terms of their function are not less important in this respect. This section will discuss the several properties of the circadian system in its response to light.

LIGHT-INDUCED PHASE SHIFTS Characteristically, the effects of light on the clock change as a function of time of day. During the night the circadian system responds to light with

a phase adjustment, while during the day this response is absent. The changing responsivity of the clock to light is essential for photic entrainment and, in fact, is an analytical necessity for the pacemaker to become entrained. When mammals are kept in a constant environment, their activity pattern is still rhythmic but the period of the cycle deviates slightly from 24 hours. The characteristic light response of the circadian pacemaker is best illustrated when animals are kept in constant darkness and exposed to a short pulse of light (e.g., 5–15 minutes) at a particular phase of the circadian cycle. A light pulse that is presented shortly after a nocturnal animal's activity onset (which corresponds to the beginning of the animal's *subjective night*) will induce a phase delay of the circadian cycle. This means that on the next cycle the animal will start its activity later than was expected on the basis of its previous activity rhythm. A light pulse presented toward the end of the animal's activity (which corresponds to the end of the animal's subjective night) will induce a phase advance of the animal's rhythm (Fig. 38.1). During the animal's resting phase (which corresponds to the animal's subjective day), light does not affect the pacemaker's phase.

The behavioral phase shifts that are induced by light pulses are permanent and an indication that the underlying pacemaker has shifted in phase (Fig. 38.1). The effects of light pulses can be summarized in a phase response curve by plotting the light-induced phase shift as a function of the phase of pulse application (Daan and Pittendrigh, 1976;

Takahashi et al., 1984). The phase response curve illustrates how the pacemaker's responsiveness changes during the course of the cycle (Fig. 38.1).

For diurnal species, the phase response curve is nearly identical, and only the time of behavioral activity is shifted from night to day. Light pulses presented at the beginning of the animal's resting phase induce phase delays in diurnal animals, and light pulses at the end of the resting phase produce phase advances. The phase delaying and phase advancing responses at the beginning and end of the subjective night are common features of circadian pacemakers and ensure that animals entrain to a light-dark cycle. For example, when nocturnal animals leave their burrow too early in the evening, the evening light will induce a phase delay, causing them to leave their burrow later on the next cycle. In contrast, the circadian system is advanced when animals return to their burrow too late in the morning and see the morning light. In conclusion, photic entrainment

FIGURE 38.1. Phase-shifting effects of light on running wheel activity in the hamster. Consecutive days are plotted beneath one another. The presence of running wheel activity is recorded with a resolution of 1 minute. Following entrainment to a light-dark cycle (L:D 14:10), hamsters were released in constant darkness, resulting in a free-running rhythm with a period that is slightly deviating from 24 hours. *A*, Presentation of a 15 minute light pulse (100lux) 2 hours after activity onset results in a phase delay of the free-running activity rhythm. *B*, An identical light pulse that is presented 7 hours after activity onset results in a phase advance of the rhythm. Parts *A* and *B* illustrate the phase dependence of the effects of light on the pacemaker. *C*, Ineffectiveness of light presentation 2 hours after activity onset to induce a phase delay in a blinded hamster. *D*, Ineffectiveness of light 7 hours after activity onset in producing a phase advance in a blinded hamster. Parts *C* and *D* illustrate that the effects of light on the pacemaker are dependent on the integrity of retinal input. *E*, Phase-response curve for the phase-shifting effects of light pulses on circadian running wheel activity rhythm in the hamster. Onset of behavioral activity is defined as circadian time 12 (CT 12). The phase-response curve shows that presentation of light in the first few hours after activity onset results in phase delays. Delays are maximal around CT 14. Toward the end of activity, light results in phase advances with maximal advances around CT 19. A dead zone exists in which the animals' circadian clock is not responding to light with a phase shift. (*C* and *D* based on Meijer et al., 1999; *E* based on Takahashi et al., 1984.)

relies on well-directed phase adjustments of the circadian pacemaker that follow from the phase-dependent responsiveness of the pacemaker to light.

Additional response properties of the circadian pacemaker to light further support the animal's ability to entrain. The magnitude of either a phase delay or a phase advance obtained at a particular phase of the cycle depends on (1) light intensity, (2) duration of the light pulse, and (3) wavelength of the light. For light pulses with durations of 5–15 minutes, light intensities up to a threshold level of about 0.1 lux or 10^{11} photons $\text{Rev cm}^2/\text{s}$ for hamsters and 1 lux for rats do not phase shift the circadian clock (Meijer et al., 1986, 1992; Nelson and Takahashi, 1991). This threshold intensity is very high compared to the thresholds for scotopic vision and is similar to the thresholds for photopic vision. Above threshold intensity, the magnitude of the phase shifts increases in a nearly linear way with light intensity. At around 100 lux, saturation occurs and further increments in intensity do not result in a further increase in phase shift. The working range of about 2 log units is very small compared to the range of light intensities that occur in the environment in the course of a day. For example, on a sunny day, intensity levels are about 10^5 lux. If we transform the environmental variations in light intensity using the intensity dependence of the circadian system, the daily cycle of light in the world becomes a rectangular waveform with transitions at dawn and dusk, allowing the system to discriminate between day and night effectively. In view of the function of light in entraining the system to the day-night cycle, this light responsiveness of the pacemaker makes sense.

The duration of light pulses is also an important determinant of light-induced phase shifts (Meijer et al., 1992; Nelson and Takahashi, 1991). In hamsters, durations ranging from milliseconds to hours can reset circadian rhythms, but the optimal duration is about 5 minutes (Nelson and Takahashi, 1991). Short pulses on the order of seconds are not effective stimuli and require very high intensities of light, whereas long pulses on the order of hours saturate the system and so are also less efficient on a quantum basis. Indeed, the intensity-response functions for durations between seconds and hours can all be explained by integration of the total quanta during the pulse. Under these conditions, reciprocity between intensity and duration holds over the range from 1 to 45 minutes, suggesting that the circadian photic entrainment system acts as a *photon counter*.

Wavelength sensitivity is determined largely by the retinal pigments that mediate photic entrainment (to be discussed later in this chapter). The circadian system shows sensitivity to green, blue, and red light (Provencio and Foster, 1995; Takahashi et al., 1984; Yoshimura and Ebihara, 1996). Sensitivity is greatest for blue/green light, with a maximum sensitivity of about 480–500 nm. Phase-shifting responses have also been reported to be induced by pulses of ultraviolet

radiation (Amir and Robinson, 1995; von Schantz et al., 1997).

COMPLEXITY IN LIGHT RESPONSE Several complexities exist in an animal's behavioral responses to light. A phase shift is often not completed on the first circadian cycle after a light pulse but can exhibit transients. Especially for phase advances, several transient cycles occur in which the phase shift gradually grows after a single stimulating light pulse (Fig. 38.1). A two-pulse paradigm has been used to investigate whether the transient cycles reflect the pacemaker's position or whether, alternatively, the pacemaker is fully shifted on the first day after the pulse. In the latter case, transients would be a reflection of secondary mechanisms, that resynchronize to the SCN only slowly (Best et al., 1999; Watanabe et al., 2001). The data indicate that the pacemaker is fully shifted on day 1, at least the light-sensitive part of the pacemaker, while interaction with secondary downstream oscillators either inside or outside the SCN determine the delayed response of the behavioral activity pattern.

The immediate phase-shifting responses of activity onset and activity offset are different. While the activity onset shows transient cycles following a phase-advancing light pulse, the activity offset shows phase shifts that are complete on the first circadian cycle. In other words, the immediate shift in activity offset is larger than the shift in activity onset (Elliot and Tamarkin, 1994; Honma et al., 1985; Meijer and De Vries, 1995). In the course of several cycles, the shift in activity onset grows and the shifts in onset and offset become similar. For phase delays, the shifts in activity onset tend to exceed the shifts in activity offset, and transients are visible in the offset only. Several lines of research indicate that the pacemaker of the SCN consists of different subsets of oscillators (Jagota et al., 2000; Pittendrigh and Daan, 1976). Differences in response properties of these oscillators to light could cause differential phase shifts in onset and offset.

Repeated or prolonged light exposure leads to saturation of the phase shift. The pacemaker shows a reduction in light response in terms of its phase shifting capacity that persists for at least 1 hour after a subsaturating light pulse (Nelson and Takahashi, 1999). Two hours after a light pulse, the pacemaker's responsiveness seems to recover (Best et al., 1999). The decreased responsiveness to light does not correspond with the pacemaker's ability to track day length and suggests that day length is coded for in a different way.

Light pulses cause period changes in addition to phase shifts (DeCoursey, 1989; Hut et al., 1999). The light-induced changes in period depend on the circadian phase of pulse application. The changes in period occur such that they may contribute to photic entrainment (i.e., period lengthening occurs after light pulses during early night, and period shortening occurs following pulses during the late night).

Light is the most important but not the only phase-resetting stimulus since behavioral activity of the animal can also cause phase shifts (Maywood, 1999; Mrosovsky et al., 1989; Reebbs and Mrosovsky, 1989). Behavioral activity of the animal causes phase shifts when the activity is triggered by, for instance, cage cleaning or by presenting a dark pulse against an otherwise illuminated background. Forced activity of the animal is less effective in producing a phase shift. Behavioral activity has phase-shifting effects when it occurs during the day but not when it occurs during the night. Nevertheless, it has the capacity at night to inhibit light-induced phase shifts. Light-induced phase advances but not delays are strongly attenuated and in some cases completely blocked by simultaneous running wheel activity of the animal (Mistlberger and Antle, 1998; Ralph and Mrosovsky, 1992). The effect of behavioral activity on the light-induced phase shift is correlated with the amount of running wheel activity of the animal. The data indicate that physical activity affects the circadian system and its responsiveness to light.

The intensity-response curves for phase shifting and melatonin suppression are different. Melatonin production in the pineal gland is high during the night and low during the day, and still cycles when animals are kept in constant darkness (Illnerova, 1991; Illnerova and Sumova, 1997). The nighttime elevation of melatonin can be suppressed by light. The SCN mediates these light effects on melatonin production. Light suppression of melatonin appears substantially more sensitive to irradiance compared to phase shifting (Nelson and Takahashi, 1991). The difference is 1.4 log units when half-saturation values are compared. As light information reaches the pineal gland via the SCN, the increased sensitivity cannot readily be explained and indicates differences in the organization of input pathways.

Neuronal input pathways

Despite the well-established role for extraretinal photoreception in many vertebrate species, mammals have lost the ability to perceive light extraretinally and photoentrainment is mediated exclusively via the retina (Groos, 1982; Meijer et al., 1999; Yamazaki et al., 1999). Action spectra have indicated a maximal sensitivity of the circadian system in its phase-shifting response to wavelengths of about 500 nm (Boulos, 1995; Provencio and Foster, 1995; Takahashi et al., 1984) and a secondary peak in the near-ultraviolet range of the spectrum (Amir and Robinson, 1995; von Schantz et al., 1997). The maximal sensitivity at about 500 nm may suggest a role for opsin-based photopigments. However, mice that are deficient in both rods and cones show normal phase-shifting responses to 509 nm monochromatic light pulses (Freedman et al., 1999) and normal suppression of pineal melatonin in response to light (Lucas et al., 1999), indicating that classical photoreceptors do not fully account for light

effects on the circadian pacemaker. Recent evidence suggests that a small subset of retinal ganglion cells (about 1% of the total population) contains the photopigment melanopsin (Hattar et al., 2002). Melanopsin is present in the axons, cell bodies, and proximal dendrites of the ganglion cells. Melanopsin-containing ganglion cells innervate the SCN bilaterally and also project to the intergeniculate leaflet (IGL), the pretectum, and, to a lesser extent, the ventral lateral geniculate nucleus. It is suggested, therefore, that melanopsin plays a role in transducing light information to non-image-forming visual brain areas (Hattar et al., 2002).

Melanopsin-containing ganglion cells show direct responsiveness to light (Berson et al., 2002). The ganglion cells also depolarize in response to light, when synaptic input from rods and cones is blocked or when they are surgically detached from the retina. This demonstrates that these ganglion cells are intrinsically photosensitive. The spectral sensitivity function of these ganglion cells shows a peak at 484 nm. Constant illumination of the cells causes a tonic depolarization and an increase in discharge rate, and the change in membrane potential appears to be a function of light intensity. Latencies in response are long, on the order of several seconds. Physiological recordings of retrogradely labeled SCN-projecting ganglion cells have shown similar characteristics. These ganglion cells showed sustained responses to light and receptive field sizes of 2 to 5 degrees (Pu, 2000). It has been suggested that converging W (or type III) cells account for the response characteristics of SCN neurons (Cooper et al., 1993; Groos and Mason, 1980; Hattar et al., 2002). The axons of these cells are fine and unmyelinated and make up the retinohypothalamic tract (RHT), which projects directly via the optic chiasm to the SCN (Moore, 1973). The terminal field is in the ventral and often also in the lateral part of the SCN in most species of rodents (Fig. 38.2). The RHT is probably sufficient for photic entrainment, and we will focus on this pathway in this chapter. Three other photic pathways reach the SCN: via the IGL of the lateral geniculate nucleus, via the raphe, and via the pretectum (see Meijer, 2001, for review). The raphe projects with serotonergic fibers to the SCN, while the IGL projects with GABA, Neuropeptide (NPY), and enkephalins containing neurons (see Harrington, 1997, and Morin, 1994, for reviews). The dominant effect of the raphe and IGL on the SCN is inhibitory.

The RHT contains three different neurotransmitters: (1) excitatory amino acids, (2) pituitary adenylate cyclase activating peptide (PACAP), and (3) substance P. Increased glutamate immunoreactivity has been demonstrated inside the SCN (Castell et al., 1993; De Vries et al., 1993; see Ebling, 1996, for review). In situ hybridization and immunocytochemical studies have indicated the presence of ionotropic and metabotropic (mGluR1) receptor subunits. Ionotropic receptors are usually divided into *N*-methyl-D-

FIGURE 38.2. Retinal innervation of the SCN in the rat as revealed by unilateral injection of cholera toxin-horseradish peroxidase. 3V, third ventricle; OC, optic chiasm. (Photograph provided by Robert Y. Moore, M.D., University of Pittsburgh.)

aspartate (NMDA) and non-NMDA receptors, and both are present in the SCN. Subunits of the NMDA receptor are NMDAR1 and NMDAR2C, and non-NMDA subunits are GluR1, GluR2, and GluR4 (Ebling, 1996). Intraperitoneal administration of a noncompetitive antagonist of the NMDA receptor (MK-801) blocks the phase-shifting effects of light pulses (Colwell et al., 1991) and of electrical stimulation of the RHT (De Vries et al., 1994), whereas application of glutamate or NMDA mimics the effects of light on the pacemaker's phase in vitro (Ding et al., 1994; Shirakawa and Moore, 1994a) as well as in vivo (Mintz et al., 1999; Vindlacheruvu et al., 1992). A role for the NMDA receptor in mediating phase shifts is therefore relatively well established. Several non-NMDA receptor antagonists also block phase shifting by light (see Ebling, 1996).

PACAP is a member of the vasoactive intestinal polypeptide (VIP)/glucagon/secretin/growth-hormone releasing hormone superfamily, and it is present in the terminals of the RHT (Hannibal et al., 1997). PACAP-containing ganglion cells contain the photopigment melanopsin (Hannibal et al., 2001a). PACAP induces phase shifts during the day when it is applied in high dosages (Hannibal et al., 1997) but phase shifts during the night when applied at lower dosages (Harrington, 1999). The latter effect of PACAP is mediated by potentiation of NMDA currents. Both light and PACAP induce phosphorylation of the transcription factor cyclic adenosine monophosphate (cAMP) response element binding protein (CREB) in the SCN (von Gall et al., 1998).

Substance P is contained in retinal ganglion cells projecting to the SCN, and after enucleation, the density of substance P-containing fibers in the SCN is markedly reduced

(Mikkelsen and Larsen, 1993). The acute effect of substance P on SCN neurons is excitatory (see Challet et al., 1998, for review). Substance P potentiates glutamatergic activation (Piggins and Rusak, 1997; Shirakawa and Moore, 1994b), and its phase-shifting effect in vitro is similar to that of glutamate or NMDA (Hamada et al., 1999; Kim et al., 2001). Substance P-induced phase shifts can be blocked not only by the substance P receptor antagonists spantide or L-703,606 but also by NMDA and non-NMDA receptor antagonists (Hamada et al., 1999; Kim et al., 2001). Conversely, however, the substance P antagonist L-703,606 does not block glutamate-induced phase delays, suggesting that glutamate is downstream from substance P (Kim et al., 2001).

Electrophysiological response properties of SCN neurons

SCN neurons are among the smallest in the central nervous system and are difficult to record using intracellular methods without causing damage to the cells. Indeed, it has been shown that membrane potential recordings of SCN neurons interfere with ongoing rhythmicity in membrane potential and membrane resistance (Kim and Dudek, 1993; Schaap et al., 1999). Only a few studies have investigated the membrane properties of retinorecipient SCN neurons with intracellular recording techniques. These studies showed that retinorecipient SCN neurons are characterized by a high input resistance and a membrane potential of about 60 mV (Jiang et al., 1997; Kim and Dudek, 1993). A circadian variation in conductance was demonstrated in SCN neurons with higher conductances observed during subjective day/dawn and lower conductances during subjective dusk, while the membrane potential appeared high during the day and low during the night (de Jeu et al., 1998; Jiang et al., 1997; Schaap et al., 1999). Optic nerve stimulation induced EPSPs in most retinorecipient neurons (Kim and Dudek, 1993; Pennartz et al., 2001; Jiang et al., 1997).

The electrical properties and light responsiveness of SCN neurons have been investigated more extensively by extracellular recordings of neuronal discharge rates. A subpopulation of SCN neurons responds to light stimulation (or stimulation of the RHT) with a change in discharge rate. These light-responsive SCN neurons are located in the terminal field of the RHT (Meijer et al., 1986), indicating that they may be directly driven by it. In the nocturnal rat and hamster, about one-third of the SCN neurons respond to light (Cui and Dyball, 1996; Groos and Mason, 1980; Meijer et al., 1986). In one study, SCN neurons were tested not only under scotopic (dark-adapted) but also under photopic (light-adapted) conditions (Aggelopoulos and Meissl, 2000). Under scotopic but not photopic conditions, light-responsive SCN neurons showed preferred firing intervals of about 18–39 msec. Possibly the higher discharge rate under light

FIGURE 38.3. Light-activated and light-suppressed responses of SCN neurons to different light intensities based on Meijer et al. (1998). *A–C*, Peristimulus time histograms show light-activated responses to a 6 minute light pulse of 0.15, 2, and 140 lux, respectively, against a dark-adapted background. The timing of the light pulse is indicated above the records. The discharge rate of the neuronal population was counted every 10 seconds. The neurons

respond with an initial transient before they reach a sustained steady-state discharge level. The sustained discharge level depends on light intensity. A transient off-response is visible at the offset of the light pulse. *D–F*, Peristimulus time histograms for light-suppressed responses. Suppressed responses lack the characteristic transient response at the onset and offset of a light pulse. The steady-state discharge response is a function of light intensity.

adaptation had unmasked these preferred intervals. The receptive fields of SCN neurons are large, often exceeding 20 degrees in diameter, and are characterized by an absence of antagonistic center-surround organization (Groos and Mason, 1980). This means that SCN neurons respond with either suppression or activation to light spots that are presented throughout large parts of the visual field. Their large receptive fields show that light-responsive SCN neurons integrate light from large areas in the visual field (Groos and Mason, 1980).

Most light-responsive SCN neurons of the rat and hamster show excitation in response to light (light-activated), while a smaller fraction is suppressed by it (light-suppressed; Groos and Mason, 1980). Studies in diurnal 13-lined ground

squirrels (*Spermophilus tridecemlineatus*) and diurnal degus (*Octodon degus*) have demonstrated that in these species, the relative contribution of activated and suppressed neurons is reversed and that the majority of light-responsive SCN neurons are suppressed by light, while the minority are light-activated (Jiao et al., 1999; Meijer et al., 1989). Response latencies are long, ranging from 25 msec to several seconds (Meijer et al., 1986; Sawaki, 1979). Most responses develop fully between 200 msec and 20 seconds after the onset of a light pulse. Very brief light flashes of less than 1 second are not very effective in stimulating these neurons (Meijer et al., 1986; Sawaki, 1979). The time course of the responsiveness is extraordinarily slow compared to responses in visually responsive brain areas and is very similar to the latencies that

have been observed in melanopsin-containing ganglion cells (Berson et al., 2002). The difference in effectiveness of long versus short stimuli reflects a remarkable property of photically responsive SCN cells.

Several features of the response properties of SCN neurons correlate well with the effects of light on behavioral circadian activity rhythms discussed earlier in this chapter. Responses of SCN neurons are typically sustained, despite a short transient “overshoot” at the onset of a light response and a short suppression at light-off. Sustained responses are also found in the pretectum (Trejo and Cicèrone, 1984), the raphe nucleus (Mosko and Jacobs, 1974), and the IGL (Harrington, 1997). Of note, these are the three retinorecipient brain areas that also project to the SCN. The sustained light responsiveness of the SCN, together with its large receptive field properties, allows the SCN to monitor ambient light levels reliably in the natural environment. The light response is also transmitted to the pineal gland to control pineal melatonin synthesis (Illnerova, 1991). During the night pineal melatonin levels are high, whereas during the day they are low. Nighttime melatonin levels can be suppressed by light presentation, and suppression of melatonin corresponds with the duration of light presentation.

The sustained response level of SCN neurons is determined by light intensity (Groos and Mason, 1980; Meijer et al., 1986, 1992, 1998). The steady-state discharge rate that is obtained during a light pulse increases with light intensity for light-activated neurons and decreases for light-suppressed neurons (Fig. 38.3). The intensity response curve for SCN neurons is sigmoid, with a small working range (Meijer et al., 1986, 1998). These response curves are nearly identical with the intensity-response curve for phase shifting (Meijer et al., 1992). The intensity response curve for melatonin suppression is also sigmoid (Nelson and Takahashi, 1991) but shows increased sensitivity. Recordings in the diurnal 13-lined ground squirrels and degus indicated that much higher light intensities were required to stimulate their SCN neurons (Jiao et al., 1999; Meijer et al., 1989). In both studies, light intensities of about 1000 lux were required. The high threshold for light responses corresponds roughly with the high thresholds for melatonin suppression in 13-lined ground squirrels (Reiter, 1985). In humans, light intensities of 180 lux are required to shift the circadian rhythm in temperature (Boivin et al., 1996). Although these intensities are not as high as was expected, they are substantially higher than the threshold intensity in nocturnal animals.

When recording light responses under scotopic conditions (dark-adapted), maximal sensitivity was observed to 505 nm wavelengths (Aggelopoulos and Meissl, 2000). Under photopic conditions, peak sensitivity was observed at 510 nm, with a secondary sensitivity peak in the near-ultraviolet region of the spectrum.

Behavioral activity of the animal attenuates the phase-shifting effects of light. To investigate whether photic and behavioral stimuli interact at the level of the neuronal membrane, electrical recordings were performed in freely moving animals. Behavioral activity by itself appeared to result in suppressions of neuronal activity in the SCN of the rat and hamster (Meijer et al., 1997; Yamazaki et al., 1998). These suppressions are long-lasting, and recovery to baseline levels takes about 20 minutes. To investigate the effect of behavioral activity on light responsiveness in the SCN, light pulses were presented shortly after the animal had been active (Schaap and Meijer, 2001). The data indicate that light and behavioral activity have opposing effects within the same population of neurons (Fig. 38.4). Thus, the discharge level that is reached during a light pulse is strongly reduced by concomitant behavioral activity of the animal and can explain the decreased phase-shifting response of the animals to light when it is active at around the time of the light pulse.

Several studies have shown that the light responsiveness of SCN neurons changes in the course of the circadian cycle (Cui and Dyball, 1996; Meijer et al., 1998). Cui and Dyball (1996) have shown in anesthetized hamsters that the proportion of neurons that responds to optic nerve stimulation during the night exceeds the proportion of responsive neurons during the day (40% vs. 16%, respectively). The increased responsiveness occurred at around the onset of the dark period. With implanted electrodes in freely moving animals, it was shown that the light response during the night is larger than the response during the day (Meijer et al., 1998). In these experiments, the animals were kept in constant darkness throughout the experiment, except for the light stimulations. The baseline discharge rate of SCN neurons in constant darkness is rhythmic and shows high electrical activity during the projected daytime (called *subjective day*) and low electrical activity during the projected night (*subjective night*). The rhythm in light responsiveness is superimposed on the rhythm in baseline activity. During the subjective day, when baseline discharge is high, light presentations elicit only small responses. During the subjective night, when baseline discharge is low, the light responses are large and exceed the response levels that are obtained during daytime (Fig. 38.5). The variation in light response is apparent as a gradual transition in responsiveness and is highest during the middle of the subjective day. These data are also consistent with enhanced NMDA receptor activity during the night (Pennartz et al., 2001). For light-suppressed responses, a similar rhythm is present, and suppressions are minimal during the middle of the subjective day and are maximal during midnight. Long-term single-unit recordings revealed that the change in light sensitivity is also present at the single-neuron level. This indicates that the rhythm is not solely determined by the number of responsive neurons that

FIGURE 38.4. Behavioral-induced suppression of neuronal activity in the SCN interacts with the effects of light. The discharge rate of SCN neurons is counted per 10 seconds. Above the records, the presentation of a light pulse is indicated. At the bottom of the figures, behavioral activity is indicated. *Left*: Behavioral activity induces a long-lasting suppression of neuronal activity in the SCN. During behavioral activity, reliable recordings of the discharge rate were not possible, which accounts for the missing data in the plot.

Center: A continuation of the same recording shows that the same neuronal population is activated by a light pulse. *Right*: Presentation of a light pulse during the aftereffects of behavioral activity results in a steady-state discharge level that is lower than the discharge rate obtained by light without preceding activity. The data indicate that behavioral activity can reduce the effects of light on SCN neurons. (Based on Schaap and Meijer, 2001.)

contribute to the signal, but this feature is determined at the single-neuron level (Schaap and Meijer, 2001).

The difference in light responsiveness between day and night is especially clear when subsaturating light intensities are applied. When light intensity is increased, response levels are higher. Application of different light intensities at a fixed phase of the cycle shows that at midnight, responses increase rapidly as a function of light intensity, whereas during midday, responses grow slowly and the system saturates at a much higher light intensity. This illustrates that the light sensitivity of the circadian system is higher during the night than it is during daytime. Hence, the light response of an SCN neuron is determined by the combination of light intensity and circadian phase at which light is presented (Fig. 38.6).

Intracellular signaling responses to light

The circadian pacemaker responds to light with a phase delay during the beginning of the night and a phase advance during the end of the night. The direction of the neuronal response to light is either excited or suppressed and does not change in the course of the circadian cycle (Inouye, 1984; Meijer et al., 1998). Thus, the sign of the neuronal light response does not correspond with the bidirectional phase-shifting response of the pacemaker. The absence of phase shifts during the day is also not reflected by the electrophysiological response of the SCN. When light intensity is raised sufficiently, neuronal responses are observed but behavioral phase-shifting effects remain absent.

FIGURE 38.5. Light response of SCN neurons as a function of circadian time based on Meijer et al. (1998). The timing of a 6 minute light pulse is indicated above the records. The discharge rate of SCN neurons is given per 10 seconds. Light pulse presentation during midsubjective day (CT 7) to a dark-adapted animal does not induce an increase in electrical activity. At the offset of the pulse,

a transient suppression is visible. During early night (CT 12), light induces a clear, sustained increase in neuronal discharge rate. Maximal light responses are obtained during midsubjective night (CT 19). Toward the end of the night, responses decrease and only small responses are obtained during early subjective day (CT 2).

FIGURE 38.6. Two-dimensionally smoothed plot of the light response of SCN neurons as a function of both light intensity and circadian time. Light response is calculated as the difference between the steady-state discharge rate during a light pulse minus the baseline discharge rate immediately preceding the light pulse. The data indicate that for low light intensities a light response is absent throughout the circadian cycle. For increasing light intensi-

ties, light responses exist during the subjective night but not during the subjective day. A further increase in light intensity triggers light responses during both the night and the day. The magnitude of the response, however, is larger during the night than during the day. (J. H. Meijer, P. H. C. Eilers, and J. Schaap, unpublished results.) (See color plate 23.)

Similar data have been obtained in the marine snail *Bulla gouldiana* (for a review, see Block et al., 1993). Pacemaker cells of the snail respond to light throughout the circadian cycle, while their phase response curve is qualitatively identical to that of rodents. For the snail, it has been demonstrated that the neuronal response to light results in an increase of intracellular calcium during the night but not so much during the day, and it was suggested that the intracellular calcium response is of major importance for phase shifting (Block et al., 1993). Recordings in mammalian SCN neurons have now shown that NMDA induces calcium transients that are large during the night and small during the day (Colwell, 2001). Thus, the rhythm in calcium response follows the rhythm in light-induced changes in discharge rate. This is not surprising, as calcium influx is triggered by depolarization of membrane potential. The intracellular calcium response is one of the best-studied intracellular responses to light, and stimulates by itself or in concert with other second messengers a complex cascade of intracellular events. A few elements of the intracellular signal transduction pathway have been identified that lead to transcriptional activation (Gillette, 1997). Light-induced release of glutamate and activation of both NMDA and non-NMDA receptors leads to an increase in intracellular calcium (Tominaga et al., 1994). Intracellular calcium can increase both by calcium influx across the membrane and by calcium release from intracellular stores. Cellular organelles such as the endoplasmic reticulum function in the storage of calcium. Stimulation of calcium channels on intracellular organelles results in phase

delays during early night but not in phase advances during late night. Blocking of the ryanodine receptor by dantrolene and ruthenium red blocks light- and glutamate-induced delays during early night but not the glutamate-induced advances during late night (Ding et al., 1998). These data indicate that the ryanodine receptors play a role that is restricted to the early night.

Intracellular increase in calcium level leads to formation of nitric oxide (NO) (Amir, 1992; Ding et al., 1994) via activation of nitric oxide synthetase (NOS). NO produces phase advances and delays, depending on the circadian time of NO application. The effects of NO are similar to those of light, and blocking of NO transmission disrupts light transmission to the SCN (Amir, 1992; Watanabe et al., 1994).

A third intracellular component of importance is cyclic guanosine monophosphate (cGMP) (Prosser et al., 1989). The SCN is reset by cGMP during the night but not during the day. The effect of cGMP is a phase advance, with a maximum phase shift at midsubjective night. The phase response curve for cGMP shows no delay zone; thus, it does not resemble the phase response curve for light. However, the sensitive part of the phase response curve is similar to the period in which the pacemaker responds to light with a phase shift (Prosser et al., 1989).

Evidence exists that NO can directly activate cGMP (see Ding et al., 1994). However, NO produces phase advances and phase delays, depending on circadian time, whereas cGMP induces advances only. It has been proposed (e.g.,

Ding et al., 1998) that intracellular signaling elements diverge. Late at night, light causes a phase advance by means of a cGMP-dependent pathway, whereas early at night, intracellular release of calcium is involved.

Light has been shown to induce phosphorylation of the CREB in the hamster SCN (Ginty et al., 1993; Kornhauser et al., 1996). CREB becomes phosphorylated on the transcriptional regulatory site, Ser133 (Ginty et al., 1993). Phosphorylation occurs within several minutes after light exposure and only at night (Ginty et al., 1993; Kornhauser et al., 1996). Increased phosphorylation of CREB can be blocked by the NMDA receptor antagonist α -amino-5-phosphonovaleric acid (APV), indicating that it results from activation of the NMDA receptor (Ginty et al., 1993). Depolarization of membrane potential by itself and in the presence of APV is also able to induce CREB, indicating that NMDA receptor activation can be bypassed if membrane depolarization occurs (Ginty et al., 1993).

Intracellular calcium also activates the mitogen activated protein kinase (MAPK) signaling pathway in the SCN. Once phosphorylated, MAPK is translocated from the cytosol into the nucleus, where it can regulate transcriptional activity (Obrietan et al., 1998). MAPK shows an endogenous circadian rhythmicity (Obrietan et al., 1998). Light induces activation of MAPK during the night but not during the day and MAPK activation depends on the duration of light exposure, with 15 minute light pulses being more effective than 5 minute pulses (Obrietan et al., 1998). Glutamate application or membrane depolarization also triggers activation of MAPK. Blocking the MAPK pathway results in a 50% reduction of glutamate-induced CREB phosphoryla-

tion in the SCN. Taken together, these results show that MAPK is an important signaling component for CREB phosphorylation in the SCN (Obrietan et al., 1998).

As discussed earlier in this chapter, low concentrations of PACAP cause phase shifts that resemble the phase-response curve for light pulses. Several studies have indicated that cAMP protein kinase A (PKA) and calcium-dependent pathways are involved in PACAP-induced phase shifts during the night (Kopp et al., 1999; Tischkau et al., 2000; von Gall et al., 1998). Moreover, PACAP can stimulate CREB (Gillette, 1997). There is substantial evidence, therefore, that PACAP is involved in photic entrainment by stimulating intracellular components that also respond to light or NMDA.

Two circadian clock genes, *mPer1* and *mPer2*, are thought to be involved in light-induced resetting of the pacemaker (Albrecht et al., 1997; Field et al., 2000; Hastings et al., 1999; Shearman et al., 1997; Takumi et al., 1998a; Yan et al., 1999; Zylka et al., 1998). These genes are homologs of the *Drosophila* circadian clock gene *period* (Sun et al., 1997; Tei et al., 1997). The expression of *mPer1* and *mPer2* is regulated not only by light but also by the CREB pathway (Gillette, 1997), by NMDA (Moriya et al., 2000), and by PACAP (Nielsen et al., 2001). Increases in *mPer1* occur within 10 minutes after light exposure, which is very rapid (Shigeyoshi et al., 1997) and show peaks in expression about 60 minutes after light exposure (Fig. 38.7) (Albrecht et al., 1997; Shearman et al., 1997; Takumi et al., 1998a). Expression of *mPer1* is initially present in the retinorecipient area of the SCN and spreads through the SCN in the course of 60–120 minutes (Albrecht et al., 1997; Shigeyoshi et al., 1997). In transgenic

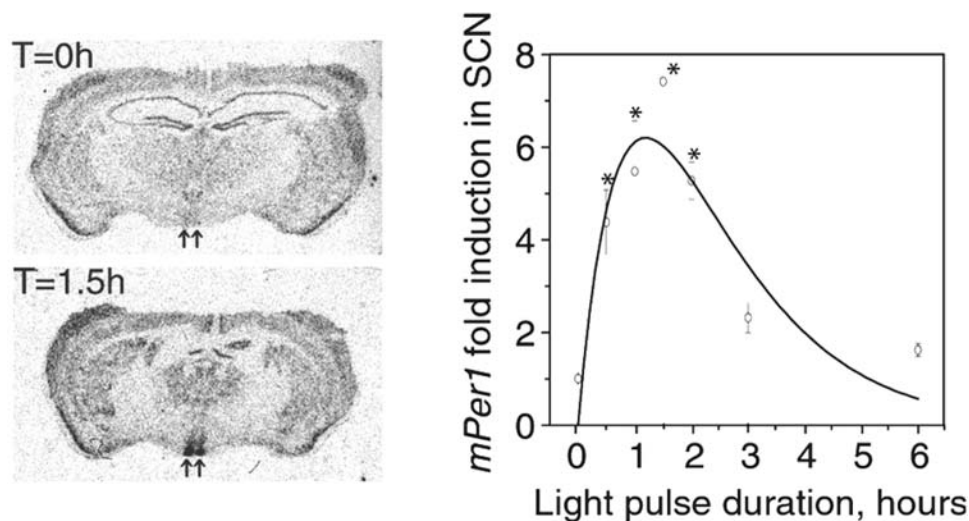

FIGURE 38.7. Light-induced *mPer1* mRNA expression in the SCN. Mice were maintained in constant darkness for at least 7 days prior to the experiment, and the endogenous circadian rhythm of each animal was measured. At CT 17, mice were transferred to a light

box. The graph to the right shows a time course for *mPer1* induction over 6 hours. The y-axis indicates the fold induction from baseline expression at CT 17. (From Wilsbacher et al., 2002.)

rats or mice with a reporter gene under the control of the *mPer1* promoter, light results in increased *mPer1* expression and in rapid shifts of the *mPer1* expression cycle (Kuhlman et al., 2000; Wilsbacher et al., 2002; Yamazaki et al., 2000). In cultured SCN slices with an *mPer1:luc* reporter gene, the cycle in *mPer1* is quickly reset by NMDA (Asai et al., 2001). As with light, *mPer1* induction by NMDA occurs only during the night.

Similar results have been obtained for *mPer2* (Albrecht et al., 1997; Shearman et al., 1997; Takumi et al., 1998a; Zylka et al., 1998). *mPer2* is induced about 90 minutes after light exposure, although different studies show somewhat different results in the time required to show maximal expression. Light-induced *mPer2* expression is dependent on circadian time, and maximal responsiveness exists at the end of the subjective day and during the first part of the night. In contrast to *mPer1* and *mPer2*, *mPer3* appears unresponsive to light (Albrecht et al., 1997; Shearman et al., 1997; Takumi et al., 1998b; Zylka et al., 1998).

Evidence for a role of *mPer1* in light-induced delays is provided by Akiyama et al. (1999), who showed that intracerebroventricular injections of antisense oligonucleotide repress light-induced phase shifts in running wheel activity and that direct application in vitro attenuates glutamate-induced delays of neuronal firing rhythms. A complete block of light-induced phase delays is obtained when both *mPer1* and *mPer2* antisense oligonucleotides are injected, indicating that *mPer1* and *mPer2* have additive effects on photic entrainment (Wakamatsu et al., 2001). In PACAP type 1 receptor-deficient mice, it has been shown that light results in phase delays instead of phase advances late at night and suggests a role for the PACAP type 1 receptor in gating of light information to the clock (Hannibal et al., 2001b). The relative contribution of *mPer1* and PACAP type 1 receptors for phase shifting remains to be shown. To further investigate the role of *mPer1* and *mPer2* in light-induced phase shifting, the responsiveness to light was tested in mice carrying a mutation in the *mPer1* or *mPer2* gene (Albrecht et al., 2001; Zheng et al., 1999). *mPer1* mutant mice appeared unable to advance in response to light stimulation late at night, while *mPer2* mutants cannot delay in response to light presentation early at night (Albrecht et al., 2001; however, see Cermakian et al., 2001). The results indicate that mammalian *Per* genes are not only light-responsive components of the circadian oscillators, but also are involved in resetting of the circadian clock.

Cryptochromes are a possible candidate for the short-wavelength responses, but thus far the mammalian cryptochromes have not been shown to be functional photopigments (Hall, 2000; Sancar, 2000). Rather, in mammals, *mCry1* and *mCry2* are essential components of the molecular clockwork (van der Horst et al., 1999; Vitaterna et al., 1999), where they play a role as negative elements in the autoregulatory feedback loop (King and Takahashi,

2000; Young and Kay, 2001). Indeed, *mCry1/mCry2* double knockouts appear to have intact *mPer1* and *mPer2* light responses in the SCN (Okamura et al., 1999).

Molecular biological lines of research have quickly provided essential contributions to our present insights concerning light-induced phase shifting of the circadian clock. It is expected that in the near future, our knowledge of this issue will be greatly enhanced. As a logical next step to the present lines of research, it will be important to demonstrate that the several clock genes are not only induced by light, but also that their expression is critical for the occurrence of a phase shift. So far, this has been performed for *mPer* but not for the other clock genes. Moreover, it is expected that more genes will become known that play an essential role in either the generation or the shaping of circadian rhythms, and it remains to be determined whether these genes also contribute to phase resetting properties.

FIGURE 38.8. Schematic overview of light input pathways to the circadian clock. Note that PACAP is thought to support light entrainment in low but not in high concentrations. See text for further details.

At a conceptual level, a major question to be answered is how the phase response curve, with its bidirectional response to light, can be explained. In *Drosophila* and *Neurospora*, there is an indication that light-regulated clock components such as *timeless* and *frq* show a unidirectional response to light throughout the circadian cycle. This response is associated with phase delays and advances solely on the basis of the time by which the response occurs. In mammals, there is substantial evidence for divergence in the intracellular transduction cascade resulting in specific cues that mediate advances and delays. Whether divergence in intracellular signals accounts for phase advances and delays remains to be proven. Alternatively, divergence in input pathways supports the bidirectional phase responsiveness of the mammalian pacemaker but is not required. It will be a major challenge to identify light-responsive elements in the intracellular biochemical and genetic machinery of the cell to construct a general model accounting for the attributes of the circadian pacemaker's light responsiveness.

Summary

It has become evident that the light responsiveness of the SCN differs in many ways from the light responsiveness in brain areas involved in vision (Fig. 38.8). When the light response of the SCN is placed in perspective, it can be concluded that specialized and distinguishable photoreceptors mediate entrainment. A set of novel ganglion cells have now been identified that show direct responsiveness to light and contain the photopigment melanopsin. Via a separate unmyelinated neuronal pathway, light information is transmitted to the SCN to stimulate a subpopulation of SCN neurons. The response of these neurons to prolonged light presentation is sustained, in contrast with that of most image-forming brain areas where responses are mostly transient. SCN neurons code for luminance in a near-linear way for light intensities occurring during dawn and dusk. A time window exists for processing the neuronal response, and while the clock is rendered blind during the day, it responds with bidirectional phase shifts during the night in order to become entrained.

39 Learning from the Pupil: Studies of Basic Mechanisms and Clinical Applications

JOHN L. BARBUR

THE FUNCTION OF the iris and its response to light in humans have been of great interest to both physiologists and neurologists, who wanted to establish the neural pathways involved in the control of the pupil response, as well as to physicists and biological engineers, who have often described the pupil light reflex (PLR) as a beautiful example of a closed-loop servomechanism. The function of this mechanism was primarily to adjust retinal illuminance with changes in ambient light, although this has often been recognized as a useful simplification. In addition, many clinical, neuro-ophthalmological, and pharmacological studies have attempted to establish the usefulness of the pupil in diagnosing lesions of the visual pathways and the normal functioning of the retina (Loewenfeld, 1999). The often circuitous involvement of a large number of neural pathways in controlling the movements of the iris makes the pupil a rich source of information, but it also ensures that its secrets are hard to unravel. The presence of numerous uncorrelated signals in the pupil makes difficult the extraction of other small signals that can reflect important retinal and cortical processing of visual information. Recent advances in instrumentation and data processing have generated renewed interest in pupil research by overcoming some of the difficulties of extracting small, stimulus-specific signals from much larger “noisy” fluctuations of the pupil that have often been wrongly regarded as random noise.

There is little doubt that the most important and best-studied afferent visual signal that drives the pupil is generated by changing the ambient illumination. The afferent pathways involved in the control of the PLR in humans have been associated entirely with subcortical projections, and this is consistent with some clinical observations which suggest that the pupils continue to respond normally to sudden changes in room illumination, even when the patients are cortically blind (Brindley et al., 1969). The PLR response has therefore been associated with a single subcortical neural pathway. Other studies have examined in greater detail the effect of visual cortical lesions on the pupil response to light, and the results do not always support the classical belief in a single light reflex pathway. We know that the ambient light level determines largely the steady-state size of the pupil and that rapid increments in light flux on

the retina cause a brisk transient constriction of the pupil that is often described as the *dynamic PLR response*. The tacit assumption that a single neural pathway mediates both of these functions has been questioned in previous studies, largely because neural mechanisms with different spatial and temporal properties would ideally be needed to serve these two functions. It is of interest to establish whether the PLR response involves more than one component and to explain why, under some conditions, this response is either absent or significantly reduced in patients with damage to the geniculostriate projection or the visual cortex (Alexandridis et al., 1979; Barbur et al., 1988; Cibis et al., 1975; Harms, 1951; Kardon, 1992).

Pupil responses to other stimulus attributes such as the onset of luminance flicker (Troelstra, 1968), spatially structured patterns (Slooter and van Norren, 1980; Ukai, 1985), coherent motion (Barbur et al., 1991; Sahraie and Barbur, 1997), or colored stimuli (Young and Alpern, 1980; Young et al., 1993) have also been reported, but the mechanisms and neural pathways involved in mediating such responses remain largely unknown. The possible involvement of the PLR and the near-reflex pathways in any of these responses has not always been ruled out. It remains of great interest to establish the extent to which such responses involve the geniculostriate projection and require the processing of specific stimulus attributes in extrastriate visual cortical areas. Finally, if any of these stimulus-specific pupil responses are mediated through central inhibition of the pupillomotor system, as demonstrated in animal studies (Koss et al., 1984; Loewenfeld, 1958; Loewy et al., 1973; Szabadi and Bradshaw, 1996), it is of interest to know how and where these inhibitory signals are integrated into the efferent pupil pathways. This chapter reports the results of recent pupil studies that have addressed some of these questions. These studies involved measurements of the pupil's response to visual stimuli that favor the processing of specific stimulus attributes, both in normal subjects and in patients with selective loss of function as a result of damaged or abnormal visual pathways. The patients studied included dichromats who cannot discriminate certain colors as a result of deficiency in one class of cone receptor, patients with cerebral achromatopsia who cannot see color as a result of lesions to

the ventromedial extrastriate visual cortical areas, patients who are clinically blind in one hemifield as a result of unilateral damage to the primary visual cortex, and patients with selective damage to the pretectal region of the midbrain.

The anatomy of the iris and related disorders, pharmacological aspects of pupil function evaluation, and clinical examination techniques have been discussed in a number of excellent recent reviews (Kardon, 1998; Thompson and Miller, 1998; Wilhelm, 1994), and will not be covered in this chapter.

Pupil pathways

The iris's movement and hence its image, the pupil of the eye, is controlled by the action of two antagonistic muscles, the sphincter and the dilator. Activation of the sphincter of the iris causes the pupil to constrict (i.e., miosis). This constriction is largely under parasympathetic control, while the dilator muscle receives mostly sympathetic innervation and causes the pupil to dilate (i.e., mydriasis). As with any aperture in a lens system, the size of the iris determines the amount of light that is captured by the system and, in the case of the eye, the level of retinal illuminance. In addition, the pupil controls the aberrations and the depth of field of the eye. The parasympathetic pathway is understood better and involves the Edinger-Westphal (EW) nucleus, the ciliary ganglion, and the short ciliary nerves (Kardon, 1998). The firing rate of pupilloconstrictor neurons in the EW nucleus is high, even in the absence of external influences (Sillito and Zbrozyna, 1973). In this respect, the pupilloconstrictor neurons in the EW nucleus act as a signal generator whose output is modulated by a number of inputs, the major one being the afferent projection from the retina via the olivary pretectal nucleus (OPN) of the midbrain (Gamlin et al., 1997; Pierson and Carpenter, 1974). The strength of these modulating inputs can, in turn, be determined by a number of other factors that may involve the cortical processing of specific stimulus attributes.

Strong inhibitory inputs to the EW nucleus from other areas of the brain have also been reported (Smith et al., 1970). The inhibition of the parasympathetic system may involve at least two pathways, a noradrenergic pathway from the nucleus coeruleus to the EW complex (Breen et al., 1983; Koss et al., 1984; Loewy et al., 1973) and a second indirect pathway from A1/A5 nuclei in the brainstem via the hypothalamus (Koss and Wang, 1972; Loewenfeld, 1958; Szabadi and Bradshaw, 1996). Signal changes in these inhibitory pathways can be used to explain a number of other pupil-related observations such as the constriction of the pupil during sleep or anesthesia (Larson et al., 1996), the gradual decrease in pupil size with age (Loewenfeld, 1972), and the slow oscillations of the pupil observed during periods of sleepiness (Lowenstein et al., 1963; Wilhelm et al., 1999).

PLR response

THE STEADY-STATE COMPONENT The accepted clinical view of the pupil's response to light is that the ambient light level largely determines the steady-state size of the pupil and that rapid increments in light flux on the retina cause a brisk constriction of the pupil (Fig. 39.1). The pupil's response to changes in ambient illumination is best served by neural mechanisms that respond to overall light flux changes, cover a large dynamic range, and exhibit large spatial summation.

THE TRANSIENT COMPONENT The transient constriction of the pupil in response to flashes of light requires neurons with different properties, since the steady-state signal is largely discarded and the response reflects only novel changes in luminance contrast (LC), not the absolute light adaptation level. The ideal properties of such neurons include limited spatial summation, bandpass temporal response characteristics, and high contrast gain. A light stimulus presented to the eye is likely to trigger both components, but the relative contribution each component makes to the constriction of the pupil will depend on the size of the stimulus, its luminance contrast, onset temporal characteristics, and location in the visual field. The sustained component also makes a contribution to the transient constriction of the pupil since the neurons involved respond to a range of temporal frequencies in addition to steady light. In other words, these neurons exhibit low-pass temporal response characteristics. The relative contribution of the sustained component is likely to be small, given the range of ambient illumination to which the eye responds. When the stimulus is large and of high LC, the response of the pupil can be dominated entirely by the sustained component because of the limited spatial summation and early contrast response saturation of the transient component. The temporal properties of both transient and sustained neurons are largely determined by the level of light adaptation of the retina. This suggests that under conditions of steady light adaptation, the pupil onset response latency, defined as the time from the onset of the stimulus to the onset of pupil constriction, should not depend on its response amplitude. Visual inspection of the pupil response traces shown in Figure 39.1A would suggest otherwise, but this is largely because the onset constriction is more gradual when the response amplitude is small. When scaled for equal amplitude, as shown in Figure 39.1B, the graphs can be fitted with a single template, and this suggests that the onset time of the response is approximately the same for all traces, independent of initial amplitude.

In spite of such observations and other electrophysiological (Sillito and Zbrozyna, 1973) and psychophysical findings (Young and Kennish, 1993; Young et al., 1993) that demonstrate the involvement of both sustained and transient

FIGURE 39.1. Examples of dynamic PLR responses (*A*) to flashes of increasing LC, that is, $\delta L/L_b = 0.3, 0.6, 0.9, 1.2, 1.5$, and 2.15 (see stimulus inset in *B*). The dark gray traces show the timing and duration of the flash. The subject was light adapted to a uniform background field (26×21 deg) of luminance 24 cd/m^2 . The test stimulus was a disc of 6 degrees in diameter, and each trace represents the average of 36 to 48 measurements. *B*, The same data scaled for equal pupil constriction amplitude to indicate the

absence of significant differences in pupil response latency. *C*, The steady-state size of the pupil varies as a function of screen luminance. The subjects viewed a uniform screen subtending 33×26 degrees of visual angle. Continuous records of pupil size (of 4 second duration at a sampling rate of 50 Hz) were taken and averaged at each light level to obtain an estimate of mean pupil size. The data points show the mean values for six normal subjects and the corresponding intersubject variation.

neurons in the neural control of pupilloconstrictor activity, the PLR response continues to be associated with a single afferent projection to the midbrain. In this chapter we describe findings from a number of diverse experiments that support the two-component hypothesis of the light reflex response.

EVIDENCE FROM DYNAMIC NOISE EXPERIMENTS Background perturbation techniques have often been used to reduce selectively the sensitivity of some visual mechanisms and hence the contribution these mechanisms can make to the detection of a subsequent test stimulus (Barbur and Ruddock, 1980; Stiles, 1978). We have extended this approach to study pupil response components by presenting a flash of light onto a textured background made up of discrete checks that vary randomly in luminance as a function of time (see inset to Fig. 39. 2). The luminance of each check is allowed to vary with equal probability every 40 to 80 msec in a range specified as a percentage of background luminance. For example, for a background luminance of 24 cd/m^2 and an LC noise amplitude of $\pm 25\%$, the luminance of each check could have any value with equal probability in the range 18 to 30 cd/m^2 . The space-averaged luminance of the textured background remains unchanged throughout the test and equal to that of the uniform background field. The results show that the presence of dynamic LC noise causes the PLR response amplitude to decrease systematically, although this reduction starts to asymptote when the LC noise amplitude exceeds $\sim 30\%$ contrast. Interestingly, a static structured background had no effect on the amplitude

of the PLR response for any of the LC noise amplitudes investigated. Examples of such data are shown in Figure 39.2C. The reduction in pupil response amplitude observed when the spatial distribution of LC noise changes every 50 to 80 msec is likely to reflect the masking of a transient pupil response component.

A further experiment was carried out in a subject with homonymous hemianopia caused by unilateral accidental damage to his left hemisphere (see the magnetic resonance imaging [MRI] scan in Fig. 39.3). Although clinically blind in his right hemifield, the subject can make use of visual information when tested in a number of different ways (Barbur et al., 1980, 1994b). In addition, the subject exhibits *blindsight* (see Chapter 40). The subject's pupil responses measured with the stimulus presented foveally or in the sighted hemifield are normal, but when the stimulus is restricted to his blind hemifield, a number of differences emerge (Barbur et al., 1980, 1993, 1998a; Weiskrantz et al., 1999). In this chapter we report results from a number of experiments that compared pupil responses to blind and sighted hemifield stimulation in this subject. PLR responses in the blind hemifield are in general reduced significantly by comparison to the sighted field. Figure 39.3 shows that the dynamic LC noise has little or no effect when only the blind hemifield is involved (Fig. 39.3B), although a normal response pattern is obtained in the sighted hemifield (Fig. 39.3A). These findings suggest that some aspect of the transient component of the PLR response requires the normal functioning of the geniculostriate projection and primary visual cortex.

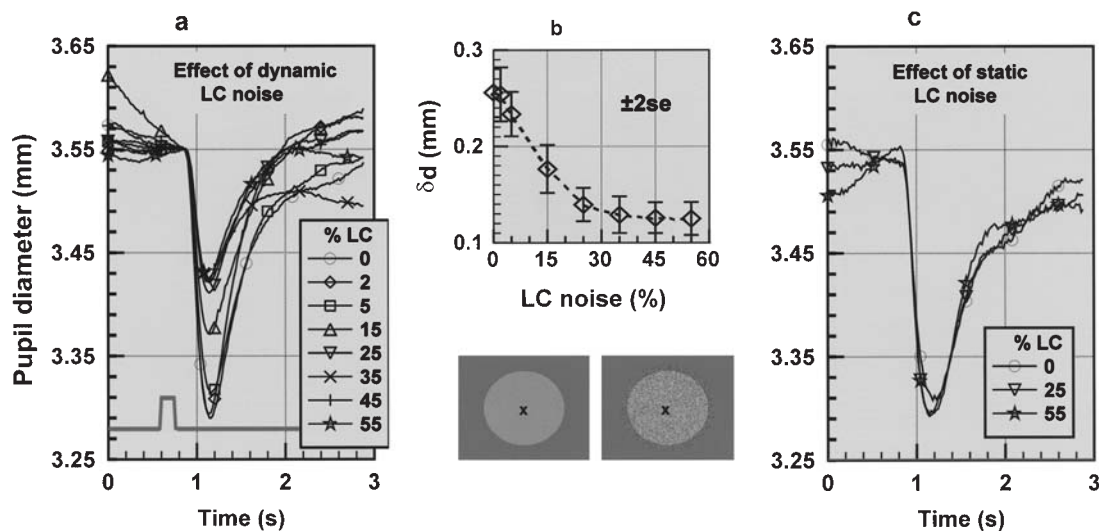

FIGURE 39.2. Effect of dynamic LC noise on pupil response amplitude to a flash of constant LC ($SL/Lb = 0.5$) presented on a uniform background field of luminance 24 cd/m^2 . An array of square checks covered an area slightly larger than the central disc stimulus (see inset). The luminance of each check was selected randomly, with equal probability within a range specified as a percentage of background luminance. This range determined the amplitude of LC noise. The spatial distribution of check luminances varied randomly every 40 to 80 msec so as to generate dynamic LC noise of mean luminance equal to that of the uniform background. Zero amplitude corresponds to a uniform background

field with no modulation (i.e., the luminance of each check remained unchanged and equal to that of the background field). The test flash generated the same light flux increment irrespective of ongoing LC noise amplitude. The peak constriction of the pupil was extracted from each of the traces shown in part *A* and plotted as a function of background noise amplitude in part *B*. The results show that the ongoing dynamic LC noise causes a significant reduction in pupil response amplitude, in spite of the constant LC increment generated by the test flash. Interestingly, static background noise does not in any way affect the pupil response amplitude and is equivalent to a uniform field (*C*).

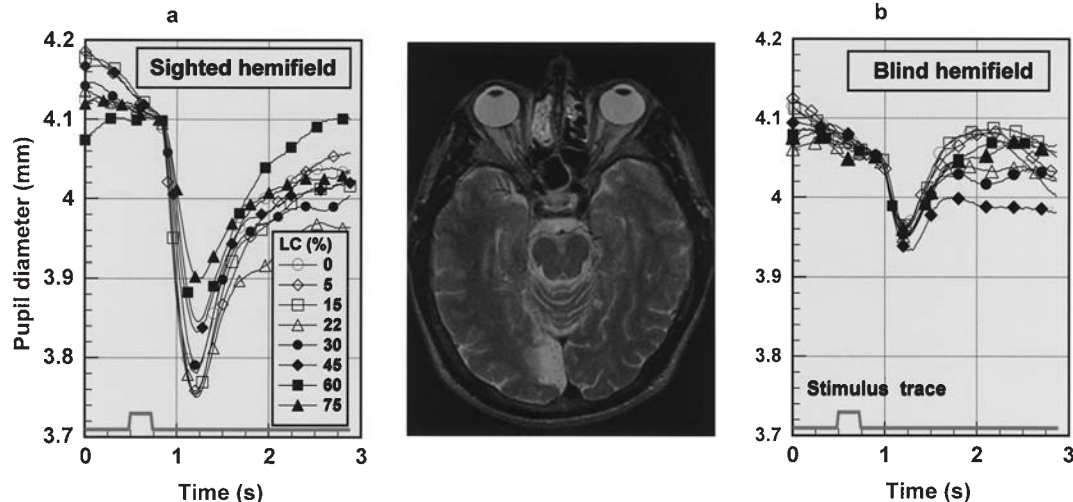

FIGURE 39.3. Comparison of sighted and blind hemifield pupil responses in a subject with homonymous hemianopia caused by damage to the left hemisphere. The MRI scan reveals significant damage to the left primary visual cortex with sparing at the pole (Barbur et al., 1993). The subject is clinically blind in the right hemifield but exhibits small (~ 3.5 degree) macular sparing (Barbur

et al., 1980). The pupil responses measured with the stimulus presented in the blind hemifield (*A*) are either absent or significantly smaller than those elicited in the sighted hemifield. In contrast to the sighted hemifield (*B*), the dynamic LC noise has little or no effect on pupil response amplitude in the blind hemifield.

EVIDENCE FROM SUBJECTS WITH OPTIC NERVE DAMAGE We studied a 12-year-old male diagnosed with optic nerve drusen that affected mostly his left eye. This condition is associated with calcified deposits that protrude over the optic disc and can cause selective damage to optic nerve fibers. Less severe signs of optic disc drusen were also observed in the subject's right eye. Visual acuity was normal in both eyes. The clinical examination revealed signs of a possible left afferent pupil defect. We measured and compared pupil responses with the stimulus presented to each eye (Fig. 39.4).

The results reveal normal consensual responses with a large steady-state afferent pupil defect in the left eye (Fig. 39.4A). In spite of this afferent defect, the PLR response to a brief flash remains normal in the affected eye. This finding is consistent with selective damage of the sustained component fibers of the pupil response, with little or no effect on the transient fibers. Figure 39.4B shows pupil responses in each eye, with and without dynamic LC noise. The results show that the normal transient pupil response in the left eye (i.e., the affected eye) is eliminated almost completely by the presence of dynamic LC noise, but not so in the relatively normal right eye. These findings are consistent with the two-component hypothesis for the control of the PLR response, with the sustained component fibers having been most affected in the subject's left eye.

FIGURE 39.4. Example of a relative afferent pupil defect that affects selectively the steady state but not the dynamic PLR response. The subject was 12 years old, with normal visual acuity and chromatic and achromatic sensitivity in the right eye. Optic nerve drusen in the left eye caused loss of visual acuity and achromatic contrast sensitivity, but no loss of chromatic sensitivity. The subject viewed a uniform display subtending 33×26 degrees either binocularly or monocularly. The test stimulus was a central disc, 6 degrees in diameter, as shown in the inset. When the subject views

EVIDENCE FROM PUPIL PERIMETRY STUDIES This series of perimetry experiments involved sinusoidal and square-wave modulation of stimulus contrast (Fig. 39.5), and was driven by the need to minimize the time required for such measurements and to make possible the automatic extraction of pupil response parameters of interest.

Figure 39.6 shows typical response amplitudes and latencies elicited at each of the 24 possible stimulus locations. Discrete Fourier transform analysis of the pupil response trace provides a measure of response amplitude, latency, signal-to-noise ratio, and response nonlinearity (Fig. 39.5). A surprising finding of these studies was the disproportionately large pupil response amplitude that can be elicited with square-wave modulation. An identical stimulus configuration with sinusoidal modulation yields a much smaller pupil response amplitude (Fig. 39.6). We also measured the response of the pupil using sinusoidal modulation of amplitude equal to that of the fundamental frequency at each of the harmonic frequency components present in the square wave. The frequency range was restricted to 5 Hz, given the limited frequency response range of the pupil when tested with sinusoidally modulated stimuli (Bishop and Stark, 1965; Stark and Sherman, 1957). The results show that even under such conditions, the pupil response amplitude to square-wave modulation is significantly larger than the sum of the responses elicited by all of its harmonic components.

the display with his left (affected) eye, the pupils are large in both eyes (~ 7 mm in diameter). The pupils are, however, normal (~ 4.7 mm) when the subject views the display either with the right (normal) eye or with both eyes. The dynamic PLR response is normal in each eye in spite of the large, steady-state, relative afferent pupil defect in the left eye (A). Another interesting observation is that the dynamic PLR response in the left eye is abolished almost completely by the addition of LC noise, but it is only reduced in the normal eye (B).

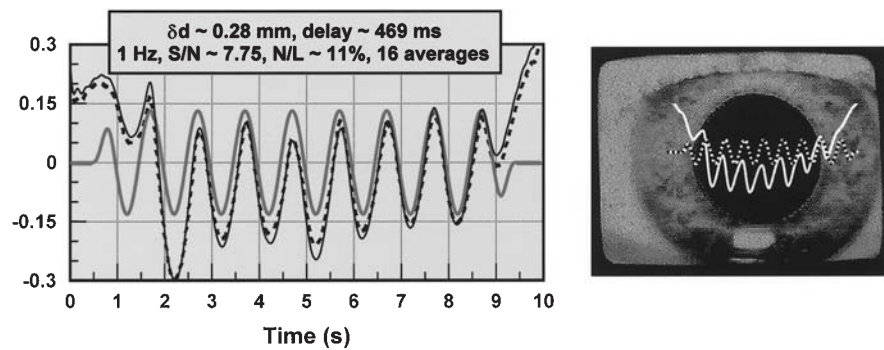

FIGURE 39.5. Example of the mean pupil response to sinusoidal modulation of stimulus luminance, as employed in our pupil perimetry program (see inset in Fig. 39.6). The stimulus trace (shown in gray) was shifted through 469 msec to match the direct (solid black line) and consensual (dotted line) pupil responses. In normal subjects, no significant differences can be measured between the direct and consensual responses. The modulation frequency was 1 Hz, and each stimulus consisted of 10 cycles (with Hanning weighting). Each of the 24 stimulus locations shown in Figure 39.6 was selected randomly and tested eight times to obtain

an averaged response. The signal power and phase shift at the modulation frequency, together with a measure of signal/noise ratio (S/N) and response nonlinearity (N/L), were computed from the discrete Fourier transform of each averaged trace. The N/L parameter was defined as the ratio of the summed signal power in all harmonics and the signal power at the stimulus modulation frequency. A more detailed description of the measurement technique and the analysis of results has been given elsewhere (Barbur et al., 1999).

FIGURE 39.6. Example of pupil perimetry data measured with either sinusoidal (*right section*) or square-wave (*left section*) modulation of stimulus luminance. In both cases, the stimulus had a peak luminance of 48 cd/m^2 and was presented against a uniform background of luminance 3 cd/m^2 . The vertical bars indicate the measured pupil response amplitude and latency (as described in Fig. 39.5) for each stimulus location in the visual field (i.e., 1 to 24).

The startling observation is the difference in pupil response amplitude between sinusoidal and square-wave modulation for the same light flux change. The human pupil exhibits low-pass temporal response characteristics with a cutoff upper limit not much above 3 Hz. The much larger pupil response amplitudes elicited with square-wave modulation cannot be accounted for by the additional contribution from higher harmonics in the square wave.

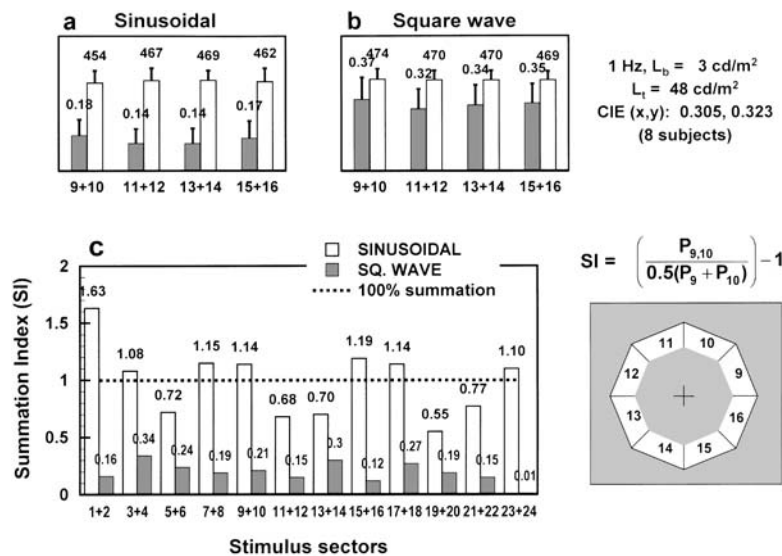

FIGURE 39.7. The spatial summation properties of the pupil response were investigated separately for both sinusoidal and square-wave modulation by comparing the response amplitudes elicited with single and paired stimuli. The top sections show averaged pupil response amplitudes and latencies for eight normal subjects for both sinusoidal and square-wave modulation using paired stimuli. Comparison of results obtained using single and paired stimuli suggests that sinusoidal modulation exhibits large spatial summation, while square-wave modulation does not. These observed differences in spatial summation can be quantified by defining an index of spatial summation that compares the response

amplitudes elicited by single and paired stimuli. Perfect summation of light flux increments over paired stimuli doubles the pupil response amplitude and results in a summation index (*SI*) of 1 (see the inset for definition of *SI*). The absence of spatial summation means no difference in pupil response amplitude between single and paired stimuli and corresponds to an *SI* index of zero. The lower section plots the computed *SI* values over the visual field for both sinusoidal and square-wave modulation. The results show large spatial summation for sinusoidal and little or no spatial summation for square-wave modulation.

In order to reduce the duration of a pupil perimetry test, we grouped together pairs of stimuli (Fig. 39.7). A comparison of pupil response amplitudes with single and double stimuli reveals the much greater spatial summation properties associated with sinusoidal modulation.

The difference in spatial summation index (Fig. 39.7C) for sinusoidal and square-wave modulation suggests that the two modes of presentation favor populations of neurons that have vastly different spatial summation properties. The relationship between stimulus contrast (or modulation depth) and pupil response amplitude was investigated in another study using a single foveal stimulus. The results obtained with sinusoidal and square-wave modulation are shown in Figure 39.8.

The pattern of response is again consistent with the two-component hypothesis. The transient component exhibits high-contrast gain but saturates above 30% to 40% contrast, while the sustained component continues to respond linearly up to the highest LC investigated. This finding is completely consistent with the results shown in Figure 39.2A. The initial rapid reduction in pupil response is amplitude when a test flash is added to a background of dynamic LC noise asymptotes to a constant value as the test flash exceeds 30% to 40% contrast.

PLR RESPONSES IN SUBJECTS WITH CORTICAL DAMAGE A number of pupil studies have demonstrated either reduced or completely absent PLR responses to small stimuli in patients with postgeniculate lesions (Barbur et al., 1988; Harms, 1951; Kardon et al., 1993). These findings are not consistent with a single afferent PLR projection that does not involve, at least indirectly, the geniculostriate pathway. Figure 39.9 shows examples of PLR response deficits in a hemianope. Stimuli of different sizes (Fig. 39.9A) were imaged separately in both the sighted and blind hemifields (see inset to Fig. 39.9). Figure 39.9B shows data for a number of luminance increments but for a fixed stimulus size selected in the middle of the range (i.e., 92 deg²).

The results show that the pupil responses in the blind hemifield are either absent or reduced in amplitude for stimuli of small size and LC. When large light flux increments are involved, the pupil responds well to both blind and sighted hemifield stimulation. The immediate hypothesis that could explain such observations requires more than one afferent pathway to control the pupil's response to light. The results suggest, contrary to classical belief, that the processing of signals along the geniculostriate pathway is normally required to generate a normal PLR response.

FIGURE 39.8. The data show the effect of LC (i.e., modulation depth) on pupil response amplitudes using sinusoidal and square-wave modulation. For this test the stimulus was a central disc 9 degrees in diameter presented against a uniform background field of luminance 12 cd/m^2 and angular subtense 26×21 degrees. The mean luminance of the test stimulus was 48 cd/m^2 , and this was modulated at 0.8 Hz . The differences in pupil response amplitude between square-wave and sinusoidal modulation suggest that two populations of neurons with different contrast response characteristics drive the PLR response. One population of neurons has high-contrast gain but saturates in response above 40% contrast. The second set of neurons continues to respond to higher LC modulation and may also exhibit larger spatial summation. This finding is completely consistent with the results shown in Figure 39.2A. The results of Figure 39.2 also show that the initial rapid reduction in pupil response amplitude when a test flash is added to a background of dynamic LC noise asymptotes to a constant value as the test flash exceeds 30% to 40% contrast.

Pupil responses to other stimulus attributes

PUPIL MOTION RESPONSE The sudden change from random to coherent motion of randomly distributed checks (see inset to Fig. 39.10) represents an ideal stimulus for studying pupil responses to moving stimuli. This stimulus ensures that there are no additional luminance transients at the onset of coherent motion that could trigger a pupil response. The sudden change from random to coherent motion requires only that the direction of displacement is the same for all checks in the array (Barbur et al., 1992).

The results yield long pupil onset response latencies, little or no dependence on stimulus contrast, and no response to motion offset (i.e., a change from coherent motion to random motion). A sudden angular change in the direction of coherent movement also triggers a transient constriction of the pupil, but only when the change of motion direction exceeds approximately ± 30 degrees (Sahraie and Barbur, 1997). These findings are not unexpected given the extensive motion selectivity and directional tuning of cortical neurons (Dubner and Zeki, 1971; Maunsell and Van Essen, 1983; Orban et al., 1981). Results of experiments that compared pupil responses to coherent motion restricted to the blind and sighted hemifields in a patient with hemianopia are shown in Figure 39.10B. The residual pupil motion response in the blind hemifield is small, but the response amplitude is statistically significant because of the large number of averages employed. These findings complement the results of other studies in this subject that demonstrate

FIGURE 39.9. Comparison of PLR responses elicited by stimulating corresponding regions in the sighted and blind hemifields in a subject with homonymous hemianopia caused by damage to the left hemisphere (see the MRI scan in Fig. 39.3). The subject viewed a uniform background of angular subtense 33×26 degrees and luminance 24 cd/m^2 . The stimulus was a sector of an annulus that

varied systematically in either size (at a fixed contrast of 0.6, part A) or LC (for a fixed size of 92 deg^2 , part B). The results suggest that stimulation of the blind hemifield can, in general, yield highly abnormal PLR responses. When the stimulus causes large increments in light flux, there is little or no difference in PLR response between the blind and sighted hemifields.

FIGURE 39.10. *A, B*, Examples of pupil responses to the onset of coherent motion. *A*, Data measured in a normal subject for two speeds of movement with the stimulus presented in the foveal region. *B*, Comparison of pupil responses to coherent motion with the stimulus restricted to either the sighted or the blind hemifield of a hemianope. The stimulus (see inset) consists of small, spatially random checks that change position randomly in a number of dif-

ferent directions every 80 msec. This generates dynamic random motion of background checks. During coherent motion, the spatiotemporal characteristics of the stimulus remain unchanged, but all the checks are displaced in the same direction. The pupil motion responses elicited with such stimuli exhibit long latency, some dependence on speed, and little or no dependence on check contrast.

FIGURE 39.11. Pupil responses to grating stimuli as a function of spatial frequency. *A*, Typical pupil traces to equal and lower luminance gratings of 5 c/degree and contrast 0.8. The grating had a diameter of 5 degrees and was generated on a uniform background of luminance 34 cd/m². For the equal-luminance condition, the space-averaged luminance remained the same as that of the uniform background. For the lower-luminance condition, only the peak luminance in the grating remained the same as that of the uniform background field, and hence the space-averaged luminance over the grating was reduced during the stimulus to about 19 cd/m². Each trace represents the average of 64 measurements.

residual vision (Barbur et al., 1980) and blindsight (Weiskrantz et al., 1995) for moving stimuli, and the corresponding activation of visual and nonvisual areas of the cortex in functional MRI (fMRI) studies when the moving stimuli were restricted to the subject's blind hemifield (Sahraie et al., 1997a, 1997b).

PUPIL GRATING RESPONSE We have employed two types of grating stimuli, as illustrated in Figure 39.11. *Equal-luminance*

In spite of a net reduction in mean luminance, the pupil constricts to the onset of a lower-luminance grating. This is followed by a second constriction at grating offset. The amplitude of this second constriction is largely independent of spatial frequency and is therefore likely to reflect a PLR response caused by the luminance increment at grating offset. *B*, Spatial frequency dependence of the pupil grating response. Interestingly, the response to an equal-luminance grating that can be described as local increments and decrements in luminance is approximately double the response amplitude elicited with lower-luminance gratings (i.e., a grating defined only by luminance decrements).

gratings consist of both increments and decrements in local luminance. The mean luminance therefore remains unchanged and equal to that of the uniform background. *Lower-luminance* gratings consist only of dark bars, causing a net reduction in mean luminance over the grating. Both gratings cause an initial constriction of the pupil that varies systematically in amplitude with the spatial frequency of the grating (Fig. 39.11*B*). The pupil onset response latency is the same for both types of grating, but equal-luminance

FIGURE 39.12. Comparison of pupil responses to equal-luminance gratings with the stimulus presented either foveally or to the sighted or the blind hemifield of a hemianope. The pupil responses in the blind hemifield are either absent or reduced significantly by comparison with those in the sighted field.

gratings generate a pupil constriction twice as large as lower-luminance gratings (Barbur, 1991). The offset of the grating causes a large constriction of the pupil, for lower-luminance gratings, that increases systematically with grating contrast. The large constriction at stimulus offset for lower-luminance gratings is likely to represent a light reflex response driven by the net increment in luminance when the grating stimulus is returned to the uniform background. Transient responses, but of greatly reduced amplitude, can also be observed at grating offset for equal-luminance gratings, but only in the low spatial frequency range.

Since both sustained and transient neurons are probably activated when a suprathreshold grating is presented to the eye, the small constriction of the pupil at grating offset is not unexpected, particularly in the low spatial frequency range. The doubling of pupil response amplitude when equal-luminance gratings are employed suggests that local increments and decrements in luminance trigger the activity of equal but separate populations of ON and OFF neurons (Fiorentini et al., 1990).

Figure 39.12 shows pupil grating response amplitudes with the stimulus presented foveally and in the sighted and blind hemifields of the hemianopic subject described earlier in this chapter. Although the absence of pupil responses in the blind hemifield is immediately obvious, the small residual response for a grating frequency of 1 c/deg correlates well with other findings from psychophysical studies (Barbur et al., 1994b) and has also been confirmed in a more extensive pupil study that employed larger grating stimuli (Weiskrantz et al., 1998).

PUPIL COLOR RESPONSE Pupil responses can also be elicited with chromatic isoluminant gratings. The gratings employed in these tests were presented in the foveal region and sub-

FIGURE 39.13. Comparison of pupil responses to luminance and color-defined gratings (see inset). Pupil responses to isoluminant, chromatic gratings are in general of longer latency, even when of equal response amplitude. (See color plate 24.)

tended a visual angle of some 5 degrees. Figure 39.13 shows two pupil response traces of approximately equal amplitude but significantly different onset latency measured in a normal trichromat. The graph also shows that the pupil responds to the offset of the achromatic, equal-luminance grating, but this response is absent in the case of the isoluminant, colored grating.

In order to avoid the difficulties of setting isoluminance, particularly when transient chromatic stimuli are employed, a new technique based on dynamic random LC masking was developed to isolate the use of chromatic signals (Barbur et al., 1994a). A two-dimensional array of LC-defined checks served as the stimulus template. Vertical bars defined by chromatic contrast (as shown in Fig. 39.14) were then presented to the eye for 0.5 second, buried in the ongoing dynamic LC noise (readers are invited to take a look at our website for a demonstration of such dynamic stimuli and the corresponding color vision tests: <http://www.city.ac.uk/avrc>).

The dynamic LC noise technique is very effective in that dichromats cannot detect the presence of the colored bars even for large chromatic saturations imposed by the phosphors of the display (Barbur et al., 1994a). Figure 39.14A shows the chromatic threshold detection ellipse for a normal trichromat, the color confusion bands for each class of dichromat, and the chromaticities of the test stimuli employed in pupil studies (i.e., crosses on the large dotted circle). We measured pupil color responses using this technique in normal trichromats and in a number of other subjects who do not see the colored pattern for a number of different reasons. The pupil constriction amplitude was computed from each pupil trace and plotted as a function of the direction of chromatic displacement in the (CIE) - (x_2, y) diagram. Each direction of chromatic displacement

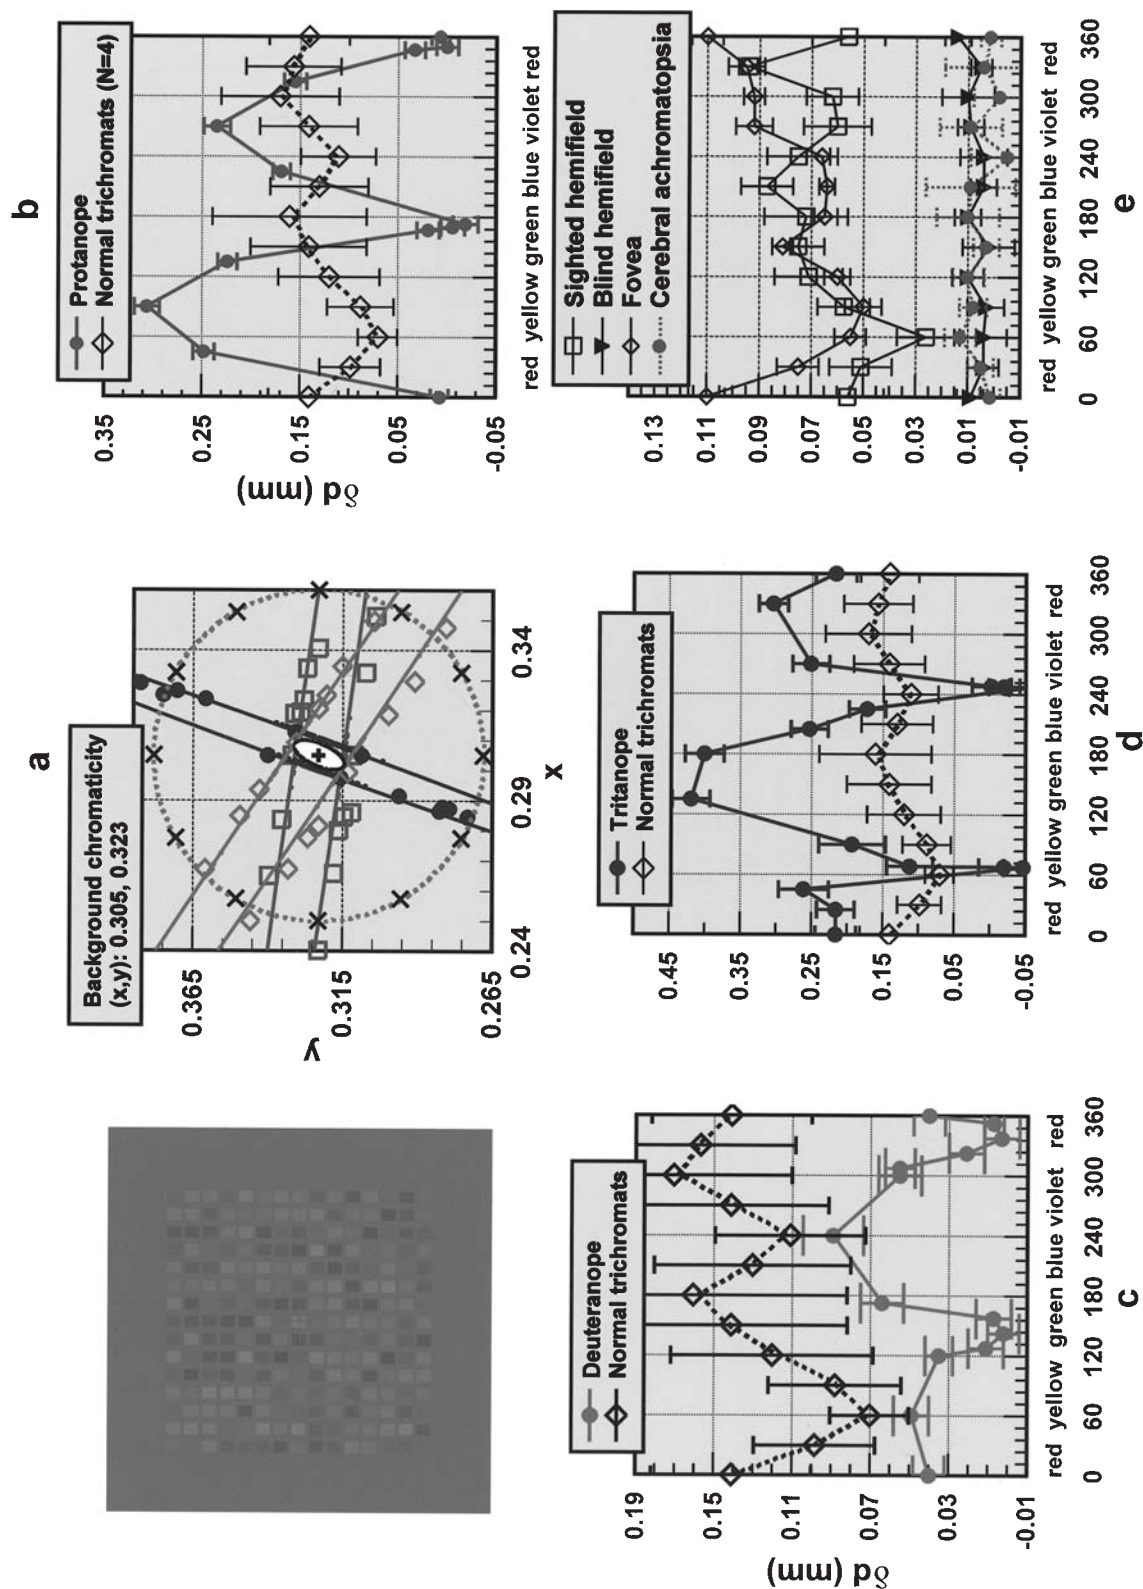

FIGURE 39.14. *A*, Chromatic threshold detection ellipse for a normal trichromat (solid black line) and the color confusion "bands" for each class of dichromat in the CIE $x-y$ chromaticity diagram. The stimulus consisted of vertically aligned colored checks (as shown in the inset) buried in a background of dynamic LC noise (Barbur et al., 1994a). The test stimulus subtended a visual angle of 5×5 degrees, and its mean luminance was 24 cd/m^2 . The stimulus was presented in the center of a uniform background of the same luminance and angular subtense 28×23 degrees. The dynamic LC masking technique isolates the use of chromatic signals even for the most saturated colors, limited only by the phosphors of the display. The dotted circle in *a* shows the suprathreshold chromatic saturation of the colors employed to elicit pupil responses. *B-D*, Pupil color responses in normal trichromats and in each class of dichromat. Pupil color responses in normal trichromats show considerable intersubject variability and exhibit the smallest amplitude for chromatic modulation along the blue-yellow axis. Pupil color responses are completely absent in each class of dichromat, but only for chromatic displacement directions along the corresponding color confusion lines. *E*, Significantly reduced or absent pupil color responses are shown when the stimulus is restricted to the blind hemifield of a hemianope. Similar results are also obtained in a subject with cerebral achromatopsia caused by lesions to the ventromedial prefrontal visual cortical areas. (See color plate 25.)

represents a different color on the spectrum locus. For example, an angle of zero degrees corresponds to a direction parallel to the abscissa and points toward the red region of the spectrum locus, while an angle of 65 degrees points toward the yellow region of the spectrum locus. Results for each class of dichromat are shown in Figure 39.14B–D. These data reveal the complete absence of pupil color responses for directions of chromatic displacement that match the corresponding color confusion lines in each class of dichromat. Figure 39.14E shows similar data measured in a hemianope and in a subject with cerebral achromatopsia. The small colored stimulus employed in this study failed to elicit significant pupil color responses in the hemianope's blind hemifield. Similar results were also obtained in the subject with cerebral achromatopsia with the stimulus presented foveally. The latter finding was surprising given that pupil responses to light flux increments and to luminance modulated gratings were normal in this subject.

Pupil responses in subjects with damage to the dorsal midbrain

PLR RESPONSE Damage to the pretectal region of the brain can cause selective disruption of the normal functioning of midbrain nuclei, and this can affect the various components of the pupil response (Wilhelm et al., 2002). The damage is usually caused by a compressive tumor in the region of the pineal gland and results in a pattern of response deficits, normally described as *Parinaud's syndrome*. These include abnormal PLR responses, vertical gaze palsy, and ocular vergence problems. The near reflex response is usually unaffected, and this observation suggests that the EW nucleus is not damaged in such lesions.

We have investigated how the two components of the PLR response and the observed pupil responses to gratings and colored stimuli are affected when the OPN and other nuclei in the pretectum are damaged. Figure 39.15A shows PLR responses in two subjects with Parinaud's syndrome as a function of the LC of the test flash (see inset). More extensive results, clinical reports, and MRI scans showing the extent of the midbrain damage in each subject have been reported elsewhere (Wilhelm et al., 2002). Comparison data averaged over six normal subjects are shown in Figure 39.15B. Unlike the normal subject group, both Parinaud's syndrome subjects show the almost complete absence of both transient and sustained PLR responses, with little or no dependence on stimulus contrast (Fig. 39.15C). A residual response of small amplitude and longer latency can be demonstrated in each subject by averaging several pupil response traces. These small pupil constrictions passed undetected in the clinical examination.

It is of interest to establish if the sympathetic innervation of the dilator muscle of the iris plays any role in the PLR

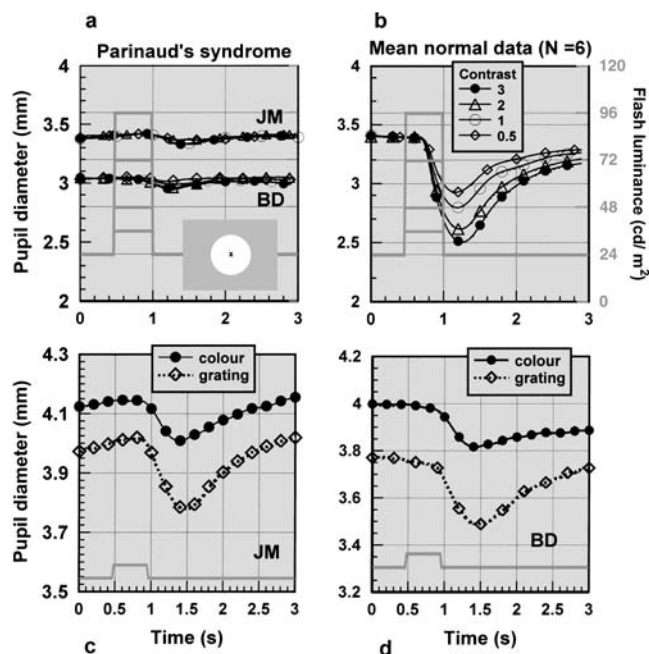

FIGURE 39.15. Pupil responses to light flux increments, isoluminant colors, and achromatic gratings of space-averaged luminance equal to that of the background field in two subjects with Parinaud's syndrome (J.M. and B.D.) caused by damage to the pretectal region of the midbrain. *A*, Examples of PLR responses elicited with a foveal stimulus (see inset) of progressively larger LC. *B*, Data obtained for the same stimuli in a group of six normal subjects. Unlike the normal subject group, the PLR response is largely absent in J.M. and B.D. The stimulus trace (shown in dark gray) shows both the duration and the luminance of the stimulus. Both J.M. and B.D. exhibit normal near-reflex responses when accommodating. The pupil color and pupil grating responses are also within the normal range (*C*, *D*).

response. Although one cannot be certain, this small, residual response to light flux increments may not necessarily involve any subcortical light-reflex projection. The sympathetic pathway involves more stages of neural processing originating in the hypothalamus, and its retinal afferent projections must rely, at least in part, on a direct cortical input (Alexandridis, 1995; Loewenfeld, 1999). A large increment in light flux on the retina could, at least in principle, initiate the weakening of sympathetic innervation to the dilator muscle of the iris in addition to facilitating the parasympathetic control of the sphincter. Such an arrangement could produce a more effective constriction of the pupil. The residual pupil responses observed in the two subjects with damage to pretectal nuclei are of very small amplitude but longer latencies (i.e. ~0.5 second compared to 0.24 second in the normal subject group). We know that pupil response latency shows little or no dependence on response amplitude when the subject is light adapted to a uniform background (Fig. 39.1B). This observation suggests that the small PLR responses that can be demonstrated in the two patients

with Parinaud's syndrome involve the action of mechanisms other than the direct midbrain pathway.

PUPIL COLOR AND PUPIL GRATING RESPONSES Pupil responses to stimulus attributes such as color, spatial structure, or movement must involve the activity of extrastriate visual areas since such responses are either absent or reduced significantly when only subcortical pathways are involved (Figs. 39.10, 39.12, and 39.14). In principle, the cortex can influence the pupil either through direct projections to the EW nucleus or indirectly via other nuclei in the pretectum such as the OPN, which is known to send afferents to the EW nucleus. The two subjects with Parinaud's syndrome have extensive damage to pretectal nuclei, and this causes a pattern of related deficits that includes the absence of a PLR response. It is therefore of great interest to establish whether an intact pretectum region is also needed to generate normal pupil color and grating responses.

The results of this study show that both subjects exhibit pupil grating and pupil color responses, as shown in Figure 39.15C, D. In addition, they exhibit normal slow oscillations of the pupil during sleepiness (Wilhelm et al., 2002). Such fluctuations have been attributed to instability in sympathetic inhibition of the pupillomotor nucleus (Lowenstein et al., 1963; Wilhelm et al., 1999).

Discussion

The diverse experimental findings presented in this chapter illustrate the complexity of the visual pathways involved in the control of the pupil response, and go a long way toward justifying why the pupil has been described by some as a beautiful example of a biological servomechanism for control of retinal illuminance and by others as the "apple of one's eye" or a "window to the soul." In spite of this great diversity of function, a unifying picture is beginning to emerge as the underlying circuitry that drives the PLR is unraveled. Although in the absence of precise anatomical and electrophysiological evidence any model for the control of the pupil response remains speculative, the following scheme accounts well for all the experimental observations reported in this chapter. It also explains the slow pupillary oscillations induced by sleepiness (Lowenstein et al., 1963; Yoss et al., 1978) and the large pupil constriction observed during deep anesthesia (Loewenfeld, 1999).

The principal component of this circuitry is the neural substrate in the pupillomotor nucleus where neurons generate a steady firing rate, even when no external inputs are involved (Sillito, 1968; Sillito and Zbrozyna, 1970, 1973). The amplitude of this signal generator determines the strength of the efferent innervation of the sphincter muscle of the iris and hence the size of the pupil. In the absence of external influences, the efferent signal to the iris is large, and

FIGURE 39.16. Schematic diagram of pupil pathways needed to explain the presence of different pupil response components in normal subjects and the absence of some components in patients with damaged primary visual cortex or pretectal nuclei. In this model, the EW nucleus acts as a signal generator whose amplitude is modulated by a number of other inputs. In the absence of such inputs the efferent signal to the retina is high, and this would normally result in miosis. A steady-state inhibitory projection from a number of cortical areas to the EW nucleus ensures that the pupil size remains normal by decreasing the strength of the efferent signal to the sphincter muscle of the iris. Perturbation of neural activity in extrastriate visual areas caused by sudden processing of stimulus attributes such as color, spatial structure, or motion can cause transient weakening of the steady-state inhibitory signal to the sphincter muscle, and this causes the pupil to constrict transiently in response to such stimuli. Changes in inhibition at the level of the EW nucleus may also explain the near-reflex response on accommodation and the irregular oscillations of the pupil caused by sleepiness. The PLR response is likely to involve two projections from the retina to the OPN. Both components respond to transient stimuli but differ in spatial summation, contrast gain, and temporal response characteristics. The sustained component exhibits large spatial summation, a low-pass temporal response, and low contrast gain. For convenience we label this as the steady-state component. The transient pathway exhibits poor spatial summation, a bandpass temporal response, and high contrast gain, properties characteristic of a transient component. The latter projection exhibits response saturation at large contrast (>40%), and its effectiveness is controlled by a direct projection from the cortex. This arrangement explains why patients with damaged primary visual cortex exhibit poor PLR responses to small, low-contrast stimuli but show no difference between the sighted and cortically blind hemifields when large, high-contrast stimuli are employed. This simplified scheme also explains why damage to pretectal nuclei, particularly in the OPN, as observed in patients with Parinaud's syndrome, can affect both the sustained and transient components of the PLR response.

this would normally cause the pupil to constrict. The normal size of the pupil observed under ordinary levels of ambient illumination is due largely to a strong steady-state cortical inhibition of the pupillomotor nucleus. Any transient decrease in this inhibition as a result of sudden perturbation of neural activity in the cortex will cause the pupil to constrict, only to return to its normal size once the steady-state inhibitory signal is restored. This is indicated in Figure 39.16 as a direct projection from extrastriate visual cortical areas to the EW nucleus. We know that the processing of stimulus color, structure, or motion can trigger small constrictions of the pupil, but these responses are either absent or reduced significantly when the normal processing of these signals is disrupted as a result of postgeniculate lesions.

The selective loss of pupil color response in patients with cerebral achromatopsia (Fig. 39.14*E*) provides strong evidence in support of this hypothesis. Central inhibition of the EW may therefore play a major role in the generation of stimulus-specific pupil responses. The exact cortical origin of this projection is not known, but extrastriate visual areas such as those listed in Figure 39.16 may be involved. All pupil responses mediated through cortical inhibition tend to have longer latencies by comparison with the PLR response (Barbur et al., 1992, 1998b; Tsujimura et al., 2001). During deep anesthesia and sleep, the weakening of central inhibition is sufficient to explain the observed miosis, while the slow oscillations of the pupil induced by sleepiness are consistent with intermittent fluctuations in the strength of central inhibition. Both sleepiness waves, the pupil near-reflex response, and pupil grating and color responses are preserved in Parinaud's syndrome, even when damage to the dorsal midbrain region abolishes the PLR response (Wilhelm et al., 2002). These observations suggest that inhibitory cortical signals are integrated into the pupillomotor pathway at the level of the EW nucleus. Some experimental observations suggest that this central inhibitory pathway may also play a part in the PLR response.

The findings presented in this chapter suggest that two distinct pathways, both based on detection of light flux changes, but one with large spatial summation and sustained responses and the other with more transient properties, high-contrast gain, and reduced spatial summation are involved in mediating the PLR response. We know that pupil responses to small, low-contrast stimuli are either absent or reduced significantly in amplitude in patients with postgeniculate lesions (Fig. 39.9*A, B*), but completely normal pupil responses can be elicited in the same patients when large, high-contrast stimuli that favor the sustained component are employed. These observations suggest that the transient PLR component may involve a direct projection to the striate cortex and the integration of this signal into the pupil pathway via the central inhibitory projection to the EW nucleus. This hypothesis does, however, predict that in

addition to the pupil color and pupil grating responses, the transient PLR response component should be spared in patients with dorsal midbrain damage.

Contrary to this prediction, the experimental findings show that both the transient and sustained components of the PLR response are absent in Parinaud patients. The OPN receives projections from the retina, and in principle it can also receive a projection from the cortex. Any cortical component of the transient PLR response could therefore be integrated into the pupil pathway directly as an excitatory signal via the OPN. In the absence of this excitatory cortical component in patients with postgeniculate damage, the afferent retinal projection to the OPN becomes less effective, and this can explain the abnormal pattern of PLR responses observed in hemianopes. The cortex can therefore exercise some influence on the pupil response at the level of the EW nucleus through a sympathetic inhibitory projection and also through an excitatory input to the OPN.

Conclusions

The study of the pupil brings together some of the best aspects of the physiology and the psychology of vision. The normal functioning of geniculostriate and midbrain projections, the detection of light flux changes, the processing of specific stimulus attributes, and the level of anxiety, excitement, and conscious awareness of the subject are among the many parameters that can be reflected in the pupil. Recent advances in visual psychophysics and pupil measurement techniques have rekindled much of the centuries'-old fascination with the pupil. We now know that the pupil's pathways are wired up to respond specifically to different features of a visual stimulus. We can use the pupil to diagnose reliably color deficiency, to measure visual acuity, and to reveal levels of visual processing in the cortex by measuring differences in response latency. We can also reveal the existence of two components in the PLR response. The latter finding can be used to explain unusual PLR response deficits when the damage affects one of these components selectively and also helps us understand better the limitations of pupil perimetry studies. Pupil color responses have been used to unravel the mechanisms for the generation of chromatic afterimages (Barbur et al., 1999), and screening programs based on pupil responses have now been developed to study residual vision and blindsight in patients with postgeniculate damage (Sahraie et al., 2002). The development of dynamic morphing of images in pupil studies makes it possible to manipulate the meaningful content of an image and to investigate the presence of accompanying pupil signals when no light responses are involved. Such techniques will extend the use of the pupil to other studies and, in particular, the measurement of response components that contribute to the sympathetic innervation of the iris that have so far remained

relatively unexplored. In summary, the pupil has become an important tool that can yield useful information in basic neuroscience and clinical research. Although the pupil may not be “the apple of one’s eye” or a true “window to the soul,” the analysis of its response components may provide a “window to the brain.”

Acknowledgments

I would like to thank J. A. Harlow and A. Goodbody for their help with software development and equipment construction and the many subjects who took part in these studies. I am also grateful to D. Edgar, L. Weiskrantz, S. Moro, G. Ruskell, and B. Wilhelm for their critical comments on the manuscript. The studies reported here were carried out with support from the Wellcome Trust and the Medical Research Council of Great Britain.

40 Blindsight

LARRY WEISKRANTZ

BLINDSIGHT IS A CONDITION associated with damage to human primary visual cortex (V1), which causes blindness in corresponding parts of the affected visual fields, the field defect having a size and shape to be expected from the classical retinocortical maps (Holmes, 1918). The term *blindsight* first arose (Sanders et al., 1974; Weiskrantz et al., 1974; Weiskrantz, 1986) to describe the demonstration of good visual discriminative capacity in patients even though they denied having any visual experience in their blind fields (Pöppel et al., 1973; Weiskrantz, 1986; Weiskrantz et al., 1974; cf. an early report by Bard, 1905). The term enjoys sufficient usage to warrant a dictionary entry: “*Medicine*: a condition in which the sufferer responds to visual stimuli without consciously perceiving them” (*Oxford Concise Dictionary*).

The historical origin of the oxymoron stems from animal work, because it has been known for some decades that monkeys with V1 removal can nevertheless carry out some visual discriminations, which is not surprising because V1 is not the only target in the brain for signals originating in the retina, although it is the major one. There are several extra-striate pathways from the retina to subcortical targets that remain intact after damage to V1, from which information can have a very wide distribution to other cerebral areas, both cortical and subcortical (Benevento and Yoshida, 1981; Cowey and Stoerig, 1991; Fries, 1981; Hernandez-Gonzales and Reinoso-Suarez, 1994; Yukie and Iwai, 1981). In apparent contrast to the animal findings, human subjects with V1 damage are said to be *densely blind* in the corresponding part of the affected visual fields.

There are problems in relating animal to human evidence. In the human brain, it is rare for any lesion of the striate cortex to occur without damage to overlying tissue, including visual association cortex, whereas it is relatively easy for lesions restricted to striate cortex to be studied in experimental animals. Importantly, the effect of enlarging a striate cortex lesion in the monkey so as to include posterior association cortex is reported to lead to a significant reduction in residual visual capacity (Pasik and Pasik, 1971). In addition, evidence regarding these closely adjoining cortical regions suggests that they are functionally segregated and may have partially specialized capacities of a modular type, such as color, movement, spatial features, and form (cf. Cowey, 1985; Zeki, 1978, 1993). Therefore, the pattern of deficits can differ considerably from patient to patient even with relatively slight differences in the disposition of the

lesions, and experimental striate lesions in monkey and clinically occurring lesions in the human are typically not like-with-like.

But there is a deeper methodological difficulty in making monkey-human comparisons. Residual vision in the animal is studied by behavioral methods, typically by making reward contingent on a particular response choice between alternative stimuli, typically entailing a long series of trials. In contrast, human visual assessment is rarely carried out in such a fashion in the clinic. Instead, the negotiation is typically verbal: the patients are given a verbal instruction and are asked to report verbally whether they “see” the preselected stimulus, and to say what it is, as in acuity measurements made with a Snellen chart. Sometimes a response key is substituted for a verbal report, as in automatic devices for plotting fields, but the underlying assumptions are the same.

Blindsight evidence emerged when patients with field defects were tested atypically with animal-type forced-choice methodology—requiring them to make differential responses to the stimuli whether or not they verbally acknowledge seeing them. The history and some of the related background issues are discussed more fully elsewhere (Cowey and Stoerig, 1991, 1992; Stoerig and Cowey, 1997; Weiskrantz and Cowey, 1970; Weiskrantz et al., 1977; Weiskrantz, 1972, 1980, 1986, 1997, 2001b).

Categories of residual visual capacities

As in other areas of neuropsychology, single cases or small-group studies can be especially illuminating because they can reveal what dissociations may be possible. In addition, for reasons alluded to above, work has tended to focus on patients with the appropriately restricted and defined lesions. Much of the intensive research has been carried out with subjects D.B., G.Y., and F.S. [D.B. had surgical removal of tumor from V1 (see Weiskrantz et al., 1974); a magnetic resonance imaging (MRI) scan is not possible because of metal aneurysm clips and CT scans are badly distorted for the same reason, but a high resolution CT scan is possible for upper bank of calcarine cortex, and shows complete loss of V1 in that bank (Weiskrantz, Cowey, and Hodinott-Hill, in preparation), corresponding to the lower visual field where testing has been concentrated. G.Y. suffered a head injury; he has been scanned several times (see Barbur et al., 1993; Baseler et al., 1999) showing complete left V1 removal except for occipital pole, corresponding to 3 degrees of

macular sparing. F.S. suffered a severe craniocerebral trauma, almost completely destroying his left primary visual cortex; the damage is well documented by MRI (see Goebel et al., 2001)]. Taking the evidence collectively, not all necessarily found in all subjects, the findings are as follows:

LOCALIZING AND DETECTION Subjects have been asked to attempt to localize the position of a brief, fixated stimulus by making an eye movement to the supposed locus of the stimulus, typically a briefly flashed spot (Pöppel et al., 1973), or by pointing or touching the locus of a target on a perimeter screen (Weiskrantz et al., 1974), even though they deny seeing the stimulus. In yet another study, G.Y. was trained to give a numerical score on a ruled scale to successfully describe the locus (Barbur et al., 1980). Localizing accuracy is typically not as good as in the intact visual field but nevertheless can be very impressive. Successful detection is obviously a necessary prerequisite for localization or any other discriminative capacity, but detection has also been studied independently of localizing (Azzopardi and Cowey, 1997; Barbur et al., 1980; Stoerig, 1987; Stoerig et al., 1985; Stoerig and Pöppel, 1986; Weiskrantz, 1986).

ACUITY D.B.'s acuity was measured with large Moiré fringe interference gratings (approximating sine-wave gratings) based on forced-choice guessing for the presence of a grating versus a luminance-matched homogeneous patch. The reduction in acuity for the region 16–20 degrees eccentric was about 2 octaves compared to the mirror-symmetric region of the intact field (2.5 c/deg compared with 10 c/deg) (Weiskrantz, 1986). Other acuity measurements have been derived from contrast-sensitivity functions in the scotoma (e.g., with G.Y.), using forced-choice detection of a grating versus a homogeneous patch. Acuity falls to zero at approximately 7 c/deg, which again is approximately a drop of about 2 octaves compared to his intact field (Barbur et al., 1994a; Weiskrantz et al., 1998). The reduction is in agreement with animal evidence (Miller et al., 1980).

ORIENTATION D.B. has repeatedly demonstrated good discriminative capacity for orientation of lines and a grating in the frontal plane in the blind hemifield, although not as sharp as in his good field. He could nevertheless discriminate a difference in orientation of 10 degrees between two gratings presented successively and briefly, even at an eccentricity of 45 degrees in the impaired field, with no acknowledged experience with the gratings or even with the brief flash. Other subjects who have been tested have shown more variable residual capacity for orientation (e.g., Barbur et al., 1980). For example, G.Y. does not show orientation discrimination using gratings, but positive evidence has been obtained using single lines (Morland et al., 1996).

COLOR Spectral sensitivity functions of the blind hemifields of several hemianopes have been measured by Stoerig and Cowey (1989, 1991, 1992; Cowey and Stoerig, 1999) and been found to be qualitatively similar to those of their normal hemifields, although with quantitatively reduced sensitivity. The profiles include the humps and troughs thought to reflect color opponency; they also show the characteristic loss of long-wavelength sensitivity following dark adaptation, the *Purkinje shift*. Strikingly, wavelength *discrimination*, such as red versus green, but even of more closely spaced wavelengths, is possible in some subjects (Stoerig and Cowey, 1992) using forced-choice guessing. Barbur et al. (1994b) demonstrated good discrimination between “colored” patches and achromatic patches matched in luminance using a two-alternative forced-choice (2AFC) paradigm in G.Y. Ruddock and his colleagues (Brent et al., 1994) have also found good discrimination between red and achromatic stimuli in G.Y. It appears, in this connection, that the discriminative sensitivity of the blind field is biased toward the red end of the spectrum. In addition to wavelength discrimination, a strong inference can be drawn from pupilometry that *successive color contrast* is intact in G.Y., another hemianopic blindsight subject (Barbur et al., 1999), and recently also confirmed with D.B.

While residual color mechanisms can be found, it should be stressed that in all of these studies, the subjects *never* reported any experience of color per se. It is worthwhile to note Stoerig and Cowey's comment about the subjects' commentaries:

the patients were often asked whether they could perceive anything when the blind field was tested. Throughout the experiments, which involved from 2 to 4 three-hour sessions per month for approximately six months, they consistently claimed that this was not the case and that they never saw or felt anything that was related to stimulus presentation. (1991, p. 1496)

MOVEMENT AND TRANSIENT STIMULI This subject has long antecedents given the classical evidence of Riddoch (1917) and Poppelreuter (1917/1990), who described wartime gunshot-wound patients who could see moving but not stationary stimuli. Reports of detection and tracking of moving stimuli in their impaired fields are among the earliest observations of human subjects (Barbur et al., 1980; Brindley et al., 1969; Denny-Brown and Chambers, 1955) and of the monkey (Humphrey, 1974). Using threshold determinations, D.B. was shown to have good ability to detect moving bars and spots, although with reduced sensitivity, depending on the location in the blind field (Weiskrantz, 1986). A number of parametric psychophysical studies of *directional* discrimination of moving spots or bars have been carried out by Barbur and his colleagues on G.Y. (Barbur et al., 1993; Sahraie et al., 1997, 1998; Weiskrantz et al., 1995; cf. also Perenin, 1991), who measured the limits of velocity and

contrast for successful directional discrimination in the blind field. Some of these studies led to the experimental exploration of the distinction between *awareness* and *unawareness* modes and also to brain imaging (see below).

While there is no question that blindsight subjects can detect moving bars or spots and discriminate their direction of movement, other modes of movement discrimination, namely, the discrimination of direction of movement of random dot kineograms and plaids, has been found to be lacking (Azzopardi and Cowey, 2001; Cowey and Azzopardi, 2001).

Temporal onset/offset transients also are of particular significance in the blind field. Weiskrantz et al. (1991) carried out a systematic study in G.Y. by varying the temporal slope of the Gaussian envelope of the onset and offset of stimuli in a 2AFC paradigm for gratings versus equiluminant homogeneous patches. Performance improved as the temporal slope increased. In a related study, the manipulation of spatial as well as temporal transients also allowed a specification to be made of both the spatial and temporal parameters required for good detection. From such determinations, it was possible to conclude that G.Y.'s blind field possesses a narrowly tuned spatiotemporal visual *channel*, with a peak of about 1 c/deg and a cutoff (*acuity*) of about 7 c/deg (Barbur et al., 1994a). This can now be linked to a closely similar channel in monkeys revealed by pupillometry (see below). It appears to be characteristic of a number of hemianopic subjects, although with a small variation in the peak spatial frequency.

A somewhat different approach had been used in an early study of D.B. in which the temporal rate of onset was varied systematically over a wide range in a forced-choice discrimination paradigm between a circular, homogeneous luminous disc versus no stimulus. Although the sharper the rate of onset the better the performance, D.B. still performed reliably well above chance, and without acknowledged awareness, even with extremely slow rates of onset (Weiskrantz, 1986, Chapter 9). Therefore, a rapid temporal transient is not a necessary feature for good detection. It also indicates that this mode of blindsight is quite different from that in the early reports by Riddoch (1917) that described vigorous movement in the blind field.

“FORM” Early reports of evidence for shape discrimination were negative or weak (cf. Weiskrantz, 1986). With reaching responses, however, when subjects are asked to grasp solid objects in their blind fields, the situation may be different. Both Marcel (1998) and Perenin and Rossetti (1996) have reported that the subject's hand adopts the appropriate configuration in advance of grasping an object in the blind field. This result is nicely in accord with Milner and Goodale's (1995) thesis that the shape and orientation of objects can be involved in directed visual actions via the dorsoventral

stream toward the objects even when subjects are unable to perceive the objects correctly. Less easy to accommodate on such a basis, on the other hand, is the evidence for color processing and the striking claim by Marcel (1998) that words flashed into the blind field can influence the interpretation of meanings of words subsequently shown in the intact field. This intriguing report is isolated and deserves to be followed up. It would require considerable expansion of the known capacity for residual processing of stationary shapes in the blind field.

EMOTIONAL CONTENT There are reports that conditioned aversive properties of stimuli in normal human subjects can give rise to autonomic responses even when the subjects have no awareness of them (Esteves et al., 1994; Öhman and Soares, 1998). Functional imaging studies have also demonstrated that conditioned fear stimuli rendered invisible by backward masking can nevertheless activate the amygdala via a colliculo-pulvinar pathway (Breiter et al., 1996; Morris et al., 1999). Behavioral evidence from monkeys with V1 removal suggests that the blind field is inert to the emotional content. For example, when a fear-evoking stimulus, such as a strange doll, is presented to the affected hemifield, the animal appears to ignore it completely, although it emits loud shrieks of fear and outrage when it is confronted in the normal visual field. Nor does it react, for example, to a highly prized banana in the blind field (Cowey, 1967; Cowey and Weiskrantz, 1963). On the other hand, no concurrent measures of autonomic activity were made, and it remains possible that emotion-provoking stimuli produce responses in the absence of overt behavioral responses, just as, for example, galvanic skin responses can be recorded to familiar faces in prosopagnosic patients who cannot distinguish familiar from unfamiliar faces perceptually (Tranel and Damasio, 1985).

A recent study of faces with emotional expression projected to G.Y.'s blind field has some direct relevance (de Gelder et al., 1999). G.Y. has been shown to be able to discriminate between different facial expressions in moving (but not stationary) video images projected into his blind field, such as happy versus sad, angry versus fearful. Strikingly, he could also identify which of four different emotional expressions were presented on any single exposure. He failed to “see” the faces as such, and his responses were at chance with inverted faces. Using cross-field interactions between blind and intact hemifields (see below), evidence was found for face processing with stationary exposures. It remains unknown whether his autonomic system would also be sensitive to emotional stimuli that he can discriminate in the absence of seeing. A recent functional MRI (fMRI) study using a conditioned fear paradigm in G.Y. demonstrated that the amygdala is activated by the conditioned stimulus presented to the blind field, and that the amygdala's activity

correlates with activity levels in the superior colliculus and pulvinar. Thus, a route that bypasses V1 evidently remains intact for activation by emotional events (Morris et al., 2001).

ATTENTION IN THE BLIND FIELD It has been demonstrated with G.Y. that attention can confer an advantage in processing stimuli in the blind field either within an attended time interval or at an attended spatial location. Using a Posner cueing paradigm, G.Y.'s discrimination of the location of a stimulus was improved by a visual cue that provides temporal information about the time window within which the targets will appear (Kentridge et al., 1999a). Cues in the blind field that provide information about the likely spatial location of a target also confer an advantage, strikingly in the complete absence of reported awareness of either the cue or the target. Cues in G.Y.'s blind field were effective even in directing his attention to a second location remote from that at which the cue was presented, again under conditions in which there was no reported awareness of the cue or the target (Kentridge et al., 1999b). Such evidence suggests that spatial selection by attention, on the one hand, and conscious awareness of attentional control, on the other, cannot be the same process.

Verbal versus nonverbal approaches

AWARENESS VERSUS UNAWARENESS With the exception of D.B., verbal reports have not been explicitly assembled until recently. But it was noted in D.B. that transient stimuli, for example, of movement, looming and recession, or abrupt onset and offset, gave rise to a report of "awareness," a "feeling," or "knowing" that an event has occurred. These experiences were apt to mislead D.B. as to the identity of the event, so such transients were avoided by varying contrast and other conditions (see Weiskrantz, 1986, Chapter 13), and hence most of the studies with him involved visual discriminations in the absence of any awareness. A similar distinction between performance with and without awareness emerged in studies with G.Y. and other subjects, and has been named as a distinction between *blindsight type 1* (no awareness) and *blindsight type 2* (with awareness but not perceptual seeing) (Weiskrantz, 1998b, 1998c, 2000). The distinction is not necessarily binary, but serves as a convenient label for distinguishing some experience of awareness from complete nonawareness. Comparisons between functions with and without awareness are assessed with a *commentary key* paradigm. In addition to the usual pair of response keys for discriminating the stimulus events, two other commentary keys were introduced with which the subject could signal awareness or no awareness after each trial (Weiskrantz et al., 1995). The application of the paradigm with discrimination of movement direction is shown in Figures 40.1 and 40.2, with variations of velocity or contrast to affect the incidence

FIGURE 40.1. Directional movement discrimination performance for a moving spot presented to G.Y.'s blind hemifield as a function of stimulus speed. The subject had to discriminate (by guessing, if necessary) whether the stimulus moved horizontally or vertically by pressing the appropriate response key. Commentary keys were provided on which he also had to indicate on each trial whether he had any experience whatever of the stimulus event. *Awareness* refers to the percentage of trials on which he pressed the "yes, had experience" key. *Correct when unaware* refers to performance during those trials when he pressed the "no, I had no experience at all" key. Performance was high even without reported awareness. (From Weiskrantz et al., 1995, with permission. Copyright National Academy of Sciences, USA.)

FIGURE 40.2. Conditions as in Figure 40.1, but with stimulus contrast varied instead of speed. The luminance of the test spot was constant, at 131 cd/m², and background luminance changed systematically. Awareness declined steeply as background luminance increased, but performance remained relatively stable. (From Weiskrantz et al., 1995, with permission. Copyright National Academy of Sciences, USA.)

of awareness reports and the corresponding discriminative performance. It can be seen that performance can remain high and relatively independent of awareness levels as such. The relationship between commentaries and confidence reports has also been examined in a further extension, as well as the use of multivalues versus binary scales (Sahraie et al., 1998). The paradigm was applied in an imaging study of the two blindsight modes (Sahraie et al., 1997; see below).

NONVERBAL, INDIRECT METHODS OF REVEALING RESIDUAL VISUAL FUNCTION Particular problems of confidence and credibility arise for many subjects (and some experimenters) about requests to make counterintuitive judgments about stimuli they cannot see. Aside from that, parametric psychophysics carried out by forced-choice guessing or reaching require multiple and lengthy sessions, often totaling thousands of trials. In other areas of cognitive neuropsychology, residual function can be tested quite readily by methods that do not directly assault credibility. For example, the amnesic patient can be asked to try to identify a word when presented with its first three letters, thereby enabling the experimenter to infer that an earlier exposure to the word (the *prime*) has facilitated its identification without requiring the subject to remember as such.

Two general indirect methods have been used in testing for residual visual function without requiring the subject to guess “without seeing”: (1) reflexes to visual stimuli in the blind hemifield and (2) interactions between the intact and impaired hemifields. The field has been reviewed by Weiskrantz (1990) and by Stoerig and Cowey (1997).

Reflexes. Reliable electrodermal responses to lights versus “blanks” in the blind hemifield were found by Zihl et al. (1980). Such responses, however, are difficult to relate in a directly quantitative way to the visual events. The pupil response, in contrast, provides a direct and incisive quantitative measure because it constricts differentially to visual stimuli, depending precisely on the parameters of spatial frequency, wavelength, and movement, even when there is no change in the total luminance of the stimuli (Barbur and Forsyth, 1986; Barbur and Thomson, 1987). As the pupil response is independent of verbal report, it can be used to assess the blind fields of human patients, of animals, and of human infants (cf. Cocker et al., 1994).

In this way, for example, the pupil has been used to measure the profile of sensitivity to gratings in the blind field as a function of spatial frequency, and thereby to obtain an estimate of contrast sensitivity and of visual acuity. Weiskrantz et al. (1998), examined the spatial frequency profiles of the affected hemifields of G.Y. and also of two monkeys with unilateral removal of striate cortex (V1), using *P-scan pupillometry* (Barbur et al., 1987). The results were very clear (Fig. 40.3). In both the human and the monkeys, there

FIGURE 40.3. Relative normalized size (peak at 100) of pupil constriction (*solid lines*) as a function of spatial frequency of an equiluminant grating presented to the blind hemifields of a human subject (G.Y.) and two monkeys (Baa and Mei). The dotted line shows psychophysical performance for G.Y. from an earlier study (Barbur et al., 1994a) for gratings versus an equiluminant featureless stimulus. (From Weiskrantz et al., 1998, with permission. Copyright Oxford University Press.)

is a narrowly tuned response of the pupil to different spatial frequencies of an achromatic grating, with a peak at approximately 1 c/deg. The acuity (the point at which the response falls to zero as spatial frequency increases) is at about 7 c/deg, a reduction of about 2 octaves compared with the intact hemifields under these conditions. G.Y.’s pupillary response could be validated psychophysically with a spatial-temporal tuning curve obtained in an earlier study (Barbur et al., 1994a). The psychophysical function and the pupillary profile map onto each other quite closely (Fig. 40.3), confirming the potential usefulness of pupillometry as a clinical screening device. Recently, it has been possible to make the same comparison between psychophysics and pupillometry for D.B. (L. Weiskrantz and A. Cowey, unpublished), with a similar close agreement (Fig. 40.4). The strikingly close similarity of the monkey and human results is further evidence that similar mechanisms are involved following V1 removal in both species, and is counter to the view that in residual function the human must depend on fragments of intact visual cortex, given that there are demonstrably no such fragments in the monkey. The occurrence of the pupillary response does not depend on the subject’s having blindsight type 2 (see above). It still constricts to a 1 c/deg isoluminant grating even when the onset and offset of the grating are smoothed so as to eliminate G.Y.’s reported awareness of the event (Weiskrantz et al., 1999). Given that pupillometric acuity changes with V1 removal, there must be a direct

FIGURE 40.4. Change in pupillary area (solid line) for subject D.B. as a function of spatial frequency, and percentage correct discrimination performance for gratings versus equiluminant featureless stimulus, with forced-choice guessing (dotted line). The subject's commentaries for each of the spatial frequencies tested are shown below the figure, together with the relevant percentage of correct performance. (Note that for this subject psychophysical sensitivity is slightly better than for pupillometry; the subjects performance is 75% correct when the pupil fails to respond.) (From L. Weiskrantz and A. Cowey, unpublished.)

downstream influence of cortex reaching the midbrain mechanism that provides the final efferent to the pupillary musculature.

Interactions between intact and blind hemifields. Torjussen's work (1976, 1978) provides the seminal example demonstrating completion of shapes shown to the blind and intact hemifields simultaneously. The subject reports seeing nothing when a stimulus is presented to the blind field but sees a normally completed stimulus which bridges the intact and impaired fields. More recently, this method has been used by Marcel in two hemianopes, one of whom was G.Y. (Marcel, 1998), and also by Perenin et al. (1985).

A related approach was designed by Marzi and colleagues (Corbetta et al., 1990) in which the reaction time of a key-press response to a light in the intact field could be increased by a light presented immediately beforehand in the impaired field of human subjects. A similar finding has been reported for the monkey: an unseen target slows the reaction time to the seen target, especially at delays on the order of 400–500 msec (Stoerig and Cowey, 1997). A contrasting approach, based on facilitation rather than inhibition, was used by Marzi et al. (1986), exploiting the fact that the reaction time to two flashes presented simultaneously is consistently faster than the reaction time to a single flash, whether or not the two flashes appear in the same hemifield or in opposite

fields. The reaction time of hemianopes can be speeded up when the two flashes are presented across the vertical meridian, even though the subject only reports seeing a single stimulus, that is, the one in the intact hemifield. Recently, the same approach has been used by Tamale et al. (1997) to demonstrate visual spatial summation in hemispherectomized subjects. de Gelder et al. (2001) also have used the method to conclude that there was facilitatory interaction of face processing between G.Y.'s blind and intact fields.

Functional brain imaging

G.Y. has been the subject of both positron emission tomography (PET) and MRI investigations. Barbur et al. (1993) studied the difference between moving and stationary bars with PET. The results focused on the activation found in area V5 in association with moving stimuli. In this situation, G.Y. was typically aware of the movement, that is, it was blindsight type 2; blindsight type 1 was not investigated.

The distinction between directional movement discrimination *with and without awareness* (e.g., type 2 vs. type 1) was the explicit focus of a subsequent fMRI study of G.Y. (Sahraie et al., 1997) using parameters that had been previously established (Weiskrantz et al., 1995) to produce good discrimination both with and without awareness. The stimulus contrast and velocity parameters that had previously been used to establish this difference psychophysically (see above) served to design the stimuli in the imaging study. There was an association between the "awareness" mode and activity in dorsolateral prefrontal activity (areas 46 and 47), both when the subject was "aware without seeing" in the blind hemifield and when he was "aware with seeing" in the intact hemifield. In the "unaware" mode but associated with good discrimination, and only in this mode, there was activation in the superior colliculus. Although these associations with awareness and unawareness modes were unique, the main conclusion of the paper stressed the general change in pattern between the two modes—from dorsolateral structures in the former to medial and subcortical structures in the latter.

Another fMRI study focused on colored stimuli, specifically of red and green, presented to G.Y.'s blind hemifield. It had previously been established, both by pupillometry and by psychophysics, that there was a differential sensitivity to red compared with green colors (although it must be stressed again that the subject did not report any experience of color as such). Activation of the superior colliculus was found by a red but not by a green stimulus in the blind hemifield. No such midbrain activation was found in the sighted hemifield (Barbur et al., 1998).

Finally, a recent fMRI study of G.Y. and E.S. reported "surprisingly strong" responses to stimulation of the blind field in ipsilateral extrastriate areas, using stimuli intended

to activate either the dorsal or ventral pathways, but no detectable activity in the early visual areas of the lesioned hemisphere (Goebel et al., 2001).

Animal homologs

As already mentioned, blindsight stemmed from the long-standing evidence that infrahuman primates can make visual discriminations in the absence of striate cortex, while humans with such damage describe themselves as being blind to experience in the relevant parts of the visual fields. With appropriate testing methods, the quantitative effects of visual cortex damage in monkeys and human blindsight subjects are similar in many respects. But an important and much deeper qualitative question remains: does the monkey without striate cortex, which can localize and discriminate visual stimuli so impressively, actually have *visual experience* of those stimuli in its affected hemifield? Seminal experiments addressing this question were carried out by Cowey and Stoerig in 1995. After confirming that monkeys could accurately localize and reach for a briefly presented visual stimulus in their “blind” hemifields, they proceeded to a second experiment with the same animals: they were trained to discriminate between randomly presented “lights” and “no lights” (i.e., blanks) in their intact hemifields and were rewarded for correct responses (reaching for a light or pressing a “blank panel” for a nonlight). The crucial question after this training was completed was, how would the animals respond to a visual stimulus in their blind hemifields? The answer was clear and robust: the monkeys pressed the blank panel. That is, even though the animals had just demonstrated that they could detect the lights with virtually perfect performance, they nevertheless treated them as blanks, as *nonlights*. This is just what a human blindsight subject would do, of course. Some further experimental extensions of this paradigm are discussed by Cowey and Stoerig (1997) in an excellent review of the comparative issues. The matter is also discussed, at a more general level, in Weiskrantz (1997, Chapter 4).

Two important studies carried out by Charles Gross and his colleagues are also relevant to the animal-human parallel. Monkeys were trained to make a saccadic eye movement from the point of fixation to a visual target in their blind hemifields (Moore et al., 1995). Performance was good when they had a warning signal (the turning off of the fixation point). But without such a warning, they failed to initiate the eye movement to the target. The authors draw the parallel with clinical testing of human patients with field defects caused by visual cortex damage: typically in clinical perimetric testing, subjects are not given warning signals and are blind to visual events in their field defects. In blindsight experiments carried out in the laboratory, however, warning signals are routinely used.

But even the need for a warning signal disappears if the unilateral V1 damage is imposed in infancy (Moore et al., 1996). Other animal work (Payne, 1994) also supports the conclusion that greater recovery is possible after early than after late damage to the visual system and is accompanied by anatomical reorganization. It may be relevant that the two most thoroughly studied human patients, D.B. and G.Y., both had visual defects in childhood, G.Y. because of head injury at the age of 8 and D.B. because of an incipient occipital tumor which first gave rise to a clinical problem at the age of 14, although the pathology might well have been present much earlier, perhaps even prenatally (Weiskrantz, 1986).

A related issue concerns the role of practice in recovery of residual function. It was demonstrated some time ago (Cowey, 1967; Mohler and Wurtz, 1977) that if monkeys with visual cortex lesions are given sustained practice with visual discriminations in their blind fields, their sensitivity increases. This increase can be substantial—as much as 3 log units. The size of the field defect also shrinks. But improvement depends directly on whether the animal is actually *required* to practice with stimuli directed within the field defect; in fact, Mohler and Wurtz showed that recovery was specific even to practice *within a subpart* of the field defect. The typical hemianope, whether human or animal, has no particular pressure to exercise the affected hemifield, given the preservation of a normal intact hemifield, which may be why specific practice has to be prescribed. The beneficial effect of practice in human patients, using a procedure based on the method of Mohler and Wurtz, has been demonstrated by Zihl and colleagues (Zihl, 1980, 1981, 2000; Zihl and von Cramon, 1979, 1985). Recently, other investigators (Kasten and Sabel, 1995; Kerkhoff et al., 1994) have also reported encouraging results with human patients, using similar techniques.

Validation issues

Some of the issues of validation and theoretical interpretation are the same throughout all varieties of implicit processing in neuropsychological subjects, and some are unique to blindsight. A fuller treatment of these issues can be found in Weiskrantz (1997, 1998a, 2001a, 2001b). Briefly, however, some of these issues relevant to blindsight are as follows:

STRAY LIGHT, INTRAOCULAR DIFFUSION, EYE MOVEMENTS, AND OTHER POSSIBLE OPTICAL ARTIFACTS Hemianopic subjects have an intact, normal visual hemifield ipsilateral to the lesion, so it is important to rule out the possibility that alleged processing by the blind field is not, in fact, being carried out by stray light or intraocular diffused light reaching the intact hemifield (Campion et al., 1983). Such a factor

could not, of course, apply to stimuli which would be severely degraded by diffusion, such as high spatial frequency gratings for measuring acuity in the impaired field. Stray light has been controlled in a variety of ways—for example, by flooding the intact visual hemifield with high levels of illumination so that if there were any stray light, it could not be detected. The stray light function has also been determined experimentally (Barbur et al., 1994a). The most demanding method to ensure that there can be no effective entrance of stray light into intact parts of the field is to use the *genuinely* blind part of the eye as a control, the optic disc, in which there are no receptors. As the size of this natural absolutely blind area is known (5×7 degrees), maximum diffusion would be no more than half the size of the disc for stimuli that are not detected on the disc. When the subject's performance is at chance for stimuli on the disc, it is above chance on the neighboring region. Weiskrantz and Warrington (cf. Weiskrantz, 1986, Chapter 10), Stoerig et al. (1985), and Tomaiuolo et al. (1997) have used this control effectively. It can be said with assurance that residual visual capacity in the blind field of hemianopes cannot be explained away as a matter of stray light or intraocular diffusion.

Eye movement recordings and monitoring are standard features of many studies, which have ruled out inadvertent fixation shifts, as well as the use of stimuli too brief to survive a saccade. A Purkinje eye-tracking device has also been used with G.Y., which ensured that even if the eye moved, the stimulus would remain fixed on the same retinal location (Kentridge et al., 1997). Residual function cannot be explained away in terms of inadvertent fixation shifts.

INCIDENCE Across a random sample of patients with hemianopias resulting from cortical damage, it is still not known how many would be likely to demonstrate blindsight. Blythe et al. (1987) found 5 patients (one of whom was G.Y.) with evidence of residual function (responses to movement and localization by reaching or eye movements) out of a studied population of 25. Similarly, Weiskrantz (1980) found, in a study of acute hospital patients, that 14 hemianopic patients out of 69 showed some evidence of residual function. In the remainder, either no such evidence was found or it remained inconclusive.

Why should the incidence of residual function apparently be low? Briefly, there are at least four reasons (cf. Weiskrantz, 1998a). One of the most important is likely to be the variable extent of the occipital lesions in human subjects and the unlikelihood of any such lesion being restricted to V1, which itself is buried deep in the medial aspect of the brain. As noted above, animal work has demonstrated that extensions of lesions beyond V1 reduce the degree of residual function, and many lesions seen clinically probably lead to the same diminution, especially as the visual association

areas in the vicinity of V1 are tightly compressed. Secondly, the age at which the lesion occurs could be important, as has already been demonstrated in animal work (Moore et al., 1996; Payne, 1994) (see above). A third reason for possibly variable incidence is the strangeness of the question that the researcher is bound to ask when testing blindsight type 1, when subjects are asked to guess about stimuli of which they have no awareness. Some refuse to do so. The problem is compounded by the need to test subjects extensively over tens of hundreds of trials to obtain parametric families of functions. This no doubt is why research has been carried out on only a relatively small number of long-suffering subjects with the appropriately delimited lesions, who are willing or able to make themselves available, and also why indirect methods have commended themselves (see above).

A final reason is that the stimulus parameters used in testing for residual function can be critical—parameters that may be suitable or even optimal for normal function may not apply to that of the blind field. Even a slight change in the slope of the temporal onset or offset of the stimulus can transform chance performance into virtually perfect performance. For example, Hess and Pointer (1989), using particular fixed parameters of temporal and spatial Gaussian envelopes of unstructured stimuli, concluded that there was no residual function in G.Y. (and other subjects). This negative result was confirmed (Weiskrantz et al., 1991) using the same parameters as Hess and Pointer, but a relatively small change in the parameters led to excellent performance by G.Y. in his blind hemifield. This and another example of an apparently unfortunate choice of parameters is discussed in Weiskrantz (1997, pp. 154–155, 247–248). A more important question lies at the heart of the issue of parameters: whether one chooses fixed parameters of visual stimuli for testing the population or varies the parameters and categories over a wide range for each patient, seeking those that will reveal residual function. The latter approach may be why Teuber et al. (1960) found not a single case of occipital damage in a war-injured population of 46 patients who did not exhibit some measure of residual visual function in the field defect. One may also cite Poppelreuter's conclusion (1917/1990) that he could never find an absolutely blind scotoma in his wartime brain-injured patients. In current research, Sahraie and Weiskrantz (in preparation) have found that in most patients, some residual function can be revealed when spatial frequency and temporal frequency parameters are varied widely until the psychophysically sensitive region is located.

COMPLETENESS OF THE VISUAL CORTIX LESION AND EXTENSIONS TO NONSTRIATE CORTIX It is a complicating fact that damage in human clinical patients is rarely confined to striate cortex. A further possible complication is that the damage to striate cortex itself may not be complete. Some

have argued—along the lines of the late-nineteenth-century view that assigns special higher properties to cerebral cortex (cf. Weiskrantz, 1961, for a critique)—that intact striate cortex is itself necessary for the capacity to make visual discriminations. In particular, Fendrich et al. (1992), Gazzaniga et al. (1994), and Wessinger et al. (1997) have argued that blindsight, when demonstrated, may depend critically not on extrastriate pathways, but on small islands of intact striate cortex. Briefly, they found small islands of intact visual function in an otherwise dead visual hemifield of occipital patients; it was blindsight because the subjects reported no awareness of the stimuli within the island. Brain imaging also revealed a small region of intact striate cortex at the occipital pole (which would be expected, of course, in a subject with macular sparing). Their evidence was found using an eye tracker, which allows the visual image to be fixed on the retina (within limited eccentricities) and which thus eliminates detection due to inadvertent or uncontrolled fixation shifts (although these have been controlled by other methods in earlier blindsight studies; see above).

It may well be that some cases are amenable to an explanation in terms of intact, tiny islands of striate cortex, but it does not follow that this is the only explanation even in such cases, nor can it be a general explanation of all examples of residual visual function with V1 lesions. The question has been reviewed more fully in Weiskrantz (1998a). Briefly, *no* islands were found in G.Y. using the same eye-tracking apparatus and the same parameters as in the Fendrich study (Kentridge et al., 1997).

Secondly, such an account cannot apply to the closely convergent evidence with monkeys, in which the completeness of the lesion and the absence of islands can be confirmed with certainty. Thirdly, “patchiness” of the visual field, when and if it is found, need not imply islands of cortex, because V1 lesions can cause patchy transneuronal degeneration of ganglion cells in the retina (Cowey et al., 1989, 1999; Van Buren, 1963), especially in the p-beta class of cells. The retina itself can be patchy. Finally, high-resolution MRI scans of the most highly studied subject do not reveal intact islands of tissue (aside from those at the pole, corresponding to his region of macular sparing), nor do PET or fMRI scans reveal any functioning visual cortex when he is stimulated in his blind field. (Barbur et al., 1993, 1998; Sahraie et al., 1997; A. Morland, personal communication).

ASSESSMENT OF BLINDSIGHT IN RELATION TO RESPONSE ASSESSMENT AND RESPONSE CRITERIA Stoerig et al. (1985) deliberately varied response criteria without affecting detection thresholds with blindsight subjects, although performance levels were admittedly relatively weak. The demonstration of discriminative performance in blindsight, when it is good, can be assessed in standard statistical terms without any reference to signal detection theory.

In contrast, theoretical concern lies more with the much lower levels of performance, usually chance or near-chance levels. Clinical procedures typically involve a “yes, I see” or “no, I do not see” response to a stimulus in the blind field, which is typically the evidence upon which a claim of blindness is based. In signal detection terms, however, a subject may have high sensitivity (d') even though the measured performance level at 50% because of response criterion bias (e.g., if the subject is very cautious and responds “no” on every trial). Experimental studies of the capacity of the “blind” field, on the other hand, are often carried out with a more rigorous procedure, such as a 2AFC, which tends to be free of response bias. Therefore, the question is whether the dissociation between the reported blindness of the affected field versus its positive residual blindsight function merely reflects different response criteria in the yes/no versus the 2AFC discriminating modes.

Azzopardi and Cowey (1997) addressed this in a signal detection comparison of these two modes of responding, 2AFC versus yes/no, in G.Y. using a grating stimulus versus an equiluminant uniform patch with a range of stimulus contrasts. For both paradigms (“Was the grating in the first or the second temporal interval?” and “Was there a stimulus or not?”), they obtained Receiver Operating Curves, and hence could derive measures of sensitivity (d') that were independent of response criteria. The result was that in normal subjects the two measures of sensitivity were identical—saying “yes” or “no” yielded the same outcome as judging in which of two intervals the stimulus occurred in the 2AFC. But for G.Y. the result was quite different: he was much more sensitive in the 2AFC paradigm than in the yes/no paradigm. This is, of course, exactly the difference implied in the meaning of blindsight itself: there is good performance when the subject is forced to make a response to a stimulus as opposed to making a see/not see judgment, as in clinical perimetry.

However, a deeper question arises regarding the applicability of signal detection theory to evidence for blindsight, which essentially is a disjunction between forced-choice discriminations and the commentaries that relate to them. Signal detection theory is useful and powerful for characterizing the sensitivity and response bias in the performance of discriminations but not for characterizing off-line commentaries made about the discriminations. This raises questions of veracity rather than bias (cf. Weiskrantz, 2001a). An alternative approach is to use scale discriminations and commentaries independently and to plot their correlations or dissociations.

DOES BLINDSIGHT DIFFER QUALITATIVELY OR JUST QUANTITATIVELY FROM NORMAL VISION? Azzopardi and Cowey take their results to imply “that blindsight is not just normal, near-threshold vision and that information about the

stimulus is processed in blindsighted patients in an unusual way" (1997, p. 14190), which is the view originally advanced for blindsight (cf. Weiskrantz, 1986). One important difference between blindsight and normal vision is the serious disjunction between on-line discriminative processes and off-line commentaries or judgments that arise in blindsight. For example, Kentridge et al. (1999a) examined correlations in G.Y. between commentary-key responses ("aware" or "not aware") and 2AFC spatial localization discriminations in the good and bad fields, selecting approximately similar levels of discrimination for both fields. In fact, a double dissociation emerged: even though G.Y.'s 2AFC performance happened to be poorer in his good field than in his blind field, he had a higher level of awareness commentary responses in the good field than in the blind one. Warrington and Weiskrantz also reported a double dissociation between the intact and impaired fields of D.B., leading to the suggestion of a qualitative dissociation between form and detection between the intact and impaired fields (Weiskrantz, 1986, Chapter 16).

Other considerations speak against the conclusion that the properties of the blind field are simply a weaker version of normal vision. The levels of performance in the blind field can also be very high, approaching or reaching 100%, even when the subject reports complete absence of awareness, unlike the degraded levels characteristic of parathreshold levels in normal vision. Another consideration is that there is a retrograde transneuronal degeneration following V1 lesions both in humans (Van Buren, 1963) and in monkeys, resulting in a shift from a predominance of p-beta ganglion cells of the affected retina toward p-alpha and p-gamma cells. The latter classes of ganglion cells have different structures, different projections in the brain, and different functional properties from p-beta. In other words, the hemiretina corresponding to the field defect is qualitatively different from the normal hemiretina (Covey et al., 1989). Other differences (see above) include the finding that color discrimination and detection, measured psychophysically or by pupillometry in the blind field, appear to favor the red end of the spectrum, unlike a normal field, and the fMRI evidence shows a different pattern of activation in the brain images when G.Y. reports awareness and when he does not, despite comparable levels of performance psychophysically under these contrasting conditions.

Concluding comment

In the absence of V1, parallel extrastriate visual pathways can mediate visual discriminations in humans as well as in other primates, but we are only beginning to characterize the emerging dissociations. The most surprising aspect has been the contrast between subjects' reported lack of experience of visual stimuli, whether registered verbally or by commentary keys, and their objectively measured capacity or, in

the case of monkeys, their classification of the visual stimuli that they objectively can detect with impressive sensitivity as being blanks. But this same counterintuitive disjunction is found across the entire neuropsychological research spectrum—for example, commissurotomy, amnesia, aphasia, prosopagnosia, and dyslexia (see Schacter et al., 1988; Weiskrantz, 1991, 1997, for reviews.). Indeed, even in normal function, it could be argued that much, perhaps even most, neural processing proceeds without any associated awareness or other off-line measure of competence. An advantage of blindsight research is the greater anatomical and physiological knowledge of the visual system in relation to other syndromes. The hope is that blindsight research, in addition to helping to characterize the function of subcomponents of the visual pathways, may help to elucidate the disjunction between awareness and unawareness more precisely and to open up a route by which its neural underpinnings can be explored.

VI PROCESSING IN PRIMARY VISUAL CORTEX

41 Functional Connectivity in the Pathway from Retina to Striate Cortex

R. CLAY REID AND W. MARTIN USREY

BECAUSE THE TERM has been used in many different ways, it is important to define *functional connectivity* as it pertains to the early visual pathway: from retina to lateral geniculate nucleus to visual cortex. Although functional connectivity can simply refer to neuronal connections that function, we prefer to use it in much the same way that Hubel and Wiesel (1962, 1977) used the term *functional architecture*. Functional architecture refers to the way anatomical organization relates to neuronal function, such as retinotopy, ocular dominance, or orientation selectivity. Similarly, functional connectivity can be thought of as the presence (or absence) of connections between neurons as they relate to the neurons' visual functions.

Although any use of the term *connectivity* implies that there is a physiological relationship between the neurons (or groups of neurons), it could have many other connotations. Connectivity has been used to describe neurons that are related by a polysynaptic chain and even more loosely for neurons that tend to be coactive. For our purposes, we will use the term *connected* only for pairs of neurons for which the existence of a working synapse has been demonstrated physiologically. The presence of monosynaptic connections between neurons studied in vivo has been revealed almost exclusively with the tool of cross-correlation analysis. While cross-correlations in general cannot demonstrate causal relationships between neurons, in strictly feedforward pathways, monosynaptic connections can be demonstrated with a high degree of certainty (Reid, 2001; Usrey and Reid, 1999).

The distinction between anatomy and functional connectivity must be emphasized. At the finest level of detail, anatomy can show a morphological synapse, but it cannot demonstrate the physiological correlates of the synapse. More importantly for our purposes, anatomy (except in the retina) cannot be used to define the receptive field of a neuron. For instance, in the lateral geniculate nucleus (LGN) of the cat, current anatomical knowledge and techniques allow us to determine whether a projection neuron is an X cell or a Y cell, but not whether it is ON-center or OFF-center or the exact position of its receptive field. Therefore, physiological experiments are necessary to study the function of any given LGN cell.

In this chapter, we will concentrate on the visual system of the cat (particularly the X cell pathway) because of the detailed knowledge of its anatomy, visual physiology, and functional connectivity. For other species, in particular Old World primates, the anatomy and visual physiology of the pathway from retina through layer 4 of visual cortex are perhaps equally well understood. It is only in the cat, however, that functional connectivity as we have defined it has been studied.

In the cat retino-geniculo-cortical pathway, receptive fields of visual neurons are strongly suggestive of the pattern of connections that might be found between each level. In both retina and LGN, neurons have concentric receptive fields with centers, either ON or OFF, and antagonistic surrounds (Hubel and Wiesel, 1962; Kuffler, 1953). Thus, neurons are classified as either ON-center/OFF-surround or OFF-center/ON-surround. In the principal laminae of the LGN, A and A1, these neurons are further classified as either X cells or Y cells on the basis of additional response criteria. X cells sum their visual inputs in a linear fashion and have sustained responses with longer latencies between stimulus and response. Y cells have nonlinear spatial summation and more transient responses with shorter latencies. Because there is very little difference between the receptive fields encountered in the retina and LGN, it has been tempting to speculate that the connections between retinal ganglion cells and geniculate neurons serve the purpose of preserving the center/surround receptive field.

In contrast, in the pathway from LGN to visual cortex there are dramatic transformations in receptive field structure. These transformations are perhaps best documented and most pronounced in the cat (Hubel and Wiesel, 1962), in which a new receptive field type emerges in layer 4: the simple cell. Simple cells have elongated receptive fields with adjacent ON and OFF subregions. They respond best to bars or edges of light of a specific orientation, while their geniculate inputs respond well to stimuli of all orientations. Based on the structure of LGN receptive fields and simple cell receptive fields, Hubel and Wiesel (1962) proposed a straightforward model for the construction of simple cell receptive fields: simple cells receive convergent input from multiple LGN cells whose receptive fields are of the same

FIGURE 41.1. The Hubel and Wiesel model for the generation of simple cell receptive fields. On the lower right is a simple cell that receives convergent input from multiple LGN cells (only four are shown). The LGN cells have receptive fields that are the same sign (in this example, ON center) and are located along a line of visual space. This organization of LGN input gives the simple cell a receptive field with an elongated ON subregion (indicated by the interrupted lines in the receptive field diagram) and two adjacent OFF subregions. (From Hubel and Wiesel, 1962.)

sign and fall along a line of visual space (Fig. 41.1). Although this model is now generally accepted (Chapman et al., 1991; Ferster et al., 1996; Reid and Alonso, 1995), it was the source of tremendous controversy for over 35 years. As this chapter will show, the study of functional connectivity was key to demonstrating the relationship between geniculate and cortex in terms of how simple cell receptive fields are constructed.

Functional connectivity between retina and LGN: anatomical considerations

Despite the central importance of physiological experiments in the study of functional connectivity, anatomy is of course necessary to put physiological studies in context. The anatomy of a feedforward pathway can be studied at multiple levels of detail. At the broadest level, anatomical techniques can simply demonstrate the existence of a projection pathway, as has been known since classical times for the retinogeniculate pathway (Wade, 1998). Next, slightly finer techniques can be used to trace the projections of smaller groups of neurons, as was done in early studies that demonstrated the retinotopic mapping in the LGN and visual cortex (Le Gros Clark and Penman, 1934; Polyak, 1933). At the next level, single-cell labeling techniques (Golgi, horseradish peroxidase, biocytin) can be used to elucidate the structures of dendritic trees or of axonal arbors. Finally, individual synapses between neurons can be identified either with electron microscopy (Famiglietti and Peters, 1972; Guillery, 1969; Hamos et al., 1987; Mason et al., 1984) or, increasingly, with multiple-label confocal microscopy (e.g., Mills and Massey, 1999).

Although it would be difficult to use anatomy to study functional connectivity, as we have defined it, in the retinogeniculate pathway, our current knowledge of anatomy

allows us to approximate the range of convergent and divergent connections that might be made. Specifically, anatomy allows us to define an upper limit of the number of ganglion cell inputs to an LGN neuron or the number of LGN neurons receiving input from a single ganglion cell. These numbers can be derived in several different ways.

In visual neuroscience, the *coverage factor* has generally been defined as the number of neurons of a certain class whose receptive fields overlap a given point in visual space. A second use of the term is in the context of anatomy: the number of axons or dendrites of a given class that overlap in a given position within a neural structure. For retinal ganglion cells, anatomical and physiological coverage factors are closely related, because receptive-field centers are roughly equal in area to a ganglion cell's dendritic arbor (Wässle et al., 1983; see DeVries and Baylor, 1997).

The anatomical coverage factor is derived by first counting the number of retinal ganglion cells of a given class in 1 mm^2 of retina and then determining the average area occupied by each dendritic arbor. The product of these values yields the total dendritic area of all ganglion cells per square millimeter of retina, which is equivalent to the average number of dendritic arbors that overlap any point. The anatomical coverage factor for β cells in the cat retina (which correspond to X cells) is roughly 3 (Wässle et al., 1981).

Although the retinal coverage factor will in fact prove important for our discussion of the pathway between LGN and cortex, coverage factors in the LGN are more pertinent to our discussion of the retinogeniculate pathway. Although less has been written specifically about geniculate coverage factors (both by ganglion cell arbors and by geniculate dendritic trees), they can be calculated from values in the literature.

The total surface area of the A laminae in the LGN (A plus A1) is roughly 80 mm^2 (10 by $4\text{ mm} \times 2$; Sanderson, 1971), and there are approximately 100,000 X cells in the retina (reviewed in Peters and Payne, 1993); therefore, there are roughly 1250 retinal arbors per square millimeter in each lamina. The axonal arbor of each ganglion cell terminates throughout the thickness of its appropriate layer, but the cross-section is roughly circular, with a diameter of 0.1 mm (area = 0.008 mm^2) (Sur et al., 1984, 1987). The coverage factor of retinal axonal arbors in the LGN is therefore $1250 \times .008 = 10$. The dendritic trees of X-cell relay neurons in the LGN have the same dimensions as the retinal axonal arbors, but because there are roughly 2.5 more relay neurons in the X-cell system than retinal afferents (Peters and Payne, 1993), the coverage factor is 2.5 times greater. In other words, a single dendritic spine of an X cell in the LGN is within the terminal arbors of ~ 10 retinal ganglion X cells, while a single presynaptic bouton is within the dendritic trees of ~ 25 relay neurons. Therefore, simply from the

morphology of single neurons, the total area of the LGN, and the number of neurons, we have bounded the possible values of divergent and convergent inputs in the retinogeniculate system. Each LGN neuron could receive convergent input from more than 10 retinal neurons (because the dendritic arbor is not a single point). Each retinal neuron could diverge to form synapses onto at least 25 relay neurons. Although these morphological features would allow each relay neuron to receive inputs from many different afferents, only a few specific connections are made onto each cell. This specificity is seen physiologically (Cleland et al., 1971a, 1971b; Lee et al., 1977; Usrey et al., 1999; see below), and has also been demonstrated in a heroic ultrastructural study (Hamos et al., 1987) that found that a given retinal afferent makes synapses on fewer than 10% of potential targets in the LGN.

Functional connectivity between retina and LGN: physiological studies

An early indication that LGN neurons receive strong input from one or a few retinal ganglion cells with similar receptive fields came from the early work of Hubel and Wiesel (1961). By recording and comparing action potentials and S-potentials—the synaptic potential evoked by a strong retinal input (Bishop et al., 1958, 1962; Freygang, 1958; Kaplan and Shapley, 1984)—of individual LGN neurons, they demonstrated that connected cell pairs have receptive fields that overlap spatially and have the same response sign (ON or OFF). The major difference between geniculate receptive fields and retinal receptive fields is in the strength of their surrounds. Surround responses from geniculate cells are stronger than surround responses from retinal ganglion cells. By comparing the receptive field of a geniculate neuron's S-potential to the receptive field of the neuron's action potential, a number of more recent studies performed in both cat and monkey have demonstrated that geniculate neurons and their strongest retinal inputs are similar in terms of color selectivity, contrast sensitivity, and X/Y classification (Kaplan et al., 1987; Lee et al., 1983; Reid and Shapley, 1992; So and Shapley, 1981).

One drawback of using S-potentials as a measure of retinal input to a geniculate neuron is the fact that S-potentials can only be measured from retinal inputs that provide very strong input to the geniculate neuron; S-potentials cannot be measured from retinal inputs that provide moderate or weak input. Given this knowledge, it should not be surprising that geniculate neurons and their strongest retinal inputs have very similar receptive fields. By recording directly from the retina and LGN, one can compare the receptive fields of connected neurons, regardless of the strength of their connection. This dual recording technique was pioneered by Levick and colleagues (Cleland

et al., 1971a, 1971b; Levick et al., 1972). By moving the retinal electrode to record from different neurons, they demonstrated that it was possible to compare the receptive fields of multiple presynaptic neurons that converge onto a single geniculate neuron. More recently, the method of dual recording was revisited for the specific purpose of determining the specificity of both strong and weak connections from ganglion cells to geniculate neurons, as determined by cross-correlation analysis (Usrey et al., 1999). As expected, these studies demonstrated that receptive fields of strongly connected cell pairs are very similar in terms of spatial location, response sign, and X/Y classification (Fig. 41.2). In addition, these studies found that even weakly connected pairs are almost always from same-sign retinal cells with partially overlapping receptive fields. In summary, as the similarity between receptive fields decreases, so does the likelihood of connection and the strength of connection.

Functional connectivity between LGN and visual cortex: anatomical considerations

As with the retinogeniculate projection, the convergence and divergence of geniculate inputs onto their cortical targets can be estimated on anatomical grounds. First, the anatomical coverage factor of the thalamic afferents can give an upper bound for the degree of convergence. As reviewed by Peters and Payne (1993), an upper bound for this value can be obtained by multiplying the total number of afferents by the size of their axonal arbors and then dividing by the total cortical area ($240,000 \text{ cells} \times 0.6\text{--}0.9 \text{ mm}^2$, $399 \text{ mm}^2 = 360\text{--}540 \text{ cells}$).

The dendrites of stellate cells in layer 4 of cat visual cortex are similar in extent to the axonal arbors of the X-cell afferents, but there are roughly 50 times more stellate cells ($10\text{--}12 \times 10^6$; Beaulieu and Colonnier, 1987; Peters and Yilmaz, 1993) than there are X-cell afferents. The anatomical coverage factor is thus roughly 50 times higher: approximately 18,000–27,000. Therefore, the upper limit of *divergence* would be extremely large, were it not limited by the total number of boutons made by each X-cell arbor: roughly 3300. Even if each X cell never made more than one synapse onto each layer 4 neuron, it would contact only a fraction of potential targets.

An upper bound for the *convergence* onto each potential target in layer 4 can be estimated by similar arguments. Again following Peters and Payne (1993), this number can be estimated by considering the number of synapses from each thalamic afferent. The strategy is first to estimate the total number of geniculate synapses to all of area 17 and then to divide this value by the total number of potential targets. There are roughly 3300 synapses per X-cell arbor (Freund et al., 1985; Humphrey et al., 1985), which gives a total of 8×10^8 synapses for the afferent pool of 240,000 X

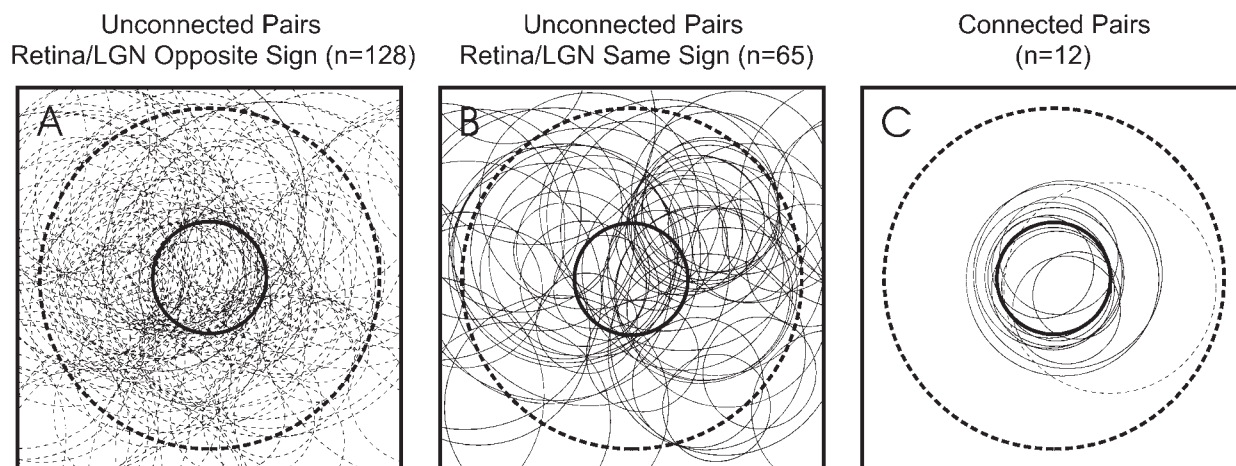

FIGURE 41.2. Summary of the specificity and strength of retinal ganglion cell input LGN neurons. Summary diagrams showing the spatial relationship of receptive fields of (A) unconnected retinal ganglion cells and LGN neurons with opposite (ON versus OFF) response signs, (B) unconnected retinal ganglion cells and LGN

neurons with the same response sign, and (C) connected pairs. In panels A–C, thick circles correspond to the LGN receptive field. Receptive fields were mapped using a white-noise stimulus; connectivity was assessed using cross-correlation analysis. (From Usrey et al., 1999.)

cells. Although we are emphasizing the X-cell pathway, Y cells provide a roughly equal number of synapses onto neurons in layer 4. Therefore, assuming that all cells in layer 4 receive an equal number of thalamic inputs, there are on the order of 150 afferent synapses per layer 4 neuron (16×10^8 synapses, 11×10^6 neurons). This value must be corrected by taking into account synapses onto apical dendrites from other layers that extend into layer 4. As outlined by Peters and Payne (1993), only 62.5% of synapses in layer 4 are onto layer 4 neurons. Therefore, a spiny stellate cell in layer 4 receives approximately 100 synapses from the LGN ($150 \times 62.5\%$).

Given approximately 100 geniculate synapses onto any given neuron in layer 4, one can then ask how many different inputs there might be. Although it is extremely difficult to approach this question anatomically, one ultrastructural study of thalamic input to individual layer 4 neurons provides some insight into the question. Freund et al. (1985) counted the number of synapses made by an individual geniculate axon onto four different cortical neurons in area 17 and found only one synapse per neuron in three cases and eight in the other case. From this very small sampling, the number of different thalamic afferents that converge onto a cortical target could therefore range between the extreme values of more than 10 to somewhat less than 100.

Functional connectivity between LGN and visual cortex: physiological studies

In primary visual cortex of the cat, two major cell types are distinguished on the basis of receptive field structure—simple cells and complex cells (Hubel and Wiesel, 1962). Simple cells, the dominant cell type in layer 4 (Gilbert, 1977),

have elongated receptive fields with separate and adjacent ON and OFF subregions. By contrast, complex cells generally have receptive fields with overlapping ON and OFF subregions. Both cell types respond best to oriented bars or edges of light. Based on the structure of LGN receptive fields (center/surround) and simple cell receptive fields, Hubel and Wiesel (1962) proposed a simple hierarchical model. According to this model, simple cells receive convergent input from multiple LGN cells whose receptive fields have the same sign and are located along a line of visual space (Fig. 41.1). This model could account for the adjacent ON and OFF subregions of the simple cell as well as the orientation selectivity of simple cells. In a similar hierarchical fashion, Hubel and Wiesel (1962) also suggested that complex receptive fields could be constructed via convergence of multiple simple cells.

Early studies examining the connections between the LGN and visual cortex used electrical stimulation to geniculate fibers to determine the functional targets of geniculate projections. As expected from the anatomy, these studies demonstrated that simple cells indeed receive monosynaptic input from the LGN (Bullier and Henry, 1979a, 1979b, 1979c; Creutzfeldt and Ito, 1968; Ferster and Lindstrom, 1983; Martin and Whitteridge, 1984; Singer et al., 1975; Stone and Dreher, 1973).

While electrical stimulation provided strong evidence for monosynaptic input to simple cells, it was unable to demonstrate either the strength of single inputs or their receptive-field properties. These difficulties were overcome by recording simultaneously the responses of cortical cells and their geniculate afferents and performing cross-correlation analysis between spike trains (Alonso et al., 2001; Reid and Alonso, 1995; Tanaka, 1983, 1985). Using this approach,

FIGURE 41.3. Summary diagram showing the relationship between the receptive fields of monosynaptically connected pairs of LGN cells and simple cells. To generate this diagram, the receptive field of each simple cell was transformed into a stylized receptive field (shown in the figure with a central subregion, indicated with solid lines, flanked by two adjacent subregions of opposite sign, indicated with dashed lines). The circles indicate the relative size, sign, and locations of the receptive field centers of monosynaptically connected LGN cells. Of the 23 pairs of connected cells (out of a total of 74 pairs recorded), very few mismatches in the sign of overlapping receptive fields were found. Receptive fields were mapped using a white-noise stimulus; connectivity was assessed using cross-correlation analysis. (From Reid and Alonso, 1995, 1996).

Tanaka demonstrated that individual connections were fairly strong—often accounting for up to 10% of the spikes in a simple cell—and that connected cells had appropriately overlapped receptive fields. In addition, Tanaka demonstrated that both X and Y afferents as well as both ON and OFF geniculate cells could project to the same simple cell. While this study demonstrated that LGN neurons with appropriately overlapping receptive fields provide monosynaptic input to a simple cell, the study did not systematically explore the factors determining whether a specific afferent would be connected to any given cortical target.

Implicit in the Hubel and Wiesel model is that certain geniculate afferents should have a high probability of connection to a particular simple cell, while others should not. Reid and colleagues specifically tested this assumption by examining the relationship between receptive field overlap and the probability of connection, again as assessed with cross-correlation analysis (Alonso et al., 2001; Reid and Alonso, 1995; Fig. 41.3). On average, 33% of cells are connected if their receptive fields overlap in any way. More specifically, these studies demonstrated that connections are made between pairs of cells when the signs (ON or OFF) of the overlapping portions of the receptive fields are the same. The probability of connection is greatest, approaching 100%, when the center of an LGN receptive field perfectly overlaps the exact center of a simple subregion. Conversely, inappropriate connections are rarely made between LGN

neurons and simple cells. Restated, if the receptive field of an LGN cell is nonoverlapping or of the opposite sign (ON versus OFF) of an overlapped simple-cell subregion, monosynaptic connections are almost never made.

These studies indicate that roughly 30 LGN afferents synapse onto any given layer 4 neuron. This value is obtained by multiplying the probability of connection (33%) by the total number of thalamic X cells whose receptive field centers overlap the simple cell receptive field in any way ($n = 90$; see Alonso et al., 2001).

Although the spatial outline of a simple receptive field is consistent with the aggregate thalamic input, this does not mean that the responses of simple cells are entirely determined by this thalamic input. Intracortical processing, both excitatory and inhibitory, of course, plays an important role (Douglas et al., 1995; Ferster and Miller, 2000; Sillito et al., 1980; Somers et al., 1995; Sompolinsky and Shapley, 1997). For instance, recent intracellular studies have validated the earlier idea that simple cell subregions are formed by a push/pull mechanism: ON excitation superimposed with OFF inhibition and vice versa (Ferster, 1988; Hirsch et al., 1998; Hubel and Wiesel, 1962; Palmer and Davis, 1981; Tolhurst and Dean, 1987; but see Borg-Graham et al., 1998).

Concluding remarks

In summary, we have examined how neuroanatomy can provide upper and lower bounds for the number of connections between neurons in the retino-geniculo-cortical pathway. These bounds, however, are extremely broad. Further, anatomical results provide only limited information about the physiology of the neurons being studied. Functional connectivity—the relationship between neuronal function (receptive fields) and synaptic connections—is currently a topic that can be addressed only with physiological experiments. In the pathway from retina through LGN to visual cortex, the connections made are strongly determined by the receptive fields of pre- and postsynaptic neurons. This finding is perhaps tautological for the strongest inputs to a cell, which can be seen as determining its receptive field. For weak inputs such as most LGN inputs to a simple cell, however, connections could be made without significantly perturbing the receptive field structure of the target neuron. Nonetheless, virtually no inappropriate synapses are made, although the axons of inappropriate inputs are intertwined with the dendrites of any given target neuron.

The approach we have described works best in the early visual system, before recurrent pathways and divergence make correlations between the spike trains of neurons difficult to interpret in terms of individual synaptic connections. So far, functional connectivity has been studied only from retina to LGN, from LGN to layer 4, and, most recently, from layer 4 to the superficial layers of visual cortex (Alonso

and Martinez, 1998). Pushing this line of research deeper into the cortical processing stream remains a challenge for the future.

42 Cell Types and Local Circuits in Primary Visual Cortex of the Macaque Monkey

EDWARD M. CALLAWAY

A MAJOR AIM OF VISION research is to understand how neural circuits mediate the computations that underlie visual perception. Since the visual response properties of cortical neurons arise largely as a consequence of the organization and function of their connections with other neurons, it is believed that understanding how neural circuits give rise to the specific visual response properties of individual cortical neurons contributes significantly to this aim.

Local circuits in the primary visual cortex (V1) of primates provide a unique venue for elucidating cortical computations. This is due largely to the highly specialized organization and function of primate V1. Parallel inputs from multiple functionally specialized pathways impinge on V1, and the local circuits here must simultaneously extract the features from each input pathway that are relevant to the computations required for the creation of output neurons with novel receptive field properties and maintain an ordered substrate for interacting efficiently with distant cortical and subcortical neurons. The result is a highly organized structure of multiple circuits that are intertwined at multiple levels of organization. Nevertheless, these circuits remain embedded within a framework that V1 has in common with other cortical areas.

At present, our understanding of the relationships between circuits and function in the visual system is strongest at the levels of areas and modules (layers or columns within an area). There is detailed information about the functional properties and interconnections of dozens of cortical areas (e.g., Felleman and Van Essen, 1991), and for some of these areas (particularly V1) we know that different layers or columns receive input from different sources and that the neurons in these locations have corresponding differences in their responses to visual stimuli (see Callaway, 1998b, and below for review).

But it is apparent that much of the computation that is carried out by visual cortical circuits will not be understood until we understand circuits and function at a finer level of resolution than cortical modules. This is most apparent from the simple observation that any given cortical module contains many functionally and anatomically distinct neuron types. In particular, it appears that the number of anatomically distinct cell types in primate V1 may far exceed that

in other cortical areas. And recent studies of functional connectivity have revealed that anatomically distinct neuron types within the same V1 module are uniquely interconnected (see below). It follows that the diversity of visual response properties within a module is likely to reflect the connectional differences between anatomically distinct neuron types. It is therefore possible to evaluate correlations between circuits and function at a finer level of resolution by taking advantage of the unique anatomical features of each cell type in V1.

The focus of this chapter is on the organization of local circuits in V1 at the level of specific cell types. It is the recognition and exploitation, as well as continuing discovery, of the functional, structural, and connectional diversity of cell types that allows circuits to be linked to function at increasingly fine levels. I will begin with a brief review of the anatomy and function of parallel pathways from the retina and lateral geniculate nucleus (LGN) to V1. I will then turn to the primary focus of the chapter: a detailed description of the cell types which compose V1's local circuits and the specific connectivity of each cell type. The circuitry of excitatory neurons will be considered first, and within this context I will also emphasize how V1 circuits mediate interactions between parallel inputs to V1 and the projection neurons that provide output to various extrastriate cortical areas. Finally, I will describe the circuits suggested by the anatomical and functional diversity of inhibitory interneurons.

The pathways from lateral geniculate nucleus to primary visual cortex

The retino-geniculo-cortical pathways in the macaque monkey are composed of at least three distinct parallel systems, the M, P, and K pathways, which originate in the retina and remain segregated until they reach V1 (see, Chapter 30 in this volume). Each of these systems seems to be specialized for the detection of a unique set of visual cues. At the other end of the visual hierarchy are dozens of extrastriate cortical areas, each of which is also specialized for the detection of particular attributes of visual scenes (cf. Desimone and Ungerleider, 1989; Felleman and Van

Essen, 1991). It is believed that the extrastriate visual areas also compose two more or less parallel systems. One system is specialized for analysis of spatial relationships and involves visual areas in parietal cortex. The other is believed to be responsible for object identification and involves areas in temporal cortex. Since virtually all of the retinal input relayed through the LGN to primate cortical areas converges on area V1 (Benevento and Standage, 1982; Bullier and Kennedy, 1983), V1 provides a unique interface between the M, P, and K pathways and extrastriate cortex. It also provides a unique opportunity for computations requiring early integration of information from more than one stream.

Our understanding of circuits underlying the contributions of the M, P, and K pathways to extrastriate cortical areas is based largely on studies of the flow of information into and out of various functional compartments in V1. These functional compartments include laminar (i.e., layers 4B, 4C α , and 4C β) and columnar (i.e., blob, interblob) divisions. But there are also different cell types within each compartment which are anatomically and/or connectionally distinct. Over the past several decades, considerable progress has been made in relating the functional characteristics of parallel pathways with the functional architecture of V1 and, in turn, the functional differences between neurons providing output to extrastriate areas (see Callaway, 1998b, and below for review). But there is still much to be learned about the functional and anatomical heterogeneities within each pathway and how these are related.

The locations in V1 which receive the combined input from the M, P, and K cells of the LGN correlate closely with the pattern revealed by staining for the mitochondrial enzyme cytochrome oxidase (CO) (Livingstone and Hubel, 1982). The most dense LGN input is to layer 4C, but there is also input to layer 1, blobs in layer 2/3, layer 4A, and layer 6. Each of the M, P, and K pathways has a unique relationship to these afferent termination zones.

THE M PATHWAY Neurons in the most ventral M layers of the LGN project most strongly to the upper division of layer 4C, to layer 4C α , and secondarily to layer 6 (Hendrickson et al., 1978; Hubel and Wiesel, 1972). Anatomical reconstructions of individual afferent axons show that they are heterogeneous. Most innervate the entire depth of layer 4C α , but a subset selectively targets the upper portion of 4C α (Blasdel and Lund, 1983). These termination zones closely mimic the laminar organization of the dendritic arbors of two types of layer 4C α spiny stellate neurons (Yabuta and Callaway, 1998a; see also below). Cells with dendrites in upper 4C α , where they would contact both types of M afferent, project axons to layer 4B and selectively to CO blobs in layer 3. Cells with narrowly stratified dendrites in lower 4C α , where they would contact only one type of M afferent, project axons densely and selectively to CO

interblobs in layer 3. These observations suggest that layer 4B and blobs are influenced by both types of M input, while interblobs are influenced exclusively by the M input that spans the entire depth of layer 4C α (see Fig. 42.1).

M cells could potentially vary from each other with respect to numerous functional attributes, and these variations might be systematically related to the anatomically defined termination zones of M afferents (upper versus lower layer 4C α). We have hypothesized that the functional differences between M afferents that terminate in upper 4C α versus those that terminate throughout 4C α might be related to their linearity (Yabuta and Callaway, 1998a). Some cells in the M layers of the LGN respond to high spatial frequency counterphase gratings with frequency-doubled responses, irrespective of spatial phase (Kaplan and Shapley, 1982; Chapter 30 in this volume). In this respect they are similar to Y cells, which in the cat's visual system arborize preferentially in upper layer 4 of area 17 (Humphrey et al., 1985; Shapley and Perry, 1986). Most M cells in the monkey, however, respond more linearly and in this respect are similar to the cat's X cells, which arborize throughout the depth of layer 4.

Although there may be functional and anatomical similarities between cat X or Y cells and subsets of LGN M cells in the monkey, it is unclear whether these pathways are truly analogous. For example, the parasol cells of the primate retina, which give rise to the M pathway (Leventhal et al., 1981), are most similar to the cat's α -retinal ganglion cells (RGCs) and not the β -RGCs which give rise to the X pathway (Leventhal et al., 1985). Furthermore, it is not clear whether there are discrete classes of linear and nonlinear M cells or whether frequency-doubled cells simply reflect extreme nonlinearity (Levitt et al., 2001). Thus, differences in linearity are just one of many possible functional differences that may distinguish M afferents in upper versus lower 4C α .

P AND K PATHWAYS Neurons in the dorsal LGN layers include not only P cells but also K cells. K cells are located primarily in the intercalated zones between the P layers (and M layers) but are also found scattered within the P layers (Hendry and Yoshioka, 1994). This arrangement has made it difficult to ascertain which layers of V1 receive input from P versus K cells or which of the functionally distinct neuron types recorded in the dorsal LGN correspond to P or K cells. For example, early studies describing anterograde labeling following tracer injections (or lesion-induced degeneration) in the dorsal layers of the LGN reported label in superficial layers (layers 1, 2/3, and 4A) as well as layers 4C β and 6 (Hendrickson et al., 1978; Hubel and Wiesel, 1972). The superficial labeling was originally believed to arise from the P pathway. But we now know that most, if not all, of the label in the superficial layers originated from K cells, not P

cells (see below). Similarly, recordings from LGN neurons in and around the P layers were all attributed to the P pathway before it was appreciated that there is a distinct K pathway. And even with this realization, recordings made in the LGN cannot distinguish P cells from the K cells that are scattered within the P layers.

Despite uncertainty about the precise anatomy and physiology of the K pathway, the available evidence strongly suggests that the great majority of LGN neurons which project axons to layer 4C β are P cells, while only K cells expressing Ca⁺⁺/Calmodulin-dependent Protein Kinase II (α CAMKII) or calbindin (Hendry and Yoshioka, 1994) project to more superficial layers (4A and layer 2/3 blobs). There are three main pieces of evidence which support this configuration: (1) Reconstructions of individual LGN afferents fail to reveal any axons which project densely both to layer 4C β and to superficial layers (Blasdel and Lund, 1983; Freund et al., 1989)—these inputs therefore appear to arise from anatomically distinct populations. (2) The K pathway originates from RGCs with the smallest-diameter axons and these axons innervate the intercalated K layers (Conley and Fitzpatrick, 1989). (3) LGN neurons retrogradely labeled from superficial layers of V1 include cells in the intercalated K layers, along with scattered cells in the P layers, and these cells stain for α CAMKII or calbindin (Hendry and Yoshioka, 1994). Although these findings are strongly suggestive, further studies are required to test more exhaustively the possibility that some afferents might innervate both layer 4C β and superficial layers or that some α CAMKII-expressing cells might connect to layer 4C β . There may also be cells projecting to layer 4A that do not express α CAMKII (Hendry and Yoshioka, 1994).

FUNCTIONAL PROPERTIES OF M, P, AND K CELLS Relative to P or K cells, M cells have excellent contrast sensitivity, prefer lower spatial frequencies and higher temporal frequencies, and lack cone-opponent receptive fields (see Chapter 30 in this volume for review). The most distinctive property of cells recorded in the dorsal layers of the LGN (P and K layers) is that, unlike M cells, they have cone-opponent receptive fields (e.g., Wiesel and Hubel, 1966). These cells are tuned along the cardinal red-green and blue-yellow color axes (Derrington et al., 1984; De Valois et al., 2000). Thus, they either receive input from long-wavelength sensitive (L) cones opposed to middle-wavelength sensitive (M) cones (red-green color opponency) or they have short-wavelength sensitive (S) cone input opposed by the L + M cones (blue-yellow color opponency).

The great majority of cells recorded in and around the P layers have red-green color opponency (Wiesel and Hubel, 1966). Since K cells are only a minority of the cells in this region, it follows that P cells must include cells with red-green opponency. But since there are no direct observations

linking these cell types with receptive-field properties, it is possible that the P pathway might also include cells with blue-yellow color opponency.

There is also compelling evidence that a substantial portion of the K pathway neurons have blue-ON/yellow-OFF receptive fields (see Hendry and Reid, 2000, for review). Blue-ON receptive fields originate with bistratified retinal ganglion cells which connect to intercalated layers K3 and K4 of the LGN. Neurons recorded in the K3 and K4 intercalated layers also have blue-ON receptive fields (see Hendry and Reid, 2000, and personal observation). Neurons with blue-OFF/yellow-ON receptive fields have also been recorded in the dorsal layers of the LGN, but they have not been linked to the P or K pathway (De Valois et al., 2000, and personal observation). It is also not known whether the K pathway includes cells with red-green color opponency.

PROJECTIONS TO EXTRASTRIATE CORTICAL AREAS The next section of this chapter will describe the cell types which receive direct input from the M, P, and K pathways and how they distribute this information to V1's extrastriate cortical projection neurons. In this context, it is therefore also helpful to review briefly the organization of V1 neurons that project to various extrastriate cortical areas and to functionally distinct compartments in area V2.

As a general rule, neurons which project to dorsal visual areas are found in layer 4B, while those that project to ventral visual areas are found in layer 2/3 (see Felleman and Van Essen, 1991, for review). For example, layer 4B neurons provide direct input to areas V3 and MT, while layer 2/3 neurons connect to area V4. But detailed connectivity between areas V1 and V2 has only very recently been studied in the macaque monkey (Sincich and Horton, 2002). Although it was previously appreciated that neurons throughout the cortical depth, from layers 2 to 4B, contain neurons connecting to area V2, their relationships to CO stripe compartments in V2 and to blobs and interblobs in V1 had not been investigated. Because each of the CO stripe compartments in V2 connects to a unique set of cortical areas, this is particularly relevant to the question of how each type of V1 cortical projection neuron distributes information to dorsal and ventral visual areas. In particular, the V2 thick stripes connect to areas V3 and MT, while thin stripes and interstripes connect to V4 (for review see De Yoe and Van Essen, 1988; Zeki and Shipp, 1988).

Input to the CO compartments in V2 is most closely related to the CO organization in V1, not to V1's laminar organization. Layer 2 to 4B neurons in (and under) interblob regions of V1 connect to V2 thick stripes and interstripes, while those in (and under) blob regions connect to V2 thin stripes (Sincich and Horton, 2002). Thus, although it had long been thought that layer 4B provided the only input to V2 thick stripes, it is now clear that layer 2/3 and 4A

interblob neurons also provide input to the thick stripes (Sincich and Horton, 2002). It had also been thought that V2 thin stripes receive input only from layer 2/3 blob neurons, but the new results indicate that the layer 4A and 4B cells under blobs also connect to thin stripes (Sincich and Horton, 2002). It is noteworthy that the input from layer 4B to V2 tends to arise from pyramidal neurons, while the direct input to MT from V1 arises predominantly from layer 4B spiny stellate neurons (Shipp and Zeki, 1989; see further below).

Excitatory cell types in V1, their local connectivity, and relationships to extrastriate cortical areas

Intracellular labeling and anatomical reconstruction of the axonal and dendritic arbors of individual neurons throughout the layers of V1 of macaque monkeys (see Callaway, 1998b, for review) have revealed at least 27 distinct excitatory neuron types (see details below). Photostimulation experiments have revealed the sources of local excitatory input to 14 of these cell types (Briggs and Callaway, 2001; Sawatari and Callaway, 1996, 2000; Yabuta et al., 2001). Systematic differences in the sources of local input to different cell types have revealed that each cell type receives input from unique sources, even when the locations of their cell bodies and/or dendritic arbors are the same (see also Dantzker and Callaway, 2000). Thus, connectivity cannot be predicted based solely on light-level anatomy, because axons that arborize in a particular location selectively connect to the dendrites of certain cell types within that location. In some cases, the sources of functional excitatory input can be highly diverse, even for neurons of the same type (Sawatari and Callaway, 2000). Differences in functional input to each cell type imply that there should be corresponding differences in their visual function in vivo. Future studies will be necessary to reveal any such correlations.

EXCITATORY CELL TYPES AND CONNECTIONS FROM LAYER 4C TO SUPERFICIAL LAYERS As described above, the most dense LGN input to V1 is to layer 4C. Layer 4C neurons, in turn, connect directly to extrastriate projection neurons in more superficial layers (Fig. 42.1). It appears that the most salient features of the classical receptive fields of neurons in superficial cortical layers can be attributed largely to the organization of these connections (cf. Callaway, 1998b). Therefore, understanding the detailed relationships between these circuits and the visual responses of the neurons that form them is expected to be particularly useful for understanding how V1 circuits function.

Within layer 4C α , three distinct types of spiny stellate neuron have been identified (Yabuta and Callaway, 1998a). The first type has dense axonal arbors only within layer 4C α and layer 6; it does not arborize in layer 5 or in superficial layers. The second cell type has dense axonal arbors in layers

4C α and 4B but also makes substantial connections with layers 3B, 5, and 6. The connections in layer 3B are located selectively in the CO blobs. The last type of layer 4C α spiny stellate is the most unusual. It has narrowly stratified dendrites at the bottom of layer 4C α that extend neither into layer 4C β nor to upper layer 4C α . Its M input is therefore limited to those afferents that terminate throughout layer 4C α and not those that target only upper 4C α (Blasdel and Lund, 1983; see also above for possible functional significance). These cells have very dense axonal arbors selectively in the CO interblobs of layer 3B. They have moderate axonal arbors within layer 4C. Together these three cell types receive information from LGN M afferents and distribute it to all three of the major compartments that contain extrastriate projection neurons—blobs, interblobs, and layer 4B (see above). But the narrowly stratified cells that provide input to interblobs are likely to receive only one type of M input, while the cells connecting to layer 4B and blobs receive both types of M input (see also above). Possible functional differences between these sources of LGN input remain unknown.

FIGURE 42.1. Schematic of the pathways from magno- (M) and parvocellular (P) LGN, through V1, to extrastriate cortical areas. Two anatomical types of M afferent terminate in either upper layer 4C α of V1 (*Ma* illustrated in black) or the entire depth of 4C α . This second type of M afferent (*Mb*) thus provides the only input to the middle of layer 4C (illustrated by the white box). P afferents terminate in layer 4C β . Layer 2/3 CO interblobs receive input from layers 4C β and middle 4C and thus get input from P and Mb but not Ma recipient neurons. Layer 2/3 blobs receive input from neurons throughout the depth of layer 4C and thus get input from Ma, Mb, and P recipient neurons. Layer 4B spiny stellate neurons receive input only from layer 4C α and thus only from M recipient neurons, while layer 4B pyramids receive input from both layer 4C α and layer 4C β and thus also receive input from P recipient neurons. Interblob neurons, in turn, project to thick stripes and interstripes of V2. Blob neurons project to V2 thin stripes. Layer 4B spiny stellates project to area MT. Layer 4B pyramids project to areas V2 and V3, with the V2 compartment that is targeted being dependent on their position relative to the blobs (see text).

There are two distinct types of layer 4C β spiny stellate cells, although subtle differences in connections to layers 5 and 6 may also be diagnostic of additional types (Callaway and Wiser, 1996; Yabuta and Callaway, 1998a). Cells near the layer 4C α /4C β border have dendritic arbors that span the border and are therefore likely to receive both M and P input. But most layer 4C β spiny stellates confine their dendrites to layer 4C β and therefore can receive LGN input only from P cells. Both of these layer 4C β spiny stellate cell types make extremely dense connections to layer 3B, and these connections lack specificity for blobs or interblobs.

These anatomical observations of layer 4C neurons suggest distinct differences in the sources of input to the extrastriate projection neurons in layers 3B and 4B. But more detailed photostimulation experiments reveal that the connections are even more precise. Neurons in layer 4B provide the output from V1 to areas in the dorsal visual pathway, including areas V2, V3, and MT (see above). Furthermore, there are differences in the cell types projecting to these areas. About one-third of layer 4B excitatory neurons have a spiny stellate morphology, while the remainder are pyramidal (Callaway and Wiser, 1996). But the less common spiny stellates provide the majority of the input to area MT (Shipp and Zeki, 1989), while the pyramids are more likely to connect to V2 and V3. Photostimulation studies (Fig. 42.2; Sawatari and Callaway, 1996; Yabuta et al., 2001) reveal that both cell types receive their strongest local inputs from layer 4C α , as expected from anatomical observations (see above). But pyramidal cells also receive substantial excitatory input from layer 4C β (Figs. 42.1 and 42.2), presumably via their apical dendrites in layer 3. This P-dominated input from layer 4C β is about half the strength of the M-dominated input from layer 4C α . Layer 4B spiny stellates receive no detectable input from layer 4C β . Thus, the direct pathway from layer 4B of V1 to area MT is influenced far less by the P pathway than are indirect pathways from layer 4B pyramids via areas V2 or V3 to MT. These observations imply that there are likely to be differences in the visual receptive field properties of layer 4B spiny stellate versus pyramidal neurons that reflect the differential contributions from the P pathway.

There are also differences in the sources of local excitatory input to different pyramidal cell types in layer 3B. About one-third of the pyramidal neurons in layer 3B of V1 project an axon into the white matter (probably to area V2), while the remaining pyramids have axonal arbors that are completely local to V1 (Callaway and Wiser, 1996; Sawatari and Callaway, 2000). The projecting pyramids have apical dendrites with tufts in layer 1 or layer 2, while the local pyramids rarely have tufted apical dendrites (Sawatari and Callaway, 2000). Photostimulation studies revealed that these anatomical differences were closely correlated with sources of local excitatory input (Sawatari and Callaway, 2000). Most notably, functional excitatory connections from layer

4C β , which provides the most dense anatomical input to layer 3B, could never be detected onto projecting pyramids. In contrast, most local pyramids received strong excitatory input from layer 4C β . There were also systemic differences in the sources of functional excitatory input to layer 3B pyramids in blobs versus interblobs. These differences were consistent with the anatomical differences in local input to blobs and interblobs (see above). It is therefore expected that future in vivo recordings will reveal differences in the visual receptive fields of local versus projecting pyramids and that there will be further correlations with location relative to blobs. Differences between local and projecting pyramids are likely to reflect the functional influence of direct input from layer 4C β . In addition, layer 2/3A also contains both local and projecting pyramids (Callaway and Wiser, 1996) which are also likely to receive different functional inputs and have different receptive fields. And anatomical observations indicate that the sources of input to these cells must differ from those in layer 3B (Callaway and Wiser, 1996; Lachica et al., 1992; Yabuta and Callaway, 1998a). Finally, layer 2/3 pyramids can also be separated into two types based on their patterns of horizontal intralaminar axonal arbors (Yabuta and Callaway, 1998b). While most pyramidal neurons have clustered intralaminar axons projecting for long distances, those located at distances of about 125 μ m from the centers of blobs tend to lack long axons.

EXCITATORY CELL TYPES IN DEEP LAYERS AND THEIR CONNECTIONS The contributions of V1 to visual processing depend on the patterns of activity that are generated in its output neurons. These include not only the extrastriate projection neurons found in superficial cortical layers (see above) but also subcortically projecting neurons found in layers 5 and 6 (Fitzpatrick et al., 1994; Hendrickson et al., 1978; Lund et al., 1975). Interestingly, however, only a minority of layer 5 and layer 6 neurons in macaque V1 have axonal projections outside of V1 (Callaway and Wiser, 1996; Fitzpatrick et al., 1994; Wiser and Callaway, 1996). The majority make connections that are entirely intrinsic to V1. This suggests that the role of these neurons is to influence the patterns of activity that are generated in the output neurons. Other deep layer neurons do project outside of V1, and their local axonal projections and input sources are often distinctly different from those that do not.

These observations, and analyses of local axonal arbors, lead to the hypothesis that there are two distinct classes of deep layer neurons. The first class has local, recurrent axon collaterals that form extensive arbors in superficial cortical layers. The layer 5 pyramidal neurons of this class have axonal arbors that target layers 2–4B, while this class of layer 6 pyramidal neurons targets layer 4C (Fig. 42.3). The second class of deep-layer pyramidal neurons has laterally projecting local axon collaterals that generally avoid superficial

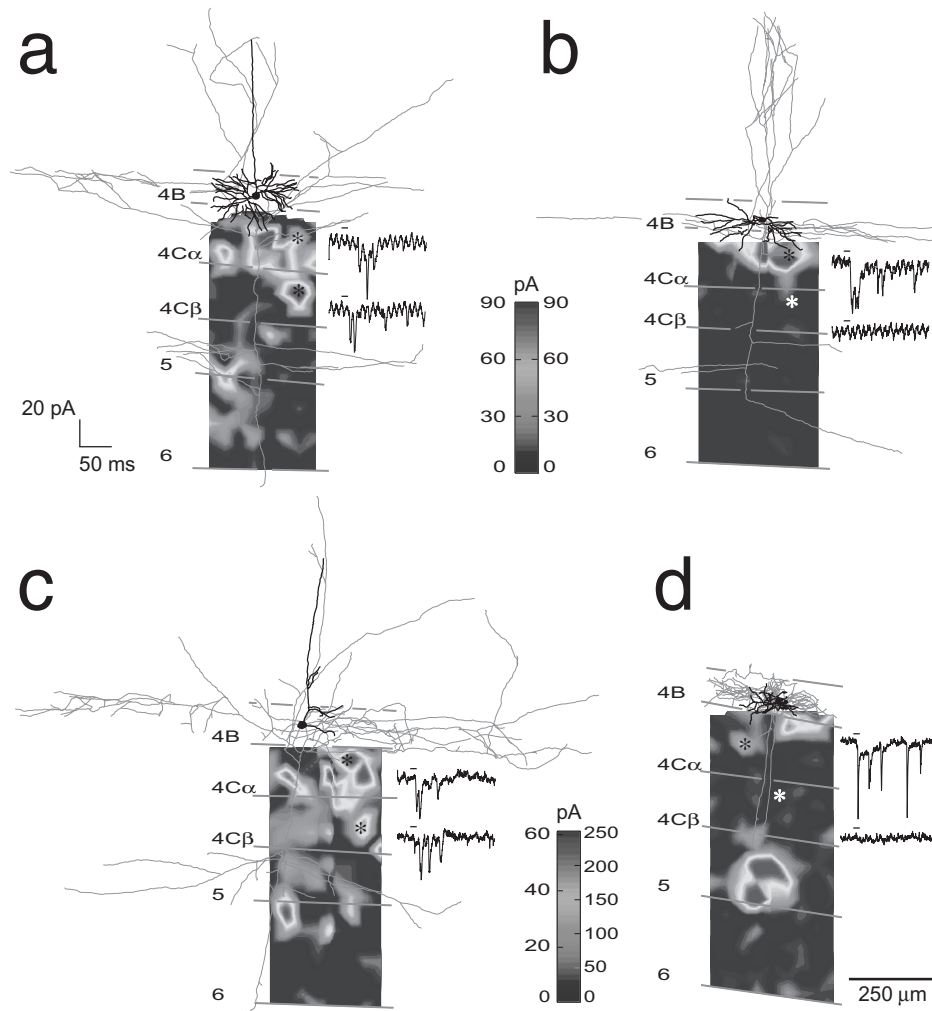

FIGURE 42.2. Laminar excitatory input to layer 4B pyramidal neurons (*a, c*), a spiny stellate neuron (*b*), and an inhibitory basket cell (*d*). The pyramidal cells receive strong excitatory input from both layers 4C α and 4C β , while spiny stellate neurons receive input from layer 4C α but not layer 4C β (see text for further details). The excitatory neurons (spiny stellate and pyramidal) get their strongest input from layer 4C, while this inhibitory neuron receives its strongest input from layer 5. These patterns of input to the excitatory neurons versus the inhibitory neurons are reminiscent of input to pyramidal neurons and a subtype of inhibitory basket cell in rat visual cortex (Dantzker and Callaway, 2000). Colored maps indicating patterns of excitatory input to each neuron are linear

interpolations of the estimated evoked input (EEI) (see Yabuta et al., 2001) values measured following photostimulation at discrete sites. Colored vertical scale bars indicate the corresponding EEI values for input maps to the left and right. To the right of each input map are example voltage-clamp recordings made while stimulating presynaptic regions (indicated by asterisks) in layer 4C α (upper traces) or layer 4C β (lower traces). Short dashes above each recording show the onset of photostimulation. Horizontal lines crossing the input maps represent the anatomical laminar borders. Anatomical reconstructions of dendritic (*black*) and axonal arbors (*gray*) are superimposed over the input maps. Scale bars apply to all panels. (From Yabuta et al., 2001.) (See color plate 26.)

cortical layers. These same two cell types have also been distinguished on both anatomical and physiological grounds in other species and cortical areas (cf. Chagnac-Amitai et al., 1990).

Because of our extensive knowledge of the functional organization of macaque V1, it has been possible to make inferences about the functional influences of the different types of deep-layer neurons (Callaway, 1998b). Specifically, deep-layer neurons with local, recurrent axonal arbors appear to have a modulatory rather than a driving influence

on the visual response properties of neurons in superficial layers. Local recurrent pyramidal neurons in layers 5 and 6 have widespread recurrent axon collaterals in layers 2–4B and layer 4C, respectively. Despite these widespread projections, the receptive fields of neurons in layers 2–4C remain relatively small. Furthermore, the projections from deep layers lack specificity for functional compartments (i.e., ocular dominance columns, blobs, interblobs), yet the visual response properties of neurons in the recipient modules appear to be reflective of their inputs from the LGN and

layer 4 (see above and Callaway, 1998b). For example, layer 6 pyramidal neurons have widespread axonal arbors in layer 4C that are not ocular dominance column specific (Wiser and Callaway, 1997). This indicates that under monocular viewing conditions, layer 6 cells connecting to ocular dominance columns corresponding to the closed eye are active, but the recipient layer 4C neurons are not driven above threshold. The layer 6 input cannot by itself activate the layer 4C neurons. The connections are therefore modulatory. A similar argument can be made for the widespread projections from layer 5 to layers 2–4B. The same argument does not hold for the deep-layer neurons that have local, laterally projecting axonal arbors.

Beyond the local, recurrent versus local, lateral distinction that can be made between deep-layer neurons, they can be further classified into at least three types of layer 5 pyramidal neuron and nine types of layer 6 pyramid (Fig. 42.3). The different patterns of axonal and dendritic arborization, as well as differential connectivity of these cell types, suggest that they are likely to be involved uniquely in information processing within V1. Each cell type receives local input from a unique set of sources and provides output to a unique combination of target layers, implying that there are also likely to be corresponding differences in their visual receptive fields.

Neurons in the deep cortical layers, 5 and 6, are even more diverse than those in superficial layers (Briggs and Callaway, 2001; Callaway and Wiser, 1996; Wiser and Callaway, 1996). Three distinct types of layer 5 pyramidal neuron have been identified in macaque V1 (Callaway and Wiser, 1996). One type includes all of the local recurrent neurons found in this layer. They have extensive axonal arbors in superficial layers (2–4B), but not deep layers, and do not project out of V1. A second type has a “back-branching” dendritic morphology, and its local axons project laterally within the bottom of layer 5. The backbranching cells project out of V1, perhaps to the pulvinar nucleus of the thalamus or to the superior colliculus (Callaway and Wiser, 1996; Lund et al., 1975). Finally, there are the Meynert cells, or “tall” pyramids (Lund and Boothe, 1975; Valverde, 1985). They have long (more than 500 μm), lateral basal dendrites and apical dendrites that extend to layer 1. Their large cell bodies suggest that they project to the superior colliculus (Lund et al., 1975). They have not been intracellularly labeled in mature animals, but tall layer 5 pyramids in prenatal animals (Callaway, 1998a) have laterally projecting local axons. Photostimulation-based investigation of the sources of local excitatory input to these cells is in progress.

Nine anatomically distinct types of layer 6 pyramidal neurons have been identified (Fig. 42.3; Briggs and Callaway, 2001; Wiser and Callaway, 1996), and photostimulation reveals systematic differences in the sources of local excitatory input to each type (Briggs and Callaway, 2001).

Layer 6 pyramids are grouped into two classes, I and II. Class I cells have apical dendritic branches and dense axonal arbors in layer 4C. These are divided into five types based on their specific patterns of local axonal arborization within subdivisions of layer 4. They project specifically to either layer 4C α (type I α), 4C β (type I β), the middle of layer 4C/lower 4C α (type Im), 4C β plus 4A (type I β A), or throughout layer 4C plus 3B/4A (type IC). These primary distinguishing features are correlated with the position of the cell body within the depth of layer 6 and with whether the cell projects an axon into the white matter. These features indicate that the class I cells are the source of feedback from V1 to the LGN (see Fitzpatrick et al., 1994; Wiser and Callaway, 1996). The feedback to P layers of the LGN comes from type I β , I β A, and perhaps IC cells. Feedback to M layers of the LGN comes from type IC cells. Type I α and Im cells are found only in the middle of layer 6 and never project axons outside of V1. Thus, each type of class I cell has unique relationships to the M and P pathways, locally in V1, and with respect to input from and feedback to the LGN (see also Briggs and Callaway, 2001). Future studies of the differences in the functional properties of each of these cell types in vivo will provide considerable insight into the functions of these circuits.

Distinct anatomical features and photostimulation studies of local input indicate that class II layer 6 pyramids are likely to have very different functions than class I cells. Only one type of class II cell, type IIA, projects an axon to the white matter. The type IIA cells are found preferentially in the middle of layer 6 and have long, lateral local axons exclusively in deep layers of V1. They are therefore very similar to claustral projecting cells in the cat (Katz, 1987) and are hypothesized to also project to the visual claustrum of the monkey (Wiser and Callaway, 1996). They may therefore have very long receptive fields and play a role in the generation of end-stopped receptive fields (Bolz and Gilbert, 1986; Grieve and Sillito, 1995; Sherk and LeVay, 1983). Type IIB cells provide dense local feedback to superficial layers of V1, while type IIC cells are unusual in receiving diffuse input from all layers of V1 and extending sparse local axons throughout the cortical layers (Briggs and Callaway, 2001). Finally, the layer 6 pyramids also include giant cells of Meynert (Winfield et al., 1981). These project to area MT and are likely to have direction-selective receptive fields (Movshon and Newsome, 1996). The distinct inputs and outputs of each type of class II cell suggest that they are each likely to also have different visual receptive field properties in vivo.

Inhibitory cell types and V1 circuits

Inhibitory neurons are likely to play a crucial role in the processing of visual information in primate V1. Although they

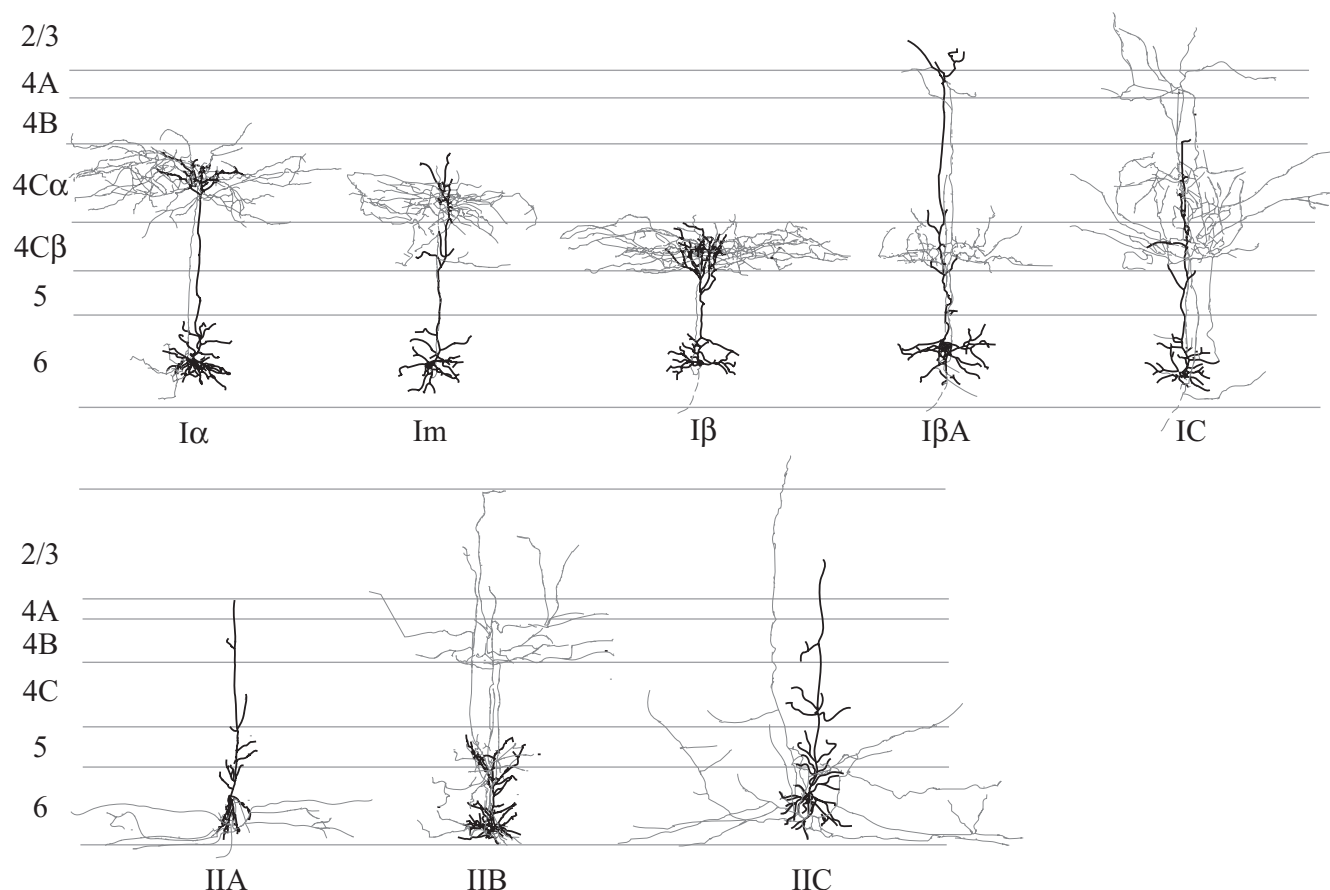

FIGURE 42.3. Eight types of pyramidal neuron identified in layer 6 of macaque V1. Class I neurons (*top row*) have dense axonal and apical dendritic arbors in layer 4C. Each type of class I neuron has a unique distribution of axons and dendrites within layer 4C and therefore a unique relationship to the magno- and parvocellular

streams. Class II neurons (*bottom row*) have more extensive dendritic arbors in layer 5 and project axons primarily to either layers 2–4B (type IIB) or deep layers (types IIA and IIC). See text for further details. (From Briggs and Callaway, 2001.)

rarely send axons outside of the local cortical area and therefore cannot directly relay information about the computations occurring in V1 to other areas, they can profoundly influence local computations and the activity of V1's projection neurons. The diversity of inhibitory interneurons found in the neocortex (see below) is likely to reflect a corresponding diversity of functional roles. Not only are inhibitory neurons believed to perform more straightforward tasks like gain control (Douglas et al., 1995; Heeger et al., 1996), but they can also control the timing of action potential generation (Tamas et al., 2000) and are likely to be able to selectively gate inputs from diverse sources impinging on different parts of the dendritic arbor (cf. Somogyi et al., 1998).

Although there have been extensive anatomical studies of inhibitory cortical neurons in primates, including macaque area V1, nearly all functional studies of inhibitory cortical neurons have been conducted in nonprimate species. Nevertheless, the basic types of inhibitory neurons appear to be conserved across cortical areas and species. We can there-

fore gain some insight into the likely function of macaque V1 inhibitory neurons by considering previous studies of inhibitory neurons in other species. I will therefore begin by reviewing these studies. Detailed Golgi studies of the anatomical features of inhibitory neurons in macaque V1 (Lund, 1987; Lund et al., 1988; Lund and Wu, 1997; Lund and Yoshioka, 1991) indicate, however, that the basic cell types found in other cortical areas/species have become highly specialized in V1. This specialization of inhibitory neurons is reminiscent of the greater diversity of excitatory neurons in V1 compared to other cortical areas or species (see above). And comparisons of the sources of local functional input to pyramidal neurons in layer 2/3 of rat visual cortex (Dantzker and Callaway, 2000), versus excitatory neurons in the equivalent layers of macaque V1 (Sawatari and Callaway, 2000; Yabuta et al., 2001), indicate that the increased anatomical diversity is accompanied by cell type specificity and increased diversity of functional connections. Thus, there is also likely to be a corresponding specificity of input to the multitude of inhibitory neuron types in

macaque V1. I will therefore also review the work of Lund and colleagues, which describes anatomical features characterizing inhibitory cell types in V1.

Cortical circuits are composed of a complex network of many neuron types. The function of the circuits in which these neurons are embedded is largely dependent on three variables: (1) which neurons are functionally interconnected, (2) how their synapses function, and (3) how the information delivered to individual neurons is integrated and transformed within the postsynaptic dendritic arbor. Although a long history of anatomical observations has led to thorough descriptions of the neuronal cell types found in the cortex and their patterns of axonal and dendritic arborization, it is only within the past decade that methodological advances have made possible more detailed functional studies of the cortical network. These studies indicate that for each type of cortical inhibitory neuron, each of the three variables described above is closely regulated (see details below).

Although conventional anatomical studies reveal spatial overlap of axonal and dendritic arbors, and therefore the potential for synaptic connectivity, until recently only tedious electron microscopic (EM) studies had been able to reveal which of the possible connections suggested by the anatomical overlap of axons and dendrites are in fact manifested. These EM studies have, however, pointed toward precisely organized cortical circuits. EM studies correlating synaptic bouton morphologies on individual neurons in layer 4 of cat visual cortex with local and thalamic afferent sources found no difference in the proportion of excitatory and inhibitory inputs received by inhibitory and excitatory neurons (Ahmed et al., 1997; Anderson et al., 1994). These observations are consistent with theories that view cortical connections as largely random, with the purpose of enabling associations among many possible stimuli (e.g., Braitenberg and Schuz, 1991). But other EM studies and increasing evidence from functional studies point to the alternative view, that the cortex is composed of extremely precise circuits mediating specific functions. EM studies suggest that inhibitory interneurons participate in cell-type-specific connections. For example, subcortical brain regions that innervate cortex target specific interneuron types (Freund and Gulyas, 1991; Gibson et al., 1999; Hornung and Celio, 1992; Staiger et al., 1996), and inhibitory neurons form selective connections to other types of interneurons or to particular postsynaptic elements on excitatory neurons (DeFelipe et al., 1999; Gonchar and Burkhalter, 1999; Meskenaite, 1997; Somogyi, 1977; Tamas et al., 1998). Finally, studies of functional cortical connections reveal that excitatory cortical neurons selectively connect to specific subsets of neuron types within the zone of axonal arborization; in particular, axons not only arborize in specific cortical layers, but they connect selectively to certain cell types within those layers (see above; Briggs and Callaway, 2001; Dantzker and Callaway, 2000;

Sawatari and Callaway, 2000; Yabuta et al., 2001). Cell type specificity of cortical connections is therefore likely to be prevalent and perhaps the norm rather than the exception.

Although cortical inhibitory neuron types are numerous, they each express specific and precisely regulated attributes pointing toward the likelihood that each type plays a unique role within the functioning cortical network. For example, each type of inhibitory neuron has diverse but highly correlated morphological, molecular, and physiological properties (Cauli et al., 1997; Gonchar and Burkhalter, 1997, 1999; Gupta et al., 2000; Kawaguchi, 1993; Kawaguchi and Kubota, 1997; Parra et al., 1998; Peters and Regidor, 1981; Thomson and Deuchars, 1997). Further complexity and precision of inhibitory cortical circuits are evident from the striking correlations between functional synaptic dynamics and the cell types that contribute the pre- and postsynaptic elements of each cortical connection (Gupta et al., 2000). And yet another level of complexity is introduced by modern studies of the properties of dendritic arbors. Dendrites are not simply passive filters; they can actively influence the integration of synaptic information (e.g., Johnston et al., 2000; Stuart et al., 1997). Thus, intrinsic membrane properties, which vary systematically among inhibitory neuron types and correlate with morphology and molecular properties, are also likely to have a strong impact on the *in vivo* function of inhibitory neurons.

Inhibitory neuron types that are common across multiple cortical areas and species can be classified according to numerous parameters, many of which are correlated. The most useful parameters include morphological features (patterns of axonal and dendritic arborization), specific targets innervated (e.g., cell bodies versus distal dendrites or axons), intrinsic firing properties, and expression of chemical markers. For organizational purposes, it is most useful to categorize these cells here primarily according to the targets of their synapses.

BASKET CELLS Basket cells make multiple large synapses on the proximal dendrites and cell bodies of pyramidal neurons (Jones and Hendry, 1984), and therefore even the connections originating from a single neuron may profoundly influence the activity of a recipient pyramid (e.g., Tamas et al., 2000). The typical basket cell expresses parvalbumin (PV) and is fast-spiking (FS) (Cauli et al., 1997; Gonchar and Burkhalter, 1997; Kawaguchi and Kubota, 1997), that is, there is no adaptation of firing frequency upon prolonged intracellular current injection. In contrast, small basket cells express cholecystokinin (CCK), not PV, and fire action potentials with frequency adaptation (referred to as *adapting* or *regular spiking*) or are burst spiking (Gonchar and Burkhalter, 1997; Kawaguchi and Kubota, 1997, 1998; Kubota and Kawaguchi, 1997). Our studies of sources of excitatory

input to FS basket cells in rat visual cortex (Dantzker and Callaway, 2000) indicate that they receive input from the same layers as pyramidal neurons. Since the FS basket cells strongly inhibit pyramidal neurons, this connectional organization is consistent with a role for this cell type in nonlinear cortical operations such as normalization or gain control (Douglas et al., 1995; Heeger et al., 1996). In macaque V1 there are numerous varieties of basket cells in each cortical layer (see below).

AXO-AXONIC “CHANDELIER” CELLS Chandelier cells (Somogyi, 1977; Somogyi et al., 1985) have physiological and molecular features similar to those of FS basket cells—they are FS and express PV (Kawaguchi and Kubota, 1997; Lewis and Lund, 1990). They are unique, however, in their morphology and cellular targets. They have a highly stereotyped appearance due to the formation of large cartridge-like synapses on the axon initial segments of pyramidal neurons (DeFelipe and Farinas, 1992). These cells therefore have the potential to strongly regulate the generation of action potentials by pyramidal neurons.

DENDRITE-TARGETING INTERNEURONS Inhibitory neurons targeting more distal dendrites of excitatory neurons are distinct from basket and chandelier cells but are nevertheless a diverse population. These include neurogliaform, double-bouquet, and Martinotti cells, each of which has distinct morphological and physiological properties (Conde et al., 1994; DeFelipe et al., 1989; DeFelipe and Jones, 1992; Jones, 1984; Kawaguchi and Kubota, 1997). Neurogliaform cells have a dense, local axonal arbor and fire spikes late following ramp depolarization (late-spiking or LS). Double-bouquet cells have dendritic tufts both above and below the cell body and fire spikes in bursts. And Martinotti cells are regular spiking, with axons extending primarily above the cell body. Calbindin (CB) immunoreactivity is associated with all of these cell types, but somatostatin (SOM) is preferentially found in Martinotti cells. Since SOM does not colocalize with CCK or PV (Kawaguchi and Kubota, 1997), this is a particularly helpful marker for distinguishing Martinotti cells from regular spiking basket cells, whose morphology can sometimes appear similar to that of Martinotti cells. Although these intrinsic features point to specific functions for each cell type, more information about the functional interactions of these cells with other cell types is needed.

INTERNEURON-TARGETING INTERNEURONS Superficial cortical layers contain a distinctive population of inhibitory neurons that are immunoreactive for calretinin (CR) and have a bipolar dendritic morphology (DeFelipe et al., 1999; Gonchar and Burkhalter, 1999). Within layer 2/3 these cells synapse predominantly onto other inhibitory neurons

(DeFelipe et al., 1999; Meskenaite, 1997), including CR-positive inhibitory interneurons (Gonchar and Burkhalter, 1999). It is therefore suggested that these cells function to disinhibit cortical pyramidal neurons (Gonchar and Burkhalter, 1999).

MORPHOLOGY OF INHIBITORY CELL TYPES IN MACAQUE V1 Most studies of inhibitory neurons in monkey cortex have relied on antibody staining to reveal the processes of neurons expressing particular neurochemicals. Although these studies can provide information about dendritic morphology or synaptic connectivity of populations at the EM level (see above), they do not reveal the detailed patterns of axonal arbors of the same neurons. The Golgi studies of Lund and colleagues have, however, revealed an extensive array of inhibitory cell varieties in macaque V1 (Lund, 1987; Lund and Wu, 1997; Lund and Yoshioka, 1991; Lund et al., 1988). These studies indicate that morphological features distinguish a highly diverse population of inhibitory cell types, each providing output to particular neuronal populations within V1, as evidenced by their precise patterns of axonal arborization.

Unlike typical inhibitory neurons found in other species or cortical areas, inhibitory neurons in macaque V1 often have not only axonal arbors within the immediate vicinity of their cell body and dendritic arbor (intralaminar axons), but also interlaminar projections that are highly specific, targeting from one to as many as five laminar divisions, depending on the cell type. Lund refers to these different cell types as *varieties* in order to avoid confusion with more general cell type classifications such as basket cells or chandelier cells (see above). She often distinguishes several varieties which have their cell bodies in the same layer and might all be of the same class (e.g., basket cells).

The inhibitory neurons of layer 4C have patterns of axonal arborization that are usually confined to a subset of the layers that receive strong input from the LGN (Lund, 1987). For example, many cells in layers 4C α and 4C β have dense intralaminar axons, along with a projection that arborizes in layer 6. Other layer 4C α or 4C β neurons have interlaminar projections specifically to layer 4A or 3B. And some layer 4C neurons have dense axons throughout layer 4C. A population of inhibitory neurons with very narrowly stratified dendrites at the border between layer 4C and layer 5 (layer 5A) has varieties with axonal arbors similar to those of the layer 4C α and 4C β cells. Because the combinations of layers targeted by the axonal arbors of individual inhibitory neurons are typically not all receiving input from the same functional stream (e.g., M, P, or K; see above), these cells might mediate gating of thalamic inputs from diverse sources or provide gain control across streams. In all, Lund (1987) describes 17 varieties of inhibitory neuron in layers 4C α , 4C β , and 5A.

Inhibitory neurons in the most superficial layers, 2–4B, are likely to have the most direct influence on the output from V1 to extrastriate cortical areas, because this output arises from excitatory neurons in the same layers. Layers 3B, 4A, and 4B differ from more superficial layers (2–3A) in that they receive direct excitatory input from layer 4C (see the discussion of excitatory cell types above). Layers 2–3A are dependent on layers 3B–4B for access to the excitatory output of 4C. Accordingly, Lund provides separate descriptions of the neurons in layers 4B, 4A, and 3B (Lund and Yoshioka, 1991) versus layers 1–3A (Lund and Wu, 1997). This distinction is further justified by striking differences in the overall patterns of axonal arbors of cells in these groups. The neurons in layers 2–3A typically confine their axons to layers 1–3A and rarely have axons extending to deeper layers. In contrast, neurons in layers 3B–4B can, as a group, have axonal arbors in any cortical layer. But, individually, layer 3B–4B inhibitory neurons make extremely precise interlaminar projections, clearly targeting specific combinations of layers while avoiding others (Fig. 42.4). The cells in layers 2–4B include the classic cell types, such as basket cells, chandelier cells, and neurogliaform cells, as well as numerous varieties. While the relative simplicity of layer 2–3A cells yields only six varieties (Lund and Wu, 1997), Lund and Yoshioka (1991) distinguish more than a dozen varieties in layers 3B–4B.

The patterns of axonal arborization of inhibitory neurons in layers 5B and 6 mimic the axonal projection patterns of the local, recurrent pyramidal neurons (see above) found in the same layers. Layer 5B neurons have rising axon projections principally in layer 2/3A, while layer 6 inhibitory

neurons have axonal arbors in layers 4C, 4A, and 3B (Lund et al., 1988). Lund et al. (1988) distinguish five varieties of inhibitory neurons with somata in layer 5B and six varieties in layer 6. These cells appear to be predominantly basket cells, plus some chandelier cells, with the varieties differing in relatively subtle features. But a large group of layer 6 cells which Lund et al. (1988) describe as a single variety (variety 6-6) have precise interlaminar axonal arbors that target either layer 4C α , layer 4C β , midlayer 4C, or layers 4C β plus 4A. These patterns of axonal arborization are again reminiscent of the excitatory cell types found in the same layer (see above). It will be particularly interesting to determine whether these layer 5B and layer 6 inhibitory cell types receive excitatory input from the same layers as their excitatory pyramidal cell counterparts or display some other trends related to the M, P, and K pathways. For example, layer 6 pyramidal neurons with axons in layer 4C receive excitatory input from both layers 4C α and 4C β , regardless of cell type. But only pyramidal cell types with axons in layer 4C α receive excitatory input from M-dominated layer 4B, while neurons with axons layers 4C β (and sometimes 4A) receive excitatory input from P- and K-dominated layer 3 (Briggs and Callaway, 2001). Will the inhibitory cell types of layer 6 show similar trends? Or will they receive specific inputs from layers 4C α , 4C β , and 4A that mimic their patterns of axonal arborization? The answers to these questions have distinctly different implications for the roles of these cells in terms of operations such as feedforward or feedback inhibition and differential shunting of input from diverse sources.

FIGURE 42.4. Schematic diagram illustrating several varieties of inhibitory neurons with cell bodies in layers 3B, 4A, and 4B. Each cell variety has axonal arbors that precisely target particular combinations of layers and sublayers in V1. These cell varieties appear to belong to the basket cell and chandelier cell classes. (From Lund and Yoshioka, 1991.)

Summary and conclusions

Understanding how neural circuits give rise to visual perception requires the understanding of numerous details, most of which are necessary but probably not sufficient for solving the problem. It is clear that we must first understand how the neurons that compose the circuits are connected—what is the circuit? But we must also correlate circuits with function and perturb function in vivo to test hypotheses that emerge from observed correlations. As we come to understand the precision of cortical circuits at increasingly fine levels, it becomes clear that it will also be necessary to develop methods and implement experiments designed to observe correlations between circuitry and function and to perturb function at increasingly fine levels. Studies of the circuitry in V1 have shown that individual cell types are precisely interconnected. Thus, future methods and experiments should be designed to attack function at this same level of resolution.

In this chapter, I have emphasized our understanding of V1 circuits at the level of individual cell types. In particular, it has become increasingly apparent that V1 of the macaque monkey contains dozens of anatomically distinct excitatory and inhibitory cell types. We now know that each of the distinct cell types whose sources of functional input have been investigated have proven to be connected differently from other cell types. This is the case even for neurons with similar cell body positions or similar laminar patterns of dendritic arborization. Our understanding of the connectivity in macaque V1 at this cell-type-specific level of detail is so far confined to excitatory neurons. However, studies of the connectivity of inhibitory neurons in rat visual cortex (Dantzker and Callaway, 2000) and the anatomical diversity of inhibitory neurons in macaque V1 (see above) strongly suggest that functional connectivity will also be strongly correlated with distinct anatomical features of inhibitory cell types in macaque V1. We are therefore likely to gain a great deal of understanding about the functional roles of inhibitory neurons and their interactions with excitatory neurons from future studies revealing the functional connectivity of each inhibitory cell type.

Regardless of the detail with which we understand the connectivity between distinct neuron types, we are unlikely to be able to understand the mechanisms by which these circuits contribute to visual perception without also correlating cell types with function. Future studies should take advantage of the strong correlations between anatomical features and connectivity in V1 in order to correlate visual responses with circuits. For example, in vitro studies show that layer 4B spiny stellate cells and projecting pyramids in layer 3B receive strong functional input from layer 4C α but not 4C β , while layer 4B pyramids and layer 3B local pyramids receive considerable layer 4C β input. Thus, comparing

the visual responses of these four anatomically distinct cell types would provide further insight into the contributions of layers 4C α and 4C β to visual responses in more superficial layers.

It should also be apparent that identifying correlations between circuits and function must be accompanied by perturbations that precisely test any hypotheses that emerge based on correlative studies. The incorporation of modern molecular and genetic methods into the experimental arsenal of primate neurophysiologists is likely to contribute importantly to this process. In particular, distinct cell types can be targeted genetically using cell-type-specific promoters (e.g., Zemelman and Miesenböck, 2001), and replication-incompetent viruses can be used to deliver these genetic constructs to neurons in the primate brain (E.M.C., unpublished observations). This genetic arsenal is in need of fortification from further development of genetic methods for perturbing function, such as methods to allow selective and quickly reversible neuronal inactivation (Lechner et al., 2002) and identification of promoters suitable for driving gene expression specifically in cell types of interest.

43 Assembly of Receptive Fields in Primary Visual Cortex

DAVID FERSTER

HUBEL AND WIESEL's characterization of receptive fields in cat visual cortex spawned several completely new lines of research (Hubel and Wiesel, 1962). Almost any description of a sensory receptive field raises similar questions. First, how are the response properties of a cell adapted to help the organism process the signals that arrive through a particular sensory modality? Why, for example, are cells in the visual cortex selective for orientation, and how does that help the brain represent the retinal image or parse it in preparation for object recognition, depth perception, motion detection, and so on? A second, related question is how receptive field properties give rise to the perceptual abilities of the organism. Can we explain an animal's ability to detect motion, for example, in light of the specific motion sensitivities of neurons in the cortex? Third, how do the responses of the neurons develop during early life? In the cortex, for example, specific types of altered experience, such as monocular deprivation or strabismus, profoundly alter some aspects of neuronal responses while leaving others intact. How much of cortical function, then, is genetically predetermined, and how much does it adapt to the environment? Fourth is the question I would like to address here: How are receptive field properties assembled from the neuronal circuitry of the cells and their inputs? In the visual cortex, neuronal receptive fields are completely unlike the receptive fields of the geniculate neurons that provide visual input to the cortex. How are the excitatory and inhibitory synaptic connections organized, both among the cortical cells themselves and between cortical cells and their geniculate inputs, so that the cortical neurons can construct their completely novel representation of the visual image?

For several reasons, this last question as it applies to visual cortex has attracted intense experimental scrutiny, numerous theoretical and computational treatments, and vigorous debate. The cortical transformation of the retinal image is at once sufficiently complex to make it highly interesting and yet extremely well defined so as to be mathematically tractable. Visual stimuli are relatively simple to control experimentally. And visual cortex performs reasonably well under anesthesia, unlike other cortical areas, where the tasks being performed, such as object recognition and high-level reasoning, do not even occur under anesthesia.

Furthermore, the exact nature of the tasks being performed in these other areas is only now being pinned down in any detail. So primary visual cortex holds out the promise of being well understood, of being a part of the brain where we have a chance to learn exactly how cortical circuitry accomplishes a complex bit of neuronal computation. For a long time, then, primary visual cortex has stood in as a proxy for the study of all cortical circuitry and its function.

Feedforward and feedback models of cortical function

Of all the receptive field properties in the visual cortex, orientation selectivity has received the most attention. In the cat, the vast majority of neurons are orientation selective, whereas the neurons of the lateral geniculate nucleus (LGN) show only rudimentary orientation selectivity. Orientation selectivity is also a very striking property and one that is easy to quantify. The first model of orientation selectivity was proposed by Hubel and Wiesel, who first described the receptive fields of cortical neurons (Hubel and Wiesel, 1962). Reasoning from the similarity between the responses of ON centers in ON geniculate neurons and the ON regions of simple cells (and the corresponding similarity between OFF centers and OFF regions), Hubel and Wiesel proposed that simple cell ON regions were constructed from the input of ON center cells whose centers overlapped the ON region. Since the simple cell ON regions are elongated relative to geniculate cell ON centers, they further reasoned that the ON region was constructed from inputs from multiple ON center cells whose receptive fields were distributed in a line down the center of the ON region (Fig. 43.1). A similar arrangement could occur for the OFF region and presynaptic OFF-center geniculate neurons. Some measure of orientation selectivity immediately falls out of the model: when a stimulus such as a bright bar is oriented correctly, it can simultaneously fall onto the centers of all of the presynaptic ON-center geniculate neurons. In the model, the resulting barrage of excitatory synaptic input brings the simple cell to threshold and causes it to fire in response to this optimal stimulus. When the bar is oriented away from the orientation of the subfields, it can only activate a fraction of the presynaptic ON center cells at any one time, so

FIGURE 43.1. To the right is the receptive field of a simple cell. Crosses represent ON subfields; triangles represent OFF regions. To the left is Hubel and Wiesel's proposal for how the ON subfield arises from excitatory input from ON-center geniculate relay cells whose receptive fields are aligned in a row. (Adapted from Hubel and Wiesel, 1962.)

that the simple cell never reaches threshold. Note that a bar passing over the simple cell receptive field evokes the same number of spikes from each presynaptic geniculate neuron, so that at every orientation the simple cell receives the same total amount of synaptic excitation. But the excitation from the many inputs is spread out in time for nonpreferred orientations as the bar passes the long way down the receptive field, whereas the excitation is nearly simultaneous for the preferred orientation when the bar hits the receptive field broadside. It is the nonlinearity of the spike threshold that converts the long-lasting, low-amplitude input evoked by the nonpreferred orientation into a lack of spike response and the short, high-amplitude input evoked by the preferred orientation into a significant spike response.

This model and its successors have been referred to as *feedforward models*, since the information flows only in the forward direction, from the LGN to simple cells (and later to complex cells). One could also characterize the cortex in these models as a passive filter: the magnitude of a neuron's response is directly and monotonically related to the strength of the stimulus and to how well the stimulus matches the cell's preferred stimulus.

Hubel and Wiesel's model has an almost irresistible elegance and simplicity that has kept it at the center of the debate for 40 years. But the physiology of simple cells is surprisingly complex, and it has not been easy to account for all the properties of simple cells in detail with quantitative elaborations of Hubel and Wiesel's ideas. The difficulties will be discussed in detail below. But to deal with them, a separate class of models of cortical function has been developed (Ben-Yishai et al., 1995; Douglas et al., 1995; Somers et al., 1995; Sompolinsky and Shapley, 1997). These models are completely different in character from the original. First, they are feedback models as opposed to feedforward models: information reverberates within an excitatory feedback loop formed by the cells in a cortical column, and the responses of the cells are refined on each pass through the loop. Second, these models depend less on the spatially specific organization of the excitatory input from geniculate cells to

FIGURE 43.2. A diagram of a feedback model of orientation selectivity in visual cortex. Excitatory neurons within a column (*open circles*) excite one another and amplify the input coming from the LGN. Inhibitory neurons are coactivated with the excitatory neurons within their column and inhibit neurons in adjacent columns. As a result, the most stable activity pattern within the cortex is a single bubble of activity (*solid curves below*), but the location of the bubble will depend on which orientation is most prevalent in the image (*dashed curves*).

simple cells and more on the orientation-specific organization of the lateral inhibitory connections within the cortex. Finally, the feedback models do not act merely as passive filters; as will be discussed below, they impose their internal structure, that is, their internal model of the world, on the representation of the retinal image in a way that the feedforward models do not. Thus, the debate over feedforward and feedback models is a debate over the essence of cortical function. In classical fashion, however, the dialectic between the two models and the interplay between experiments and models has increased our understanding of the cortex dramatically.

The structure of the feedback models is illustrated in Figure 43.2. Though details vary from one implementation to another, the models rely on three key features of cortical organization. First, neurons within a column excite one another and, by doing so, amplify any signals coming from the LGN (hence the *feedback*). Second, the amplification from within any one column is prevented from spreading to adjacent columns by lateral inhibitory projections that originate from within the column. (The inhibitory interneurons are coactivated with the excitatory feedback neurons.) Third, the neurons in each column all prefer the same orientation. The circuits operate by implementing a form of winner-take-all behavior. Imagine, for example, that two nearby columns (representing nearby orientations within a small region of the image) are receiving significant input from the LGN, but

one is receiving somewhat stronger input. The column with the stronger input will initially be activated more strongly, and its lateral inhibitory projections will partly suppress the feedback amplification in the column with weaker input. As the feedback develops within each column, the activity and therefore the inhibition originating from the more strongly activated column will grow. At the same time, the more strongly active column will inhibit activity in the more weakly activated column, which will in turn disinhibit the more strongly activated column. Eventually, the column with stronger initial input will become fully active and the column with weaker input will become almost completely silent. The result is a single bubble of activity centered on the location of the strongest input from the LGN, that is, in the column in which the visual stimulus most closely matches the preferred orientation.

The feedback models have a number of important properties. (1) The orientation selectivity of cortical neurons does not depend on strongly orientation-sensitive input from the LGN, as would be generated by the Hubel and Wiesel model. (2) The overwhelming majority of the excitatory input to simple cells comes from other cortical cells and not from the LGN. (3) Only a weak orientation bias in the geniculate input is necessary. (4) Because of the lateral inhibition and local excitatory feedback, the cortex responds to many stimuli that contain more than one orientation with a single bubble of cortical activity centered on one orientation column (Carandini and Ringach, 1997). This relative lack of dependence of the shape of the cortical response on the exact details of the stimulus or of the organization of the geniculate input gives the feedback models their power to account for some properties of cortical neurons. But it also is the way in which the models impose their internal model of the world on the retinal image.

Experimental evidence and the feedforward and feedback models

STRENGTH AND SPATIAL ORGANIZATION OF INPUT TO SIMPLE CELLS FROM THE LATERAL GENICULATE NUCLEUS One basic premise of the feedforward models is that the ON and OFF subregions of simple cells arise from the synaptic input from ON-center and OFF-center geniculate neurons with overlapping receptive field centers. Electrical stimulation of the LGN and intracellular recording in cortex have shown that geniculate relay cells do make strong monosynaptic connections with simple cells (Douglas et al., 1991; Ferster and Lindström, 1983). Convincing evidence for the appropriate spatial arrangement of geniculate input comes from cross-correlation experiments (Reid and Alonso, 1996). In simultaneous recording from neurons in LGN and cortex, these authors found strong short-latency spike correlations which

they identified as monosynaptic connections from geniculate relay cell to simple cell. Such correlations were detected only when the receptive field center of the geniculate relay cell overlapped a subregion in the simple cell of the same polarity (ON or OFF). Thus, the subfields of the simple cell appear to originate from direct geniculate input, exactly as was predicted by Hubel and Wiesel's feedforward model. Furthermore, these monosynaptic connections from the LGN appear to account for much of a simple cell's response. That is, individual inputs from the LGN account for up to 15% of the spikes in the simple cell, and each simple cell likely receives multiple geniculate inputs (Alonso et al., 1996). The geniculate input can therefore account for a large fraction of the visual responses of simple cells.

CORTICAL INACTIVATION EXPERIMENTS The feedback models make an important prediction: that orientation selectivity depends on participation by the full cortical circuit. Unlike the feedforward models, then, the feedback models predict that orientation selectivity should collapse almost completely when the cortex is inactivated. This prediction has been tested in two experiments. In the first, the cortex was inactivated by cooling while simple cells were recorded intracellularly (Ferster et al., 1996). At surface temperatures below 10°C, most cortical cells stopped firing in response to optimal stimuli (except for cells in layer 6, which were reduced in activity by a factor of 5). At the same time, inhibition evoked by electrical stimulation in the LGN disappeared from cortical cells (presumably since the inhibitory interneurons were also silenced by the cooling). And finally, the amplitude of visually evoked modulations in membrane potential was reduced in amplitude by up to 15-fold. All these changes indicate that most of the cortical circuit was inactivated by cooling and that the remaining membrane potential responses recorded intracellularly in simple cells originated from the LGN, which was not affected directly by the cooling. Yet the orientation tuning of these residual responses was almost identical to that seen in the intact cortex. Neither the preferred orientation nor the width of tuning was significantly broadened.

In a second experiment, the cortex was silenced by electrical stimulation rather than by cooling (Chung and Ferster, 1998). A shock to the upper layers of the cortex evoked a large, long-lasting (200 msec) inhibition in nearly every cell within a 1 mm radius throughout the depth of the cortex. During the early part of this inhibition, a briefly flashed, optimally oriented grating evoked no spikes in any of the affected cells, even though it evoked vigorous responses in the absence of the electrical stimulus. In intracellular recordings from simple cells with direct input from the LGN, the electrical stimulus reduced the membrane potential response to the flashed grating by about 50% in amplitude.

Therefore, about half of the visually evoked synaptic input to these simple cells appeared to come from the cortex, whereas the remaining half presumably came from the LGN. Interestingly, the orientation selectivity of this remaining input was not significantly different from the selectivity of the responses recorded while the cortex was fully active.

Both the cooling and electrical stimulation experiments suggest, then, that the geniculate input to simple cells makes up a large fraction of the total input, and that the tuning of the geniculate input is comparable to that of the total input. The amplification of the geniculate input by the cortical circuit appears to be modest in size and appears not to sharpen orientation selectivity significantly.

PREDICTION OF ORIENTATION TUNING FROM THE SPATIAL ORGANIZATION OF THE RECEPTIVE FIELD MAP Despite all this seemingly good news for the feedforward models and bad news for the feedback models, can the feedforward models account quantitatively for all the behavior of simple cells? In the feedforward models, for example, the orientation selectivity of a simple cell arises from the elongation of the receptive field subregions, which in turn is derived from the arrangement of the receptive fields of presynaptic geniculate neurons. As a result, the longer and narrower the receptive field subregions are, the more sensitive the cell should become to small changes in orientation around the preferred orientation, that is, the more sharply tuned for orientation the cell will become. One can test this prediction by making quantitative comparisons between the elongation of the subfields and orientation tuning width in real cells. In several experiments, the tuning width of simple cells was predicted from subfield shape by assuming that the simple cells combine their inputs linearly (Gardner et al., 1999; Jones and Palmer, 1987a, 1987b). Receptive fields were mapped with high precision using small spots of light flashed throughout the receptive field, and orientation selectivity was predicted from those maps using linear summation. In most cases, the predictions failed. Whereas the preferred orientation was always well predicted by the orientation of the receptive field subregions, the width of tuning was not: the cells were most often much more sharply tuned for orientation than the elongation of the subfields would predict.

And yet, in experiments in which receptive fields and orientation tuning were measured extracellularly, this result may not be unexpected. In these experiments, the receptive field maps should predict the orientation tuning of the *synaptic input to the cell*, whereas the orientation tuning was measured from the *spike output*. It has now been shown directly that the orientation tuning measured from spikes is significantly narrower than that measured from synaptic input, that is, the subthreshold changes in membrane poten-

tial. This narrowing originates from the so-called iceberg effect (Carandini and Ferster, 2000; Volgushev et al., 2000): at the fringes of the orientation tuning curve, some orientations evoke small membrane depolarizations that remain subthreshold and therefore do not evoke spikes. Thus, because of the iceberg effect, the mismatch that is observed between predicted and measured orientation tuning is expected.

In two experiments, the orientation tuning of the membrane potential responses were compared to that predicted from the receptive field map. In the first experiment (Volgushev et al., 1996), the mismatch observed in the extracellular experiments remained, whereas in the second experiment (Lampl et al., 2001) the width of the predicted orientation tuning curve matched that of the measured tuning curve in the majority of cells. In this latter experiment, the changes in tuning width that occur with change in stimulus spatial frequency were also accounted for, which is a strong prediction of the feedforward models. It is difficult to know why the two sets of experiments gave different results, but there were differences in experimental design. Volgushev et al. used long-duration flashing spots to map the receptive fields and flashing bars to measure orientation tuning, whereas Lampl et al. used briefly flashed spots and drifting gratings. Lampl et al. also mapped the receptive fields with somewhat higher resolution. Nevertheless, that the orientation tuning of simple cells can be predicted robustly from the receptive field maps under at least one set of experimental conditions lends strong experimental support to the feedforward models, particularly if much of the synaptic input evoked by the flashing stimuli really does originate from geniculate relay cells.

DYNAMICS OF ORIENTATION TUNING For flashing stimuli, the feedforward and feedback models differ in the development of orientation selectivity during the early phase of a response. In the feedforward models, assuming that all the geniculate relay cells presynaptic to a simple cell begin responding to a flashed stimulus at the same time, and that their responses all grow in proportion to one another, the synaptic potentials measured in the simple cell should be well tuned for orientation from the first moment that orientation tuning can be measured. Furthermore, the width of tuning and the preferred orientation should remain stable throughout the early phase of the response. Feedback models, on the other hand, make a different prediction. At the earliest phase of the response, the response is dominated by the geniculate input, which is postulated to be poorly tuned for orientation on its own. Several milliseconds later, the feedback that originates from within the cortex will begin to build, sharpening the orientation tuning relative to what the geniculate can provide. Thus, the orientation tuning width should narrow

during the first several milliseconds of the response. This sharpening has been observed in extracellular recordings from the monkey visual cortex (Ringach et al., 1997). These authors found that orientation tuning at early phases of the response to flashed gratings is, in some cells, relatively broad, narrowing as the response reaches its peak. Such narrowing is not seen, however, when orientation tuning is measured intracellularly from the subthreshold changes in membrane potential (Gillespie et al., 2001). In these experiments, from the earliest moment that the responses emerge far enough out of the noise to allow the orientation tuning to be measured precisely, the width of tuning is identical to that seen at the peak of the response. What is seen in about half of the cells is a downward shift of the membrane potential at all orientations. This shift appears just prior to the peak of the preferred response and could account for any narrowing of the orientation tuning curve seen in extracellular recordings. That is, a lowering of the entire tuning curve relative to threshold could narrow the tuning of the spike output by the iceberg effect. Note that this downward shift is not equivalent to the narrowing of the orientation selectivity of the excitatory input that is predicted by the feedback models. The origin of the downward shift, whether from synaptic inhibition or by depression in the excitatory inputs (see below), remains to be determined.

CONTRAST INVARIANCE OF ORIENTATION TUNING One of the properties of simple cells that seems most difficult for the feedforward models to account for—and most natural for the feedback models—is the contrast invariance of orientation tuning. Orientation tuning curves predicted by the feedforward model for the excitatory geniculate input to a simple cell at different contrasts are shown in Figure 43.3A. Tuning curves recorded intracellularly from a real simple cell are shown in Figure 43.3C. Note that the width of tuning of the real cell is truly invariant with contrast—the curves simply scale in amplitude (Anderson et al., 2000)—whereas the model predicts that the baseline of the curve rises with contrast in addition to the observed rise in amplitude. The spike output of the feedforward model cell is also at odds with what is observed. With a fixed threshold, the rise in both the baseline and the amplitude of the membrane potential tuning curve with contrast means that orientation tuning of the spikes in the feedforward models will gradually broaden and eventually collapse altogether at high contrasts, and the responses of the cell will fail even for the preferred orientation at low contrasts (Fig. 43.3B). And yet, real cells are much better behaved. At all orientations, the spike output of simple cells scales in amplitude with contrast (Fig. 43.3D). As a result, there is no significant change in the width of orientation tuning with contrast (Sclar and Freeman, 1982; Skottun et al., 1987). These apparent failures of the feed-

forward model in explaining the contrast invariance of orientation selectivity for both membrane potential and spike output must be addressed if the model is to lay claim to any validity in describing cortical function.

THE UNTUNED COMPONENT OF THE GENICULATE INPUT Why do the orientation tuning curves in Fig. 43.3C, recorded from real simple cells (Anderson et al., 2000b), not show the rise in baseline with contrast predicted by the simple feedforward models (Fig. 43.3A)? The baseline rise (equivalent to the “untuned” or “DC” component of the responses to sinusoidal grating stimuli) occurs in the model because geniculate neurons themselves are orientation insensitive (Troyer et al., 1998). As discussed at the beginning of this chapter, an orthogonally oriented bar passing across the receptive field of a simple cell evokes the identical responses in each geniculate relay cell as does a properly oriented bar. The only reason the peak response in the simple cell is smaller at the null orientation is that the inputs from all the geniculate neurons are spread out in time as the bar passes down the rows of the geniculate receptive field that make up the ON and OFF subfields. Even though it is small, however, this excitatory input at the null orientation should grow with

FIGURE 43.3. Orientation tuning curves at different contrasts for (A) membrane potential for the simple feedforward model, (B) spike output of the simple feedforward model, (C) the membrane potential as recorded intracellularly in simple cells, and (D) spike output of simple cells as recorded intra- or extracellularly.

contrast in proportion to the growth of the input at the preferred orientation, and so the baseline of the tuning curves should rise with contrast (Fig. 43.3A).¹

Why, then, does this predicted input at orthogonal orientations not appear in the intracellular records from simple cells (Fig. 43.3C) and why does it not grow with contrast (Anderson et al., 2000b)? The feedback models solve this problem elegantly (Somers et al., 1995). Remember that the feedback models respond with a bubble of activity in the cortex centered on the column with the preferred orientation that most closely matches the orientation present in the stimulus. Most importantly, the shape of the activity bubble depends little on the details of the input from the LGN, as determined either by the anatomical arrangement of the projection from the LGN or by the exact configuration of the stimulus. Instead, the activity pattern is determined largely by the extent of the lateral inhibitory projections within the cortex. The pattern of activity will therefore be relatively independent of the amplitude (contrast) of the stimulus as well. Since the orientation tuning of individual cells is directly related to the spatial pattern of activity in the cortex, the feedback models nicely solve the contrast invariance problem and mimic the contrast invariance observed in real simple cells.

While the simplest form of the feedforward model of Hubel and Wiesel, which relies on geniculate input alone, cannot explain the lack of a rise in baseline, there are two ways in which the model might be amended to account for the missing input at the nonpreferred orientations. The first addition to the feedforward model is a feedforward (not feedback) inhibition via cortical interneurons (Troyer et al., 1998). This inhibition would have exactly the same spatial organization and contrast dependence as the geniculate input to a simple cell. In other words, the interneuron's receptive field would look exactly like that of the simple cell it was inhibiting. As such, it would exactly counteract the predicted rise in baseline of the excitatory geniculate input to the simple cells at nonpreferred orientations. The trick is to prevent the inhibition from counteracting the geniculate input at the preferred orientation. To do so, the subfields of

the interneuron are flipped, OFF for ON and ON for OFF. At the preferred orientation, the interneuron will still respond strongly, but at the opposite spatial phase from the geniculate input. When the bar is maximally stimulating the ON geniculate inputs, it is centered on the interneuron's OFF region, so that the interneuron will not be active and will not affect the simple cell's response. The inhibition and excitation never occur simultaneously in response to stimuli of the preferred orientation, leaving the geniculate input free to fire the simple cell. But at the nonpreferred orientation, the interneuron responds in proportion to its geniculate input, thereby suppressing the effects of the excitatory geniculate input to the simple cells it inhibits (Troyer et al., 1998).

A second mechanism that might account for the lack of a rise in baseline in Figure 43.3C is synaptic depression. Synaptic depression has a disproportionately greater effect on steady-state or slowly varying inputs than it does on rapidly changing inputs (A. E. Krukowski and K. D. Miller, private communication). Thus, it will shorten the duration of the synaptic input from each geniculate neuron evoked by the passage of the stimulus. That is, the synaptic input to the simple cell will tail off faster than the spiking in the geniculate neuron itself. Note that this shortening will have little effect on the peak amplitude of the preferred response of the simple cell when the geniculate inputs are simultaneous. The shortening will, however, reduce the amplitude of the long, slow response to the orthogonal orientation by reducing the degree of temporal overlap between the asynchronous geniculate inputs. Krukowski and Miller estimate that depression at the geniculocortical synapse could reduce the size of the input at the nonpreferred orientation by as much as 60% relative to what is predicted by the simple feedforward models (though depression will have less of an effect in the response to gratings of temporal frequencies above 4 Hz). Whether depression occurs or can play this role in orientation selectivity remains to be determined experimentally.

MODIFYING THE ICEBERG EFFECT Even if the lack of a contrast-dependent baseline shift in the tuning curves of Figure 43.3C can be explained (by feedback, feedforward inhibition, or depression), how can the orientation tuning of the spike output of the neuron remain contrast invariant? Note that a fixed threshold applied to the tuning curves in Figure 43.3C (horizontal line) would appear to generate spike output tuning curves of different widths at different contrasts. In order to answer this question, one must first realize that the graphs of Figure 43.3C and Figure 43.3D are derived from the *averaged* responses of simple cells. That is, each point is derived from the averaged response to many trials of a stimulus with a particular combination of orientation and contrast. The *individual* responses that make up

¹One might think that at the orthogonal orientation, the bar would evoke a decrease in the activity of OFF-center geniculate cells making up the OFF region of the simple cell at the same time that it is evoking an increase in the ON-center cells in the ON region. These effects cannot balance one another at high contrasts, however, since the decrease in OFF-center cell activity saturates at 0 spikes/sec from a starting value of about 15 spikes/sec, which is the spontaneous rate, whereas the increase in ON-center cell activity can increase to well over 200 spikes/sec. Thus, at high contrasts and nonpreferred orientations, the feedforward models predict the presence of a small but nonzero synaptic input, which grows with contrast.

those averages, however, are extremely variable from trial to trial. The response to a low-contrast stimulus at the preferred orientation, for example, can occasionally be as large as the response to a high-contrast stimulus at the preferred orientation. Any orientation that evokes a nonzero response on average can evoke a response that is almost as large as the response to an optimally oriented high-contrast stimulus. What makes the average response to nonoptimal stimuli small (and subthreshold) is that these large individual responses are rare (Anderson et al., 2000b). Unlike optimal responses, on the majority of trials nonoptimal stimuli evoke little or no response at all. Nevertheless, the few suprathreshold responses that do occur contribute enough to the tuning curves at low contrast to broaden them significantly relative to what would be expected from the average membrane potential tuning curves.

Another way to look at the effect of response variability (or noise) is from the perspective of the threshold mechanism. The thick black line in Figure 43.4 shows the typical relationship between membrane potential and spike rate found in neurons: a nonzero threshold followed by a linear relationship. The trial-to-trial variability of the response to a stimulus, however, can be seen as effectively changing the threshold relative to the fixed mean response (Fig. 43.4, green curves). When the noise is high, the threshold is effectively lowered because the noise boosts the chance that the visual response will fire the cell. When the noise is low, the threshold remains effectively high. The average effective threshold can then be calculated by averaging together the numerous curves for individual stimulus trials (Fig. 43.4, red curve). This average can be shown to approximate a power law in which the spike rate is proportional to R^n (Fig. 43.4, blue curve), where R is the mean amplitude of the visually evoked response (relative to rest) and n is approximately 3 (Hansel and van Vreeswijk, 2001; Miller and Troyer, 2002). Thus, the noise has effectively smoothed the discontinuity of the threshold curve intrinsic to the cell's electrical properties. This smoothing is akin to the smoothing-by-noise or dithering phenomenon known in electrical engineering.

It is now possible to understand the relationship between the membrane potential (input) tuning curves of Figure 43.3C and the spike rate (output) tuning curves of Figure 43.3D: the latter should simply be equal to the former raised to the third power. The curves in Figure 43.3C can be well described by Gaussians of different amplitudes but the same of width, σ_1 . And raising a Gaussian to the third power yields a new Gaussian with $\sigma_2 = \sigma_1/\sqrt{3}$.

$$R(\theta, C) = (A_c e^{(\theta - \theta_{\text{pref}})^2 / \sigma_1^2})^3 = A_c e^{(\theta - \theta_{\text{pref}})^2 / (\sigma_1 / \sqrt{3})^2}$$

As a result, if all the widths of the input tuning curves are identical, then all the widths of the output tuning curves will be identical as well, though narrower than the input curves.

FIGURE 43.4. Smoothing-by-noise of the average relationship between membrane potential and spike rate. *Black curve*: the relationship between membrane potential and spike rate defined by the cell's electrical properties. *Green curves*: the effective threshold is shifted by the presence of trial-to-trial noise in the response to a visual stimulus. Thresholds are distributed normally. *Red curve*: the average of the green curves. *Blue curve*: An approximation to the blue curve by a power function (exponent of 3).

Thus, smoothing by noise predicts contrast invariance of the spike output from the contrast invariance of synaptic input, and yet at the same time allows for a narrowing of tuning relative to that of the synaptic input. This narrowing is similar in magnitude to that observed in real simple cells (Carandini and Ferster, 2000; Volgushev et al., 2000).

CROSS-ORIENTATION INHIBITION Even before the advent of feedback models of cortical function, it was generally thought that intracortical inhibition must sharpen orientation selectivity relative to that provided by the direct geniculate input to simple cells (for all the reasons outlined above). This inhibition would arise from cortical cells with preferred orientations different from the preferred orientation and thus has been called *cross-orientation inhibition*. Evidence for cross-orientation inhibition comes from experiments in which two stimuli are presented to a cortical cell, a test stimulus at the preferred orientation and a conditioning stimulus at the orthogonal orientation (Bonds, 1989; DeAngelis et al., 1992; Morrone et al., 1982). Even though the conditioning stimulus by itself evoked no spikes at all, it still reduces the response to the preferred stimulus alone. The simplest explanation for this behavior is cross-orientation inhibition. Several lines of evidence support this view. Local inactivation of nearby cortical columns with a preferred orientation orthogonal to that of a recorded cell increases the response of the recorded cell to stimuli of the orthogonal orientation, as if that column is providing strong inhibition (Crook et al., 1998; Eysel et al., 1998). Anatomical evidence

has been presented for inhibitory connections between columns of different orientation preference (Matsubara et al., 1985). Similarly, when GABA_A antagonists are applied to the cortex near a recorded cell, orientation selectivity is lessened or abolished, as would be expected were cross-orientation inhibition to play a role in orientation selectivity (Sillito, 1975; Tsumoto et al., 1979).

Effects of GABA_A antagonists can be difficult to interpret, however, since they increase the general excitability of the network and may thereby cause a nonspecific loss of selectivity unrelated to cross-orientation inhibition. Indeed, intracellular blockade of inhibition in one cortical cell seems not to reduce its orientation selectivity (Nelson et al., 1994). Another difficulty with attributing cross-orientation effects to cortical inhibition is that cross-orientation effects tend to be monocular: the suppressive effect of the orthogonal conditioning stimulus is much weaker or absent when present in the opposite eye from the preferred test stimulus, suggesting that cortical cells, which are strongly binocular, may not be the origin of cross-orientation inhibition effects. Finally, intracellular recording shows that synaptic inhibition is much stronger at the preferred orientation than at the orthogonal one, though some inhibition is present at all orientations.

Recent work provides an alternative explanation for cross-orientation effects (Freeman et al., 2002). These authors measured cross-orientation effects under two special circumstances, with the conditioning stimulus drifting at very high temporal frequencies and after prolonged adaptation to the conditioning stimulus. The responses of cortical cells activated by the conditioning stimulus are greatly diminished under both circumstances, and yet cross-orientation effects are almost completely unaffected. This would suggest either that cross-orientation effects are not mediated by cortical neurons at all or that cross-orientation inhibition is mediated by a very special and rare class of cortical neurons that, unlike the vast majority of cortical cells, respond at high temporal frequency *and* are unaffected by adaptation. The authors argue strongly for the first possibility, that cross-orientation effects are mediated not by cortical inhibition but by depression at the synapses between geniculate relay cells and simple cells. They then go on to model the depression and show that it can account for cross-orientation effects. In essence, the extra activity evoked in the relay cells by the conditioning stimulus increases the level of depression at their synapses, thereby reducing the excitatory drive evoked by the test stimulus.

Conclusions

It may seem paradoxical that orientation selectivity, the receptive field property most closely associated with the visual cortex, is largely established at the first synapse in

the cortex, between the axons of the LGN and the simple cells of layer 4. And yet that is what I believe the evidence as summarized here most strongly supports. The original model of Hubel and Wiesel, with minor modifications of smoothing-by-noise, and perhaps synaptic depression and/or feedforward inhibition from other simple cells, can account for many of the properties of simple cells. The strength and spatial organization of the geniculate input are exactly as the model predicts. The spatial organization of the inputs can account quantitatively for the orientation selectivity of the modulatory component of the simple cell membrane potential responses. The threshold nonlinearity can explain the discrepancy between the orientation tuning of the synaptic input and spike output. The orientation selectivity of the synaptic input to simple cells is stable over the course of the response to a flashed stimulus. And nearly complete suppression of the rest of the cortical circuit leaves the major components of orientation tuning of the synaptic input to simple cells intact. This leaves the question of what the vastly complex interconnections among cortical cells are meant to achieve, if not orientation selectivity. But the exact manner in which other receptive field properties—direction selectivity, disparity sensitivity, end stopping, surround suppression and facilitation, spatial frequency selectivity, the effects of attention—act has yet to be determined. Surely these properties, and others yet to be described, will require the fully functional cortical circuit to elaborate them.

44 A Modern View of the Classical Receptive Field: Linear and Nonlinear Spatiotemporal Processing by V1 Neurons

GREGORY C. DEANGELIS AND AKIYUKI ANZAI

Framework

The receptive field is a central construct in virtually all physiological and computational accounts of the workings of the early visual system. It describes how visual inputs are transformed into neural responses and thus represents the computations performed by a neuron. For this reason, studies of receptive fields are essential for understanding the neural basis of visual perception.

The receptive field of a visual neuron was originally defined as the region of the retina that must be illuminated in order to evoke a response from the neuron (Hartline, 1940). In addition to defining the spatial extent of the receptive field, traditional descriptions specified that particular regions of a receptive field could respond to luminance increments (ON subregions), luminance decrements (OFF subregions), or both (ON-OFF subregions). Using this basic scheme, the spatial organization of receptive fields in the retina, lateral geniculate nucleus (LGN), and striate cortex was elucidated in a series of classic studies (e.g., Barlow, 1953; Hubel and Wiesel, 1961, 1962; Kuffler, 1953), some of which are described below. However, research over the past two decades has revealed a number of response properties that are not easily described within the basic scheme of ON and OFF subregions, suggesting that an expanded view of the receptive field is needed.

There are two major limitations to the traditional characterization of receptive fields. One is that it does not describe the temporal dynamics of neuronal responses. The response of a neuron to a very brief stimulus rises after some delay and then decays over time, and the time course of this response varies among neurons in the early visual pathways (e.g., DeAngelis et al., 1993a; De Valois et al., 2000; Wolfe and Palmer, 1998). In addition, the temporal dynamics may vary dramatically from one spatial location to another within the classically defined receptive field (DeAngelis et al., 1993a; McLean et al., 1994). Thus, it is essential for any

modern description of receptive fields to incorporate both spatial and temporal dimensions.

The second major limitation of the traditional description of receptive fields is that it does not allow for a rigorous characterization of nonlinear response properties. The response of a neuron to multiple stimuli distributed across space and time is often not equal to the linear summation of the responses to the individual stimuli, and in many cases the dominant component of the response is due to nonlinear interactions among stimuli. Thus, a modern description of the receptive field must be able to represent nonlinear response properties in addition to linear characteristics.

In this chapter, we define a receptive field as the spatiotemporal structure that characterizes the transformation between the visual image and a neuron's response, a view that has emerged from research done over the past few decades in numerous laboratories. The main advantage of this modern view is that it describes temporal dynamics of neuronal responses, and it considers the information processing performed by neurons through spatiotemporal interactions (both linear and nonlinear) within the classical receptive field. We show that this view provides new and better explanations for some of the response properties of neurons in primary visual cortex. It should be noted, however, that we do not deal with response modulations originating from outside the classical receptive field, which are described elsewhere in this volume (Chapter 45). Although nonclassical surround effects constitute important receptive field properties, they are not generally elicited by the types of stimuli discussed here and will not be a part of our descriptions.

To characterize the transformation from visual image to neuronal response, it is useful to start by considering the relevant dimensions of the visual input (Adelson and Bergen, 1991). Ignoring color for the sake of simplicity, the image formed on the retina of each eye is a time (T)-varying pattern of luminance across two spatial dimensions (X, Y),

which we denote as $I(X, Y, T)$. The response (instantaneous spike rate) of a neuron, on the other hand, is a function of only time and will be represented here by $R(T)$. In our framework, the receptive field transforms the image, $I(X, Y, T)$, into the neuronal response, $R(T)$, in two possible ways: linearly or nonlinearly (Fig. 44.1A, B). In the linear case, the neuron's response, $R(T)$, is described by a convolution of the image, $I(X, Y, T)$, with the spatiotemporal receptive field, denoted by $RF_L(X, Y, T)$:

$$R(T) = \int \int \int_{X, Y, \tau} RF_L(X, Y, \tau) I(X, Y, T - \tau) d\tau dY dX \quad (1)$$

In other words, the neuron's response is the linear summation of $I(X, Y, T)$ weighted by $RF_L(X, Y, T)$. We shall call $RF_L(X, Y, T)$ a *linear receptive field map* or a *linear map* for short. For a linear neuron, $RF_L(X, Y, T)$ can be obtained by measuring the neuron's response to a small, brief stimulus (i.e., a spatiotemporal impulse) presented at various locations throughout the receptive field. In turn, $RF_L(X, Y, T)$ can be used to predict the response of the linear neuron to any arbitrary stimulus according to equation 1. It follows that the response to a combination of multiple stimuli can be predicted by the sum of responses to the individual stimuli. In reality, neurons' behavior cannot be strictly linear due to the threshold for spike generation. However, if neurons behave otherwise linearly, equation 1 still holds for a limited range of inputs, that is, above threshold. In the third section, we will examine the spatiotemporal structure of linear receptive field maps for neurons in the central visual pathways. We will see that linear maps provide a good account of the response properties, including directional selectivity, of many neurons.

On the other hand, if a neuron combines visual inputs across space and time in a nonlinear fashion, the response will deviate from that predicted by the convolution integral of equation 1. For instance, the response of a nonlinear neuron to a combination of two stimuli would be the sum of responses to the individual stimuli (linear response) combined with the response caused by interactions between the two stimuli (nonlinear response). Thus, to describe the response, $R(T)$, of a nonlinear neuron completely, the nonlinear response due to interactions among combinations of inputs must be specified (Fig. 44.1B). We will call maps that describe this transformation *nonlinear receptive field maps* or *nonlinear maps*. For example, the map that describes nonlinear interactions between two inputs i and j (i.e., second-order interactions) will be a function of the spatial and temporal dimensions associated with the two inputs. We denote this second-order nonlinear map as $RF_{N2}(X_i, Y_i, T_i, X_j, Y_j, T_j)$. Then the response, $R(T)$, of a second-order nonlinear neuron can be described as the sum of two components: a linear response given by equation 1 and a nonlinear

FIGURE 44.1. A visual neuron can be viewed as a system that takes an image, $I(X, Y, T)$, as input and produces a response, $R(T)$, as output. $I(X, Y, T)$ represents a luminance distribution over two dimensions of space (X, Y) and time (T), whereas $R(T)$ denotes the instantaneous spike rate as a function of time. The receptive field of a visual neuron can then be defined as a spatiotemporal structure that characterizes the transformation between the image, $I(X, Y, T)$, and the response, $R(T)$. *A*, For a linear neuron, this transformation is a linear summation of the image $I(X, Y, T)$ weighted by $RF_L(X, Y, T)$, which we will call a linear receptive field map. *B*, For a nonlinear neuron, the response is the sum of a linear component due to $RF_L(X, Y, T)$, and a nonlinear component due to interactions among visual inputs over space and time. Transformations between combinations of inputs and nonlinear responses are represented by nonlinear receptive field maps, RF_{Np} , where the subscript p indicates the order of nonlinear interaction. For example, the second-order nonlinear interaction between two inputs, i and j , is denoted by $RF_{N2}(X_i, Y_i, T_i, X_j, Y_j, T_j)$. *C*, Space-time separable and inseparable receptive fields. Each contour plot shows a spatiotemporal receptive field map, $RF_L(X, T)$, for a hypothetical V1 simple cell (the Y -axis of $RF_L(X, Y, T)$ has been eliminated for simplicity). Solid and dashed contours represent responses to luminance increments (bright stimuli) and decrements (dark stimuli), respectively. The receptive field map on the left is space-time *separable*, meaning that $RF_L(X, T)$ can be described as a product of a spatial function $G(X)$ and a temporal function $H(T)$, that is, $RF_L(X, T) = G(X)H(T)$. The map on the right is *inseparable*; it cannot be decomposed into a spatial function and a temporal function.

response given by a combination of two visual inputs, $I(X_i, Y_i, T_i)$ and $I(X_j, Y_j, T_j)$, weighted by the nonlinear map $RF_{N2}(X_i, Y_i, T_i, X_j, Y_j, T_j)$:

$$R(T) = \iiint_{X_i, Y_i, T_i} \iiint_{X_j, Y_j, T_j} RF_L(X, Y, T) I(X, Y, T - \tau) d\tau dY dX + \iiint_{X_i, Y_i, T_i} \iiint_{X_j, Y_j, T_j} RF_{N2}(X_i, Y_i, \tau_i, X_j, Y_j, \tau_j) I(X_i, Y_i, T - \tau_i) I(X_j, Y_j, T - \tau_j) d\tau_i d\tau_j dY_i dY_j dX_i dX_j \quad (2)$$

In theory, nonlinear interactions can be of any order. Therefore, the receptive field of a nonlinear neuron is generally represented by multiple maps. However, responses of many neurons in early visual pathways are well described by just two maps: a linear map and a second-order nonlinear map. As we will see in the fourth section, second-order nonlinear interactions are characteristic of *complex* cells and can be measured with appropriately chosen pairs of stimuli. These interactions serve to extract useful information from the visual image, such as motion and binocular disparity. We will see that the essence of such second-order nonlinear computations can be captured with an *energy* model.

It is worth noting that the temporal dimension, T , of the linear and nonlinear receptive field maps represents the time over which the neuron integrates visual inputs. Thus, it differs from the temporal dimension of the image, $I(X, Y, T)$. One of the central tenets of our framework is that the time dimension needs to be considered as part of receptive field descriptions. If the temporal dynamics of a receptive field map do not depend on spatial location, then the map can be summarized by separate spatial and temporal profiles: $RF_L(X, Y, T) = G(X, Y) H(T)$. This case is referred to as *space-time separable* (Fig. 44.1C). However, as we will see shortly, receptive field maps of neurons in the primary visual cortex often depart from space-time separability in functionally important ways. For these neurons, a joint space-time map is the minimum acceptable descriptor of the receptive field.

Mapping receptive fields in space and time: the white noise approach

The formulation of the receptive fields in terms of equations 1 and 2 is based on linear and nonlinear systems analysis theory, the details of which are beyond the scope of this chapter and will be left for other excellent references (e.g., Marmarelis and Marmarelis, 1978; Pinter and Nabet, 1992; Schetzen, 1980). However, modern methods for mapping receptive fields rest entirely on this theory, and some conceptual understanding of the theory is helpful for interpreting the data described in the following sections. As illustrated in Figures 44.1A and 44.1B, a neuron can be considered a system that takes an input and produces an output. The goal of receptive field mapping is to infer a function that describes the transformation between input and output based solely on measurements of the output to some known

inputs. If one could record from a neuron indefinitely, then one might consider testing the neuron with every conceivable stimulus. Obviously, that approach is not only inefficient but also impractical. Methods are needed that allow one to efficiently collect information that is equivalent to testing a neuron with all possible stimuli. It is also desirable that these methods allow one to measure the linear receptive field map and various orders of nonlinear receptive field maps separately, without one measurement affecting the others.

The approach based on the use of *white noise* stimuli satisfies these requirements (Marmarelis and Marmarelis, 1978). White noise is so named because its frequency spectrum is flat, analogous to the spectral distribution of white light. This means that it contains all possible frequency components and hence can test a neuron exhaustively. When applied to a nonlinear neuron, it allows independent estimation of linear and nonlinear receptive field maps by means of cross-correlation analysis. It also guarantees that when nonlinear maps are truncated at some order of interaction, the maps for interactions up to that order still provide the best approximation to the response of the neuron in a mean-squared error sense. However, these benefits come at the expense of the generality assumed in equations 1 and 2. That is, linear and nonlinear receptive field maps are no longer independent of the stimuli used to obtain them (Marmarelis and Marmarelis, 1978). Nonetheless, as we will see in the next two sections, the maps obtained with various stimuli capture basic linear and nonlinear characteristics of neurons' responses in a qualitatively similar manner.

In recent years, several research groups have implemented receptive field mapping techniques based on white noise analysis (e.g., Anzai et al., 1999b; Chen et al., 1993; De Valois et al., 2000; Eckhorn et al., 1993; Emerson et al., 1987; Jacobson et al., 1993; Jones and Palmer, 1987; Livingstone, 1998; Ohzawa et al., 1990; Reid et al., 1997; Ringach et al., 1997; Victor et al., 1977). In these methods, a sequence of visual stimuli is presented rapidly and randomly to the neuron under study, and the resultant spike train is cross-correlated with the stimulus sequence to obtain linear and/or nonlinear maps of the receptive field. The specifics of the methods vary in a number of ways. Some have presented stimuli one at a time (sparse noise: e.g., DeAngelis et al., 1993a; Jones and Palmer, 1987; Ohzawa et al., 1990), whereas others have presented many stimuli simultaneously (dense noise: e.g., Anzai et al., 1999b; Jacobson et al., 1993; Reid et al., 1997). Some stimuli have contained many levels of luminance (Gaussian noise: e.g., Jacobson et al., 1993), while others have had only a few levels (ternary noise: e.g., Emerson et al., 1987; binary m-sequence: e.g., Anzai et al., 1999b; Reid et al., 1997). Most have operated in the space-time domain, but others have

used sinusoidal stimuli and mapped receptive fields in the spatiotemporal frequency domain (Victor et al., 1977; see also Ringach et al., 1997). Receptive field mapping has generally been performed in anesthetized, paralyzed animals, but has recently been done in alert, fixating animals by compensating for eye movements (Livingstone, 1998; Livingstone and Tsao, 1999). Although each has its strengths and weaknesses, all of these methods share two principal advantages: they allow one to obtain spatial maps of receptive fields efficiently and quantitatively, and they reveal the temporal dynamics of the receptive fields.

Figure 44.2 illustrates one of these receptive field mapping approaches (reverse correlation) developed by Palmer and colleagues (Jones and Palmer, 1987; McLean et al., 1994). The visual stimulus is a sequence of small, briefly flashed bars, and each location on a two-dimensional grid is tested using both bright and dark bars. The result of cross-correlating the stimulus sequence with the spike train is a sensitivity profile as a function of space (X, Y) and time (T , correlation delay). This cube of data corresponds to the linear spatiotemporal receptive field map, $RF_L(X, Y, T)$, that provides the best linear characterization of the neuron's response in a mean-squared-error sense (e.g., Victor, 1992). Strictly speaking, the linear map represents responses to bright bars minus responses to dark bars. However, it is common to call positive values of the map *ON responses* or *bright-excitatory responses* and to call negative values *OFF responses* or *dark-excitatory responses*. We will follow this convention unless otherwise noted.

To obtain a nonlinear receptive field map for the interaction of order p (i.e., RF_{Np}), one needs to use stimuli that contain at least p elements (such as spots and bars) so that interactions among them can be measured. In reality, however, the number of interactions explodes exponentially as the order p increases, and an ordinary recording time is generally not long enough to obtain accurate measures of all interactions. Fortunately, neurons in early stages of visual pathways exhibit relatively modest nonlinearities, mostly second-order. Still, many researchers have focused on specific subsets of second-order interactions (e.g., Fig. 44.8) and tailored their methods for efficiency (e.g., Anzai et al., 1999b; Emerson et al., 1987; Ohzawa et al., 1990).

The procedure for computing nonlinear receptive field maps is the same as that for linear maps: a cross-correlation between the stimulus and the spike train. However, the stimulus in this case is a combination of stimulus elements for which interactions are sought. For second-order interactions, this produces a sensitivity profile as a function of space and time associated with two inputs i and j , $RF_{N2}(X_i, Y_i, T_i, X_j, Y_j, T_j)$. The value at each point on the map represents the difference between responses to a pair of polarity-matched stimuli (bright-bright and dark-dark combinations) and a pair of polarity-mismatched stimuli (bright-dark and dark-bright

FIGURE 44.2. Illustration of a reverse correlation method for obtaining the linear spatiotemporal receptive field map. *Top*: a portion of the stimulus sequence is shown. Each stimulus is a small bright or dark bar that is presented for 30 to 50 msec on a gray background at one of 20×20 grid locations. The position and polarity of the bars are randomized. Stimuli are presented in rapid succession, with no interstimulus interval. The spike train of the neuron (which is generally much sparser than the stimulus sequence) is shown below the stimulus sequence. *Bottom*: to obtain the linear receptive field map, one averages together the sections of the stimulus sequence (shaded cubes at the top) that precede each spike. Once this procedure is completed for all spikes, the result is equivalent to that obtained by taking a cross-correlation between the spike train and the stimulus sequence. It is a cube of data that represents neuronal sensitivity in two spatial (X, Y) dimensions and one temporal (T , the correlation delay) dimension. A spatial profile of the receptive field map is generally taken at the value of T that yields maximum neuronal sensitivity (shown inside the cube). Alternatively, the cube can be integrated along the Y -axis (which is typically chosen to be parallel to the neuron's orientation preference) to obtain an X - T profile of the receptive field map (shown below the cube). (Adapted from Ohzawa et al., 1996.)

combinations). We will refer to positive and negative values of the map simply as *polarity-matched* and *polarity-mismatched responses*, respectively.

Linear receptive field maps

SPATIAL ORGANIZATION OF RECEPTIVE FIELDS IN THE CENTRAL VISUAL PATHWAY In most mammals, the dominant visual pathway runs from the retina through the LGN of the thalamus to the primary visual cortex (V1). Spiking neurons along the retino-geniculo-cortical pathway exhibit

one of three main receptive field configurations, as illustrated in Figure 44.3. For retinal ganglion cells and LGN neurons, the receptive field has a roughly circular, center-surround organization (Hubel and Wiesel, 1961; Kuffler, 1953). Two primary configurations are observed: one in which the receptive field center is responsive to a luminance increment (ON-center) and the surround is responsive to a luminance decrement (OFF-surround) (Fig. 44.3A), and another in which the respective stimulus polarities are reversed (i.e., OFF-center and ON-surround). As predicted from the circular symmetry of these receptive fields (assuming linear spatial summation), ganglion cells and LGN neurons are generally nonselective for stimulus orientation and broadly tuned for spatial frequency.

A striking transformation of response properties occurs between the LGN and V1, where orientation selectivity and direction selectivity emerge in primates and felines (Hubel and Wiesel, 1962, 1968). Simple cells, which receive most of the geniculate input to V1, have spatially oriented receptive fields (Fig. 44.3B), with alternating elongated subregions that are responsive to bright or dark stimuli. As discussed below, simple cells act roughly as linear filters, and their orientation and direction selectivity can be understood in terms of the spatiotemporal structure of their linear receptive field maps. Hubel and Wiesel (1962) originally proposed that simple cell receptive fields are constructed from arrays of ON- and OFF-center LGN inputs, and a number of elegant recent experiments provide strong support for this view (Chapman et al., 1991; Ferster et al., 1996; Reid and Alonso, 1995; see Ferster and Miller, 2000, for review). Complex cells, the other major physiological cell type in the striate cortex, respond to both bright and dark stimuli placed anywhere within their receptive fields (Fig. 44.3C). Although complex cells are also orientation selective, it is evident from Figure 44.3C that this selectivity cannot be deduced from conventional receptive field maps. As we will see in the fourth section, however, this and other properties of complex cells can be explained by the nonlinear receptive field structure.

SPATIOTEMPORAL RECEPTIVE FIELD MAPS ALONG THE GENICULOSTRIATE PATHWAY The traditional depictions of receptive fields (Fig. 44.3, *left*) are qualitative and strictly spatial in nature. We now describe linear spatiotemporal receptive field maps and examine their temporal dynamics. The spatiotemporal receptive field map can be summarized by an X - T plot. An X - T plot represents how the one-dimensional spatial profile of the receptive field map changes with time (see Fig. 44.2, *bottom*). Figure 44.4 shows X - T plots for seven representative neurons and illustrates how the linear receptive field structure changes along the geniculostriate pathway.

FIGURE 44.3. Spatial receptive field structure of the major classes of neurons in the geniculocortical pathway. *A*, Schematic and empirical receptive field profiles for an LGN neuron from the cat. In the traditional depiction (*left*), the receptive field has a central ON region (+) that is responsive to luminance increments and a surrounding OFF region (−) that is responsive to luminance decrements. On the right is shown a measured two-dimensional spatial (X - Y) receptive field profile. Solid and dashed contours represent regions of visual space in which the cell responds to bright and dark spots, respectively. Gray level saturation is proportional to response strength in each type of subregion. *B*, Depicted schematically on the left, the receptive field of a simple cell consists of alternating elongated subregions that are responsive to either bright (+) or dark (−) stimuli. A measured receptive field profile for a simple cell in cat striate cortex (area 17) is shown on the right (conventions as in *A*). *C*, Spatial receptive field structure of a complex cell. In the traditional illustration shown on the left, pluses and minuses scattered across the receptive field indicate that the cell responds to both bright and dark stimuli anywhere within the receptive field. Panels on the right show the receptive field profiles of an area 17 complex cell in cat. Because regions responsive to bright and dark stimuli overlap extensively, a separate profile is shown for each stimulus. (Adapted from DeAngelis et al., 1995a.)

LGN neurons For LGN cells (Fig. 44.4A, *B*), the X - T plot typically exhibits a center-surround organization in space and a biphasic structure in time (Cai et al., 1997; De Valois et al., 2000; Wolfe and Palmer, 1998). To a first approximation, the X - T profiles of LGN cells are space-time separable; however, many LGN cells (e.g., Fig. 44.4A) show two subtle, yet clear, deviations from separability. The temporal profile of the surround is often delayed slightly with respect to that of the center. In addition, the first temporal phase of the

surround often appears to converge with the second temporal phase of the center, although this may simply be a consequence of the delay in the surround.

Neurons in the magnocellular and parvocellular divisions of the primate LGN appear to have different temporal dynamics. It has long been appreciated that magnocellular neurons prefer higher temporal frequencies and exhibit more transient responses (Merigan and Maunsell, 1993). Recent studies (De Valois and Cottaris, 1998; De Valois et al., 2000) report that the temporal response profiles of magnocellular neurons are typically biphasic (i.e., odd-symmetric), whereas those of parvocellular neurons are roughly monophasic. We shall return to the importance of this temporal diversity shortly.

The feline LGN does not have magno- and parvocellular subdivisions. Nevertheless, cats appear to have two distinct classes of LGN neurons—*lagged* and *nonlagged*—with different temporal properties (Humphrey and Weller, 1988; Mastronarde, 1987; Saul and Humphrey, 1990; but see Wolfe and Palmer, 1998). As in the monkey, both types typically have bi- or triphasic temporal profiles but differ in phase by roughly 90 degrees. For nonlagged cells (e.g., Fig. 44.4A), the first phase of the temporal profile is largest, whereas for lagged cells (e.g., Fig. 44.4B) the second phase typically dominates. This property accounts for the delayed response of lagged cells to a flashed spot stimulus (Cai et al., 1997).

Simple cells Many simple cells, like their LGN inputs, have linear receptive field maps that are space-time separable, as

shown in Figures 44.4C and D. These X - T profiles typically exhibit multiple lobes in both space and time, and are well approximated by the product of a spatial profile and a temporal profile. Thus, the traditional notion that each receptive field has a unique spatial configuration still pertains to these neurons. The spatial profile typically exhibits one to five distinct subregions of alternating polarity and all possible types of spatial symmetry (i.e., spatial phases) (DeAngelis et al., 1993a; Field and Tolhurst, 1986; Hamilton et al., 1989). The temporal profile is typically biphasic

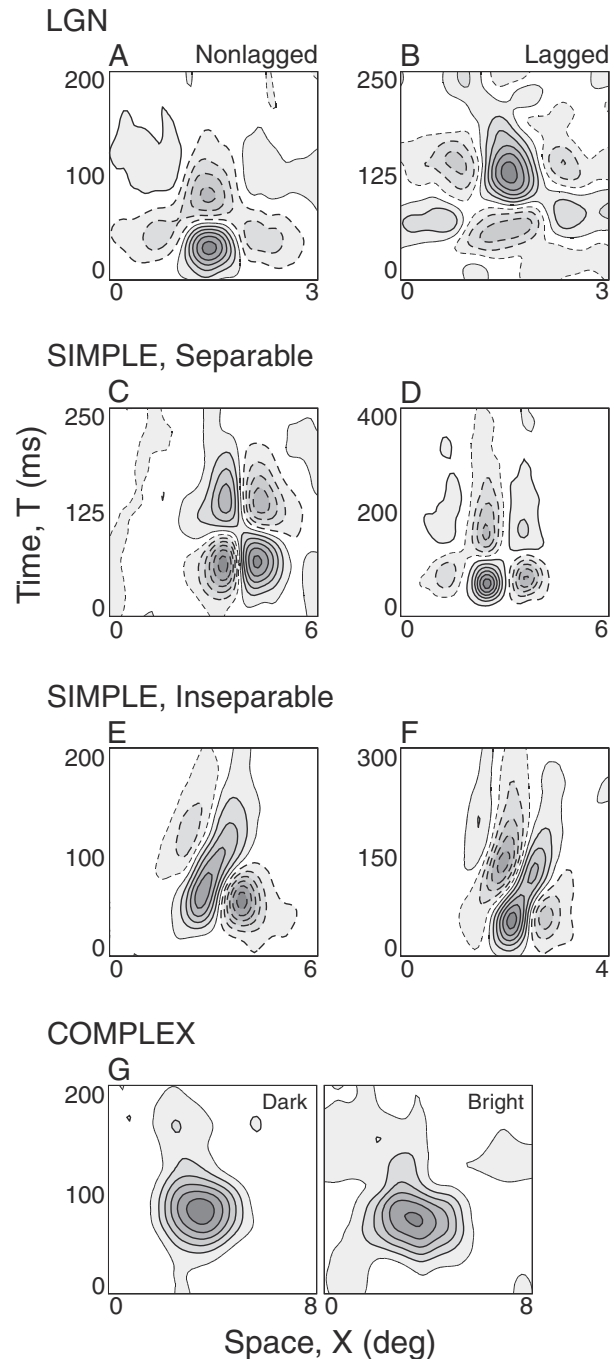

FIGURE 44.4. Linear spatiotemporal receptive field maps (X - T plots) for neurons recorded from LGN and V1 of the cat. For panels A–F, solid contours delimit bright-excitatory (ON) regions, whereas dashed contours indicate dark-excitatory (OFF) regions. A, An X - T profile is shown for a typical ON-center, non-lagged X cell from the LGN. For $T < 50$ msec, the receptive field profile has a bright-excitatory center and a dark-excitatory surround. However, for $T > 50$ msec, the receptive field center becomes dark-excitatory and the surround becomes bright-excitatory. B, An X - T plot for an ON-center, lagged X cell. Note that the second temporal phase of the profile is strongest. C, An X - T profile of a simple cell that is space-time separable. For $T < 100$ msec, the receptive field map exhibits a dark-excitatory subregion to the left of a bright-excitatory subregion. For $T > 100$ msec, each subregion reverses polarity, so that the bright-excitatory region is now on the left. D, Data for another simple cell with an approximately separable X - T profile. E, An inseparable X - T profile of a simple cell. Note how the spatial arrangement of bright- and dark-excitatory subregions (i.e., the spatial phase of the receptive field profile) changes gradually with time. F, Another example of an inseparable X - T profile from a simple cell for which a two-dimensional spatial profile is shown in Figure 44.3B. G, X - T profiles of the complex cell shown in Figure 44.3C. Responses to bright and dark stimuli are shown separately because they overlap extensively. (Adapted from DeAngelis et al., 1995a.)

in cats, although some simple cells exhibit either monophasic or triphasic profiles (DeAngelis et al., 1993a). In monkeys, a much larger fraction of simple cells have monophasic profiles (De Valois et al., 2000).

Hubel and Wiesel (1962) originally suggested that simple-cell receptive fields are created by combining inputs from a group of ON- and OFF-center geniculate neurons with receptive fields that are arranged in rows, a concept that has recently received some strong experimental support (e.g., Alonso et al., 2001; Ferster et al., 1996; Reid and Alonso, 1995). In this light, it is interesting to note that the temporal profile in a single subregion of a separable simple-cell receptive field (e.g., Figs. 44.4C and D) is similar to the temporal structure seen within the receptive field center of either an ON- or OFF-center LGN cell (e.g., Fig. 44.4A). Thus, the temporal organization of separable simple-cell receptive fields seems consistent with the idea that these receptive fields are constructed from arrays of LGN receptive fields (De Valois et al., 2000).

Unlike LGN neurons, however, many simple cells in both cats and monkeys exhibit marked space-time inseparability in their linear maps (e.g., DeAngelis et al., 1993a; McLean and Palmer, 1989; McLean et al., 1994). Two such examples are shown in Figures 44.4E and F. The X - T plots for these cells exhibit ON and OFF subregions that are distinctly tilted in the space-time domain. As a result, there is no unique spatial (or temporal) receptive field profile, because ON and OFF subregions move within the envelope of the receptive field as a function of time. Clearly, for these cells, the very definition of the receptive field must incorporate both space and time.

How are these space-time inseparable receptive fields constructed in V1? Computational studies showed that a pair of separable receptive fields that differ in spatial and temporal phase by 90 degrees could be used to build inseparable receptive fields (Adelson and Bergen, 1985; Watson and Ahumada, 1985). This scheme builds on the previous findings of Pollen and Ronner (1981), who described pairs of adjacent simple cells with receptive field profiles that differed in spatial phase by 90 degrees. Other studies have shown that a population of simple cells with separable receptive fields has the requisite variety of spatial phases to account for the observed diversity of inseparable receptive fields (see also DeAngelis et al., 1993a; De Valois et al., 2000; Field and Tolhurst, 1986; Hamilton et al., 1989). But do simple cells have the necessary diversity of temporal phases? DeValois et al. (1998, 2000) have recently reported that separable simple cells in the monkey form two groups differing in temporal phase by roughly 90 degrees. They suggest that these two groups are driven by magno- and parvocellular neurons of the LGN. In the cat, however, separable simple cells may lack the diversity of temporal phases that would be needed to build inseparable receptive fields (DeAngelis et al.,

1995b). Thus, in the cat, inseparable receptive fields may be constructed directly from a combination of lagged and nonlagged geniculate inputs, as suggested by Saul and Humphrey (1992).

Complex cells Figure 44.4G shows X - T profiles for a complex cell. Responses to bright and dark stimuli are shown separately. Note that the bright and dark responsive regions overlap almost completely in the space-time domain, and no distinct subregions are visible within either domain. Thus, unlike for simple cells, linear receptive field maps give little insight into the stimulus selectivity of complex cells. We shall return to the subject of complex cells in the fourth section.

SPATIOTEMPORAL MECHANISMS UNDERLYING DIRECTION SELECTIVITY In contrast to their geniculate antecedents, many V1 neurons are quite selective for the direction of stimulus motion (e.g., Hubel and Wiesel, 1962; Movshon, 1975; Schiller et al., 1976; Thompson et al., 1994). What accounts for the sudden emergence of directional selectivity in V1 simple cells? Hubel and Wiesel initially suggested that direction selectivity in simple cells could be explained based on the arrangement of ON and OFF subregions within the receptive field. However, subsequent studies revealed that these predictions often failed (Heggelund, 1984; Peterhans et al., 1985). Therefore, it was suggested that direction selectivity is mediated by fundamentally nonlinear mechanisms involving delayed excitation and/or inhibition between different parts of the receptive field (e.g., Barlow and Levick, 1965; Ruff et al., 1987).

In the mid-1980s, theoretical (Adelson and Bergen, 1985; Watson and Ahumada, 1985) and psychophysical (Burr et al., 1986) studies suggested that direction selectivity could be generated from linear filters that are tilted (i.e., inseparable) in the space-time domain. The intuition for this idea comes from the realization that horizontal motion of an object is represented by an oriented stripe in the X - T plane. According to this hypothesis, simple cells with inseparable X - T profiles (e.g., Fig 44.4E, F) should be direction selective, whereas those with separable X - T profiles should not. Several groups have now confirmed this prediction experimentally (e.g., Albrecht and Geisler, 1991; DeAngelis et al., 1993b; McLean et al., 1994; Reid et al., 1991). Figure 44.5 shows data from one of these studies (DeAngelis et al., 1993b), in which direction selectivity of simple cells was measured using drifting sinusoidal gratings and compared with predictions from linear receptive field maps. Note that linear predictions give the correct direction preference for the vast majority of neurons, as evidenced by most of the data points falling in the upper right quadrant of Figure 44.5A (gray shading). However, the linear predictions tend to underestimate the strength of direction selectivity (most points fall

FIGURE 44.5. *A*, Comparison between the direction selectivity index (DSI) measured with drifting grating stimuli (horizontal axis) and the DSI predicted from the linear receptive field map (vertical axis). The DSI is defined as $(R_p - R_n) / (R_p + R_n)$, where R_p is the response to the preferred direction of motion and R_n is the response to the null (opposite) direction. Linear predictions of DSI were obtained from the two-dimensional Fourier transform of the X - T profile (see DeAngelis et al., 1993b). Data are shown for 190 simple cells, 65 from adult cats (*circles*), 55 from 8-week-old kittens (*squares*), and 70 from 4-week-old kittens (*triangles*). A majority of data points fall below the unity slope (*solid line*), indicating that the linear predictions underestimate DSIs measured with gratings. The dashed line shows the result of linear regression ($R = .64$, $P < .0001$); there was no significant main effect of age (ANCOVA, $P > .2$). *B*, The distribution of exponents (n) that would be required to place all of the data points in panel *A* onto the unity-slope diagonal. *C*, The distribution of exponents measured by Albrecht and Hamilton (1982) for a population of 127 cells from cat V1. The exponent value for each neuron was obtained by fitting the contrast-response function with a hyperbolic-ratio curve. (Adapted from DeAngelis et al., 1993b.)

below the diagonal), indicating that simple cells are not strictly linear in their behavior.

Two groups have shown that this discrepancy can largely be accounted for by an expansive nonlinearity at the output of simple cells (Albrecht and Geisler, 1991; DeAngelis et al., 1993b; but see Emerson, 1997). The nonlinearity is generally well described by a power function ($y = x^n$ for $x > 0$). Figure 44.5*B* shows the distribution of exponents (n) that would be needed to equate the predicted and measured indices of direction selectivity for each neuron in Figure 44.5*A* (see also Gardner et al., 1999). For comparison, Figure 44.5*C* shows the exponents measured for a large population of V1 neurons (Albrecht and Hamilton, 1982; see also Anzai et al., 1999b). Although both distributions are rather broad, there is a striking agreement in the shape of the distributions. Therefore, with respect to direction selectivity, responses of simple cells are consistent with those predicted by a linear spatiotemporal filter followed by a static (output) nonlinearity (e.g., Heeger, 1992b). We will discuss this model further in the next section.

Nonlinear receptive field maps

We have thus far examined the spatiotemporal structure of linear receptive field maps for neurons in the LGN and striate cortex. If these neurons indeed sum visual inputs linearly, then their responses to any arbitrary visual pattern can be predicted by convolving the image with the linear receptive field map. On the other hand, if the neurons perform nonlinear summation, then the responses predicted from linear maps will not match the actual responses to stimuli. The deviations of the actual responses from the predicted ones, which can be represented by nonlinear receptive field maps, provide valuable insights into the functions of nonlinear processing.

As described in the first section, these deviations can be attributed to nonlinear interactions among visual inputs. In particular, second-order nonlinear interactions are of fundamental importance in early visual processing. Suppose, for example, that a bar stimulus is presented at one location (x, y) at time t and is subsequently shifted to a new location $(x + \Delta x, y + \Delta y)$ at time $t + \Delta t$. The stimulus will appear to move, provided that Δx , Δy , and Δt are chosen appropriately. Thus, the nonlinear interaction between $I(x, y, t)$ and $I(x + \Delta x, y + \Delta y, t + \Delta t)$ could be a significant factor contributing to detection of the motion. Suppose, instead, that two bars separated by Δx are presented simultaneously (i.e., $\Delta y = 0$, $\Delta t = 0$), one to each eye. They will appear to be a single bar at a certain depth, provided that Δx is within limits. In this case, Δx corresponds to a binocular disparity, and the second-order nonlinear interaction between the two eyes could be an important mechanism for signaling depth. By examining second-order nonlinear receptive field maps, we can learn

how neurons extract information about second-order attributes of the visual scene such as motion and binocular disparity.

We now describe second-order nonlinear spatiotemporal receptive field maps of simple and complex cells. As discussed in the previous section, linear receptive field maps of simple cells account for much of their responses. However, there are some residual responses that can be attributed to static nonlinearities (i.e., nonlinearities that depend on amplitude, not spatial and temporal factors). In contrast, linear maps of complex cells generally explain little of their responses. Responses of most complex cells are dominated by second-order nonlinear interactions and are well described by an energy model.

NONLINEAR INTERACTIONS EXHIBITED BY SIMPLE CELLS

Figure 44.6 shows examples of nonlinear receptive field maps for simple cells. In these maps, solid contours indicate responses to polarity-matched stimuli (e.g., a pair of bright or dark stimuli), whereas dashed contours show responses to polarity-mismatched stimuli (e.g., bright-dark combinations). The map in Figure 44.6A describes the nonlinear spatial interaction between two small squares presented to the same eye (Jacobson et al., 1993). Responses along the main diagonal (X_c) are due to the nonlinear interaction of a stimulus with itself (self-interaction) at various positions in space. Responses along one of the parallel off-diagonals represent the interaction between a pair of stimuli that have a fixed spatial interval between them. The map consists of alternating response regions (solid and dashed contours), which reflect the alternating ON and OFF subregions of the neuron's linear receptive field map (not shown). A pair

FIGURE 44.6. Nonlinear receptive field maps for simple cells and predictions of an $L-N$ model. *A*, A monocular spatial interaction map for a simple cell from monkey V1. The horizontal and vertical axes of the map represent the positions of two stimuli (*small spots*). *Solid contours* indicate responses to polarity-matched stimuli (a pair of bright or dark stimuli), whereas *dashed contours* correspond to responses to polarity-mismatched stimuli (bright-dark combinations). Responses along the X_c diagonal indicate nonlinear interactions when the two stimuli occupied the same location of space (self-interaction). *B*, A binocular spatial interaction map for a simple cell from cat area 17. Nonlinear response is shown as a function of the position of stimuli in the left (X_L) and right (X_R) eyes. Contour conventions are the same as in *A*. Linear receptive field profiles are also shown for each eye along the margins of the plot. The vertical axis, D , represents binocular disparity, whereas the horizontal axis, X_F , indicates position along the frontoparallel plane. *C*, Contours show the binocular interaction map predicted from the product of the monocular receptive field profiles for the same simple cell as in *B*. There is good agreement between the measured (*B*) and predicted (*C*) interaction maps. (*A* adapted from Jacobson et al., 1993; *B* and *C* adapted from Anzai et al., 1999b.)

of bright stimuli presented in ON subregions, or a pair of dark stimuli presented in OFF subregions, produce more response than expected from linear summation (solid contours), and the same is true for a pair of bright and dark stimuli presented in ON and OFF subregions, respectively (dashed contours). The responses vary along the main diagonal (X_c) as well as the opposite diagonal, indicating that the nonlinear interaction depends not only on the spatial interval between two stimuli but also on the individual positions of the stimuli.

Figure 44.6*B* shows that a similar pattern of nonlinear spatial interaction can be observed for a pair of stimuli presented to the two eyes (Anzai et al., 1999b). Solid and dashed contours in the map correspond to regions where linear receptive field profiles for the two eyes (shown in the margins of the nonlinear map) have matching (ON-ON or OFF-OFF) and nonmatching (ON-OFF) subregions, respectively. The responses vary along the diagonal (X_f) as well as the opposite diagonal (D). Thus, the nonlinear interaction depends not only on the interocular position difference, or binocular disparity, but also on the individual monocular positions.

Second-order temporal interactions (between two stimuli presented at the same spatial location but with various time delays) also exhibit similar response patterns (Mancini et al., 1990). In this case, the pattern seems to reflect the bi- or triphasic nature of the temporal profile of the linear receptive field map (e.g., Fig. 44.4). Similar to spatial interactions, nonlinear facilitation occurs when a pair of bright stimuli are presented during ON phases, a pair of dark stimuli are presented during OFF phases, or bright and dark stimuli are presented during ON and OFF phases.

A common feature of the nonlinear receptive field maps of simple cells is the alternating pattern of responses to polarity-matched and polarity-mismatched stimuli, which appears to reflect the arrangement of ON and OFF subregions in the linear receptive field map. These nonlinear maps are generally separable and can be described as a product of two functions. In fact, second-order interaction maps are expected to be proportional to the product of the linear receptive field profiles if the system structure of neurons is consistent with a linear filter followed by a static nonlinearity (L - N structure; Marmarelis and Marmarelis, 1978). However, if the linear map is inseparable in space-time, the second-order space-time interaction map will not be separable even though the system conforms to the L - N structure. It has been shown that some simple cells exhibit inseparable space-time interaction maps (Baker, 2001; Emerson, 1997). Although this second-order space-time inseparability can contribute to direction selectivity of the neuron (Baker, 2001), it does not necessarily require more than a static nonlinearity. A space-time inseparable linear filter followed by a static nonlinearity would exhibit separable maps for

space-space and time-time interactions but would show an inseparable map for space-time interactions.

SYSTEM STRUCTURE OF SIMPLE CELLS If a simple cell can be modeled as a linear filter followed by a static nonlinearity, then the second-order nonlinear map would be proportional to the product of the linear receptive field maps. Anzai et al. (1999b) have examined this prediction by comparing the binocular interaction map (Fig. 44.6*B*) with a product of monocular receptive field profiles (Fig. 44.6*C*). As expected, the nonlinear maps of many simple cells are proportional to the product of their monocular receptive field profiles, consistent with the L - N prediction. Similar analyses have been conducted in the temporal domain (Jacobson et al., 1993; Mancini et al., 1990) and the monocular space-time domain (Baker, 2001; Emerson, 1997; Jacobson et al., 1993). In all of these studies, it was found that many simple cells followed an L - N structure. However, some simple cells deviate from this model in a manner that suggests multiple L - N subsystems arranged in parallel (Anzai et al., 1999b; Baker, 2001; Emerson, 1997; Jacobson et al., 1993). It should be noted that a parallel L - N structure would create some overlap between ON and OFF subregions of different L - N subsystems. Receptive field maps of such neurons would have a profile that is intermediate between the canonical simple and complex types. Although quantitative studies of the simple/complex classification do find a bimodal distribution, there are certainly a fair number of cells that fall between the two modes (Skottun et al., 1991). While it is likely that these neurons may be classified as simple by some criteria, one should realize that they could be classified as complex on other grounds. The existence of such neurons does not diminish the fact that most simple cells are well described by the L - N model.

For simple cells that conform to an L - N structure, it is useful to identify the shapes of the linear filter and the static nonlinearity. Luckily, the shape of the linear filter is already known; it is given by the linear receptive field map (subject to a scaling factor). The shape of the static nonlinearity can then be estimated by plotting the relationship between its input and output. The input to the static nonlinearity is the output of the linear filter, which can be obtained by convolving the visual stimulus with the linear receptive field map. The output of the static nonlinearity is the response of the neuron to the stimulus. Using this method, Anzai et al. (1999b) found that the static nonlinearity of simple cells is an expansive function that can be modeled well by a half-rectified power function (Fig. 44.7*A*; see also Emerson et al., 1989). The exponent of this function across the population of simple cells had a mean of 2.17 (Fig. 44.7*B*), suggesting that the nonlinearity is approximately a half-squaring function (Heeger, 1992b). The distribution in Figure 44.7*B* is completely overlapping with, but narrower than, the

distributions of exponents shown in Figure 44.5*B* and Figure 44.5*C*. This is likely explained by differences in stimulus contrast among the studies, which may have introduced differential effects on contrast gain control (Ohzawa et al., 1985). The data of Figure 44.7*B* were obtained using dense noise stimuli of fixed contrast, whereas the data of Figure 44.5*B* (DeAngelis et al., 1993b; see also Gardner et al., 1999) were derived from responses to two kinds of stimuli, sinusoidal gratings and sparse noise, that had markedly different effective contrasts. The data of Figure 44.5*C* (Albrecht and Hamilton, 1982) were measured with sinusoidal gratings of various contrasts.

NONLINEAR INTERACTIONS EXHIBITED BY COMPLEX CELLS

The first quantitative attempt to characterize the nonlinear

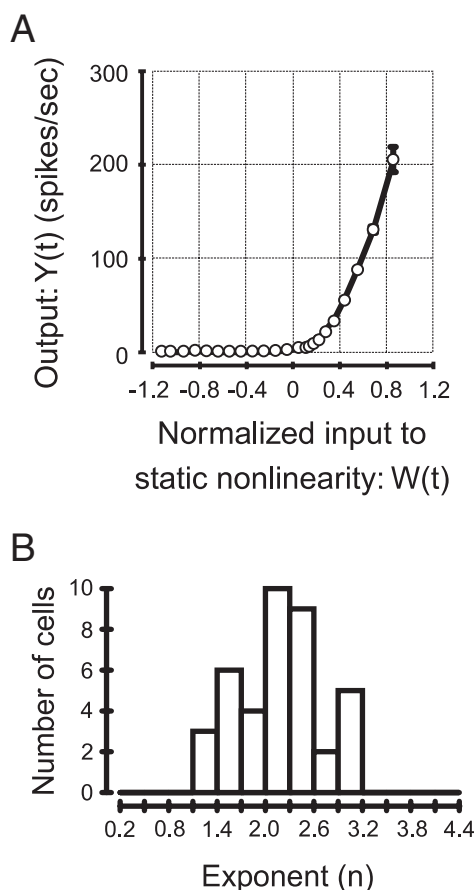

FIGURE 44.7. *A*, Characterization of the static nonlinearity for a simple cell from cat area 17. The input-output relationship of the static nonlinearity is shown. The output, $Y(t)$, is the response of the neuron to receptive field mapping stimuli, and the input, $W(t)$, is obtained by convolving the mapping stimuli with the linear receptive field map. The data are well described by a half-rectified power function ($y = x^n$, for $x > 0$) with an exponent (n) of 2.08. *B*, Distribution of exponents from a population of simple cells. The mean of the distribution is 2.17, indicating that the static nonlinearity is approximately a half-squaring function. (Adapted from Anzai et al., 1999b.)

properties of complex cells was made by Movshon et al. (1978), who measured two-bar interaction profiles by presenting pairs of bars at various positions along the axis perpendicular to the cell's preferred orientation. These interaction profiles exhibited alternating flanks of opposite polarities, similar to ON and OFF subregions of simple cells (see also Baker and Cynader, 1986; Gaska et al., 1994; Rybicki et al., 1972). Importantly, the interaction did not change with bar position as long as the spatial interval between the two bars was kept constant. These two-bar interaction profiles could explain the spatial frequency tuning of complex cells, whereas their linear maps could not (see also Gaska et al., 1994). This supports the idea that complex cells are made up of simple cell-like subunits with overlapping receptive fields (Alonso and Martinez, 1998; Hubel and Wiesel, 1962).

Numerous subsequent studies have examined second-order nonlinear interactions exhibited by complex cells (e.g., Anzai et al., 1999a; Baker, 2001; Emerson et al., 1987; Gaska et al., 1994; Livingstone and Tsao, 1999; Ohzawa et al., 1990; Szulborski and Palmer, 1990). Figure 44.8*A* shows a nonlinear spatial receptive field map measured with two-dimensional white noise presented monocularly (Gaska et al., 1994). Since the spatial interaction is independent of stimulus position, the map is plotted on $\Delta X - \Delta Y$ axes by summing responses over various positions for each spatial interval. This nonlinear map resembles the linear receptive field map of a simple cell, as Movshon et al. (1978) found using pairs of bar stimuli. In addition, the tuning for orientation and spatial frequency predicted by the nonlinear map matches well with that measured using sinusoidal gratings (Heggelund, 1981; see also Gaska et al., 1994; Szulborski and Palmer, 1990).

Figure 44.8*B* shows that a similar result is obtained for complex cells when nonlinear binocular interactions are examined with dichoptic white noise stimuli (see also Anzai et al., 1999a; Livingstone and Tsao, 1999; Ohzawa et al., 1990, 1997). For comparison, these data are shown in the same format as those of the simple cell in Figure 44.6*B*. Unlike simple cells, complex cells show nonlinear maps that are elongated along the constant-disparity diagonal (X_d). Thus, the nonlinear binocular interaction is independent of monocular position, analogous to the findings of Movshon et al. (1978) for monocular spatial interactions. In other words, complex cells respond to stimuli at any position within their receptive field as long as the binocular disparity is appropriate.

Second-order nonlinear interactions have also been examined for complex cells in the space-time domain (Anzai et al., 2001; Baker, 2001; Baker and Cynader, 1986; Emerson et al., 1987, 1992a; Gaska et al., 1994). Figure 44.8*C* shows a nonlinear space-time receptive field map for a complex cell in cat primary visual cortex (from Emerson et al., 1987). The

nonlinear response is plotted as a function of the spatial and temporal intervals between pairs of bar stimuli ($\Delta X - \Delta T$ plot). The map shows a tilt of the response pattern in this domain, reminiscent of the space-time inseparable linear maps for direction-selective simple cells. The space-time structure of these nonlinear maps predicts the direction selectivity of complex cells, whereas their linear maps (Fig. 44.4G) do not.

FIGURE 44.8. Nonlinear receptive field maps for complex cells illustrating second-order interactions. *A*, A monocular spatial interaction map of a V1 complex cell from the monkey. The nonlinear response is plotted as a function of the horizontal (ΔX) and vertical (ΔY) separation between a pair of spots presented over the receptive field. Solid and dashed contours indicate responses to polarity-matched and polarity-mismatched stimuli, respectively. *B*, A binocular spatial interaction map for a complex cell from cat area 17, plotted in the same format as Figure 44.6B for comparison. The linear receptive field profiles shown along the margins are fairly flat, whereas the nonlinear map (contours) exhibits subregions elongated along lines of constant disparity (parallel to the X_F axis). *C*, A monocular space-time interaction map for a complex cell from cat area 17. The nonlinear response is plotted as a function of the spatial (ΔX) and temporal (ΔT) interval between a pair of bars presented across the classical receptive field. (*A* adapted from Gaska et al., 1994; *B* adapted from Anzai et al., 1999a; *C* adapted from Emerson et al., 1987.)

Overall, second-order nonlinear maps account well for the orientation tuning (Gaska et al., 1994; Szulborski and Palmer, 1990), spatial frequency tuning (Gaska et al., 1994; Movshon et al., 1978), temporal frequency tuning (Gaska et al., 1994), direction preference (Emerson et al., 1987; Gaska et al., 1994), speed preference (Baker, 1988), and binocular disparity tuning (Anzai et al., 1999a; Ferster, 1981; Ohzawa et al., 1997) of most complex cells. Thus, second-order nonlinear interactions explain the essential response properties of complex cells, which in turn suggests that higher-order nonlinearities may contribute relatively little. We have noted that the spatiotemporal organization of the subunits of complex cells is strikingly similar to that of simple cells. Although this is consistent with the hierarchical model of Hubel and Wiesel (1962), we must emphasize that these measured subunits do not necessarily represent individual afferent neurons. Because these nonlinear maps are likely to reflect responses of multiple afferent neurons, the subunits should be regarded as functional rather than anatomical.

SYSTEM STRUCTURE OF COMPLEX CELLS AND THE ENERGY MODEL The results described above suggest that complex cells consist of subunits that resemble simple cells. This implies that complex cells may be modeled as a parallel $L-N$ system. If so, how many $L-N$ subunits are necessary to make up a complex cell, and what are the relationships between the subunits?

Recall that nonlinear spatial interaction maps for complex cells are relatively invariant to stimulus position within the receptive field. This suggests that receptive field subunits share common preferences for stimulus parameters such as orientation, spatial frequency, direction of motion, and binocular disparity. However, because complex cells respond to both bright and dark stimuli throughout the receptive field, the ON and OFF regions of subunits' receptive fields must

overlap extensively. In other words, the spatial relationship of subunit receptive fields must be one of the following: (1) subunit receptive fields are located at slightly different positions, as Hubel and Wiesel (1962) originally suggested; (2) they are located at the same position but have different spatial phases; or (3) they vary in both spatial position and phase.

Various models of complex cells have been built upon one of these suppositions (Cavanagh, 1984; Emerson et al., 1992a, 1992b; Glezer et al., 1980, 1982; Jacobson et al., 1993; Ohzawa et al., 1990; Pollen and Ronner, 1983; Pollen et al., 1989; Spitzer and Hochstein, 1985, 1988). Of these models, the *energy* model (Adelson and Bergen, 1985; Watson and Ahumada, 1985) has been the most popular. An energy model generally consists of two parallel L - \mathcal{N} subunits that are in a quadrature phase relationship. Each subunit is a linear bandpass filter followed by a squaring nonlinearity. Figure 44.9 shows a physiologically plausible version of the energy model in that each linear filter is subdivided further into two linear filters that are sign-inverted versions of each other, and their outputs are rectified and then squared. This basic structure has been used to model the monocular spatial characteristics (Pollen and Ronner, 1983), direction selectivity (Emerson et al., 1992a), and binocular disparity selectivity (Fleet et al., 1996; Ohzawa et al., 1990; Qian and Zhu, 1997) of complex cells.

The energy model makes a specific prediction as to the number of subunits and relationships between subunits. That is, two functionally distinct subunits that are in quadrature phase relationship would be sufficient to build a complex cell receptive field (two of the four subunits in Fig. 44.9 are not functionally distinct, differing only in sign from the other two). Anzai et al. (1999a) tried to determine if second-order binocular interaction profiles of complex cells (e.g., Fig. 44.8B) are consistent with this prediction. They performed a singular value decomposition (SVD) analysis to obtain the minimum number of quadrature subunits that are needed to account for the interaction profile. They found that a majority of complex cells required only two subunits (four if sign-inverted versions are assumed), a result consistent with the prediction of an energy model.

Although an energy model provides excellent functional descriptions for many complex cells, some second-order nonlinear maps are not well characterized by an energy model. In the SVD analysis, Anzai et al. (1999a) found that some complex cells required more than two functional subunits. Some of these cells may have had a quadrature pair that consisted of subunits that were not exactly sign-inverted versions of each other. This could explain why linear maps of some complex cells are not completely flat. Another possibility is that spatial pooling of subunits is more extensive than an energy model permits. This could account for some complex cells showing nonlinear receptive field profiles that

FIGURE 44.9. Schematic illustration of an energy model for a complex cell. The model consists of two major units (enclosed by dashed boxes) that are in quadrature (differing in spatial phase by 90 degrees), which makes the model respond to a stimulus independent of its spatial position/phase. Each quadrature unit consists of a pair of simple cell-like subunits with receptive field profiles of opposite signs so that the model responds equally to both bright and dark stimuli at the same position in space. Each subunit is modeled as a linear filter followed by a static nonlinearity (half-squaring). The linear filters here are depicted by one-dimensional spatial profiles of subunit receptive fields. In reality, each filter is a function of space and time, and can be monocular or binocular. They share similar selectivities for orientation, spatial and temporal frequencies, direction of motion, and binocular disparity.

are larger (i.e., more elongated diagonally in Fig. 44.8B) than expected from an energy model (Anzai et al., 1999a; Ohzawa et al., 1997). This type of spatial pooling could improve the reliability of signals being detected (Fleet et al., 1996; Qian and Zhu, 1997).

Summary and conclusions

Spatiotemporal receptive fields describe how neurons process visual inputs across space and time; hence, they characterize the functionality of neurons. Linear receptive field maps represent the best linear characterization of the transformation between visual input and neuronal response. They provide a good description of the response properties of simple cells, accounting for orientation selectivity, spatial and temporal frequency tuning, direction preference, binoc-

ular disparity tuning, and more. Nonlinear receptive field maps, on the other hand, characterize the responses of neurons that cannot be accounted for by linear summation of visual inputs across space and time. Second-order nonlinear receptive field maps are particularly important at early stages of visual processing since they represent the neural encoding of fundamental visual attributes such as motion and binocular disparity. Second-order nonlinear interactions are relatively modest for simple cells, whereas they account for virtually the entire repertoire of response properties for most complex cells.

Examination of linear and nonlinear maps allows one to formulate quantitative models for visual neurons. The maps of simple cells are consistent with the model of a linear filter followed by a static nonlinearity similar to half-squaring (L - N model). Complex cells are well characterized by an energy model, a parallel combination of simple cell-like L - N subunits that are in a quadrature phase relationship. Although some cells certainly deviate from these two canonical models, the models provide an excellent foundation upon which to build a better understanding of early visual processing. It should be noted, however, that these models exclude some important known nonlinear properties of cortical neurons, such as contrast gain control (e.g., Ohzawa et al., 1985), surround inhibition (e.g., DeAngelis et al., 1994), and contextual modulation (e.g., Zipser et al., 1996). These phenomena are likely to be the result of feedback connections from higher visual areas or lateral connections within V1, and they need to be incorporated eventually into the types of models described here (see Carandini et al., 1997; Heeger, 1992a, 1993).

The receptive fields discussed in this chapter can be thought of as spatiotemporal image filters. The visual system uses them to extract certain spatiotemporal patterns from the stream of visual images striking the retina. A linear filter followed by a squaring nonlinearity acts to extract energy in the input signal that conforms to the spatiotemporal structure of the receptive field. The linear filter creates stimulus selectivity, which in turn is enhanced by the expansive nonlinearity. Simple cells perform this computation for a given position (or phase) in space and time. Complex cells remove this position/phase dependence by combining simple cell-like subunits across space. This makes complex cells behave as spatiotemporal filters for second-order image attributes, which makes them ideally suited for encoding visual cues such as motion and binocular disparity.

45 Beyond the Classical Receptive Field: Contextual Modulation of V1 Responses

VICTOR A. F. LAMME

Receptive field tuning properties define the functions of visual areas

The receptive field (RF) of a neuron in visual cortex is the part of the visual field from which action potential responses can be elicited by presenting a stimulus. This stimulus has to meet a number of requirements for the cell to respond; that is, the RF is “tuned” to particular features. For example, cells in primary visual cortex (V1) respond better to some orientations of luminance contrast than to others (Hubel and Wiesel, 1968, 1977). Traditionally, the function of a visual area is derived from the set of features to which the neurons in the area are tuned. MT is called a *motion* area because many of its cells are tuned to direction, speed, or other aspects of motion (Allman et al., 1985a; Maunsell and Newsome, 1987; Maunsell and Van Essen, 1983; Movshon et al., 1986; Newsome et al., 1986); V4 is a *color* or *form* area because cells are tuned to certain wavelengths (Zeki, 1973, 1980) or elementary shapes (Desimone and Schein, 1987; Gallant et al., 1996); and so on. This view is further corroborated by the fact that lesions in these areas typically cause deficits that are related to the processing functions we attribute to these areas by means of their receptive field tuning properties (Dean, 1979; Heywood and Cowey, 1987; Maunsell and Newsome, 1987; Newsome et al., 1985; Schiller, 1993; Schiller and Lee, 1991; Wild et al., 1985). Thus, we arrive at a view whereby visual processing is subdivided into specific modules, each solving a particular subproblem of vision (Livingstone and Hubel, 1988; DeYoe and Van Essen, 1988). Although the strictness of this view is much disputed, it has profoundly pervaded our thinking about the roles of cortical areas in vision.

Combining the distributed information

When the visual field is analyzed by limited RFs within functionally separate modules, extensive and dynamic interactions are required to combine the distributed information. Anatomical connections provide the framework for those interactions (Felleman and Van Essen, 1991). Within each cortical area, horizontal interactions integrate information

from separate parts of the visual field (Gilbert, 1992; Gilbert and Wiesel, 1989). Between areas, information is transferred in a feedforward fashion from low-level areas to higher-level ones. But in addition, feedback connections transfer information in the reverse direction (Salin and Bullier, 1995). When going upstream through the hierarchy of visual areas, RFs obtain increasingly complex tuning properties and rapidly increase in size (Maunsell and Newsome, 1987). These tuning properties can be observed as soon as the neurons start to respond to a visual stimulus. So, RF properties strongly reflect the convergent-divergent feedforward cascade of information processing. But what effect do the horizontal and feedback connections exert on the neural activity? Feedback connections are highly diverging, so their influence on cells in lower areas is not reflected by the small RFs of an area such as V1 (Salin and Bullier, 1995). Also, horizontal connections within V1 spread over much larger distances than the size of RFs would necessitate (Gilbert, 1992, 1993). So, if not “visible” in the tuning properties of cells, when and how do these connections exert their effect on the neuron’s responses?

Once an RF contains some stimulus, the response to this stimulus may be modulated by surrounding stimuli. A key feature of this phenomenon is that the modulating stimuli do not evoke a response when presented alone; they are outside the “classical” RF. The early experiments, in area 17 of anesthetized cats, typically used bars or gratings to stimulate both the RF and its surround. Modulatory effects could be evoked at large distances but were strongest at small distances. Both facilitory and inhibitory effects were found that could be either nonspecific or any combination of orientation and direction of motion specific (Albus and Fries, 1980; Allman et al., 1985b; Blakemore and Tobin, 1972; Jones, 1970; Maffei and Fiorentini, 1976; Nelson and Frost, 1978). Modulation from outside the RF was also reported in areas beyond V1 (Allman et al., 1985a, 1985b; Desimone et al., 1993). The phenomenon thus seems to be a general property of visual cortical cells.

In this chapter, we will review the phenomenon of contextual modulation and focus on primary visual cortex of the monkey in particular. It will be shown that contextual modulation indeed reflects widespread interactions within

and between cortical areas, interactions that are related to high-level processes such as perceptual organization, object recognition, and visual awareness. V1 is an interesting area in this respect. Its RFs are very small, and their tuning properties are simple. For these reasons, activity reflecting perceptual interpretation of the scene as a whole is least expected here. On the other hand, it can be said that the area is at the top of the hierarchy in terms of feedback connections. If some feedback-related activity is present here that represents the convergence of information from all visual areas, this activity would be expected to clearly reflect a fully evolved perceptual interpretation. In V1, therefore, we can expect RF processing of a sort most detached from scene perception, while contextual modulation might be closely related to it.

Phenomenology of contextual modulation in V1

SINGLE VERSUS MULTIPLE IMAGE ELEMENTS Line segments form ideal stimuli for V1 cells. V1 RFs are typically tuned for their orientation, direction of motion, disparity, size, contrast, or color (DeValois et al., 1982; Hubel and Wiesel 1977; Livingstone and Hubel, 1988; Poggio, 1995; Schiller et al., 1976). V1 neurons are therefore viewed as encoding information about contour segments within their RFs. However, a single line segment on a blank background is a visual scene rarely encountered. In natural scenes, contour segments are combined with many others, forming edges, textures, object boundaries, the one occluded by the other, and so on. In those natural situations, the perceptual interpretation of a single line segment strongly depends on its context. What happens to the V1 responses when the perceptual context of a line segment within the RF is manipulated?

Compare the single line segment of Figure 45.1A with the multiple line segments of Figure 45.1B. The isolated line segment strongly draws attention to itself, while the set of line segments draw attention as a group, where each line segment is of much less importance. In V1, this is expressed in the neuronal responses by means of contextual modulation. If the line segment of Figure 45.1A falls on a V1 RF, and the surrounding line segments that are added in Figure 45.1B fall outside, the response of the neuron is much stronger in the first situation than in the second (Knierim and Van Essen, 1992).

The reduced salience of the center line segment in Figure 45.1B can be increased by having its orientation differ from those of the surrounding elements, as in Figure 45.1C. This results in a perceptual *popout* of the center element (Nothdurft, 1991, 1994). This (partial) restoration of perceptual salience is again expressed by a modulation of V1 responses, which are larger in Figure 45.1C than in Figure 45.1B, although not as large as the response would be for a

FIGURE 45.1. The context of a line segment changes its perceptual salience. *a*, A lone line segment is perceptually most salient. *b*, The same line segment, now embedded in similar ones, is much less conspicuous. *c*, The line segment may popout when its orientation differs from that of the surrounding line segments, restoring its perceptual salience to some extent. *d*, Global stimulus aspects are taken into consideration, since a similar local orientation difference does not produce popout when surrounding elements all have different orientations. When a V1 neuron is stimulated by presenting these displays, so that its RF only covers the same center line segment in all cases, contextual modulation signals the perceptual salience of the center line segment.

lone element (Fig. 45.1A) (Knierim and Van Essen, 1992). That this is not a purely local phenomenon, that is, governed only by the orientation difference between center and surround stimuli, is illustrated by Figure 45.1D. Here the center line segment is surrounded by line segments of different orientations, as in Figure 45.1C. There is no perceptual popout, however, because the orientation difference between center and surround is not different from the orientation differences among the elements in general (Landy and Bergen, 1991; Nothdurft, 1985, 1994). Likewise, responses of V1 neurons to stimuli like those in Figure 45.1D are not different from the responses to Figure 45.1B stimuli (Kapadia et al., 1995; Knierim and Van Essen, 1992).

A similar phenomenon can be observed in the luminance domain. The perceived brightness of a surface can be modulated by changing the brightness of surrounding surfaces. V1 neurons modulate their activity according to such changes in perceived brightness (Rossi et al., 1996).

GROUPING OF LINE SEGMENTS Another factor that makes line segments segregate from a background of randomly oriented line segments is grouping into elongated chains (Fig. 45.2A). Perceptually, such groupings depend on the relative alignment of the line segments, and important factors are colinearity, relative distance, angle, and axial offset (Field et al., 1993; Kapadia et al., 1995; Kovacs, 1996). For example, the linking is much stronger (and the contour is more visible) in Figure 45.2A than in Figure 45.2B. This is because the relative axial offsets are smaller. By doing experiments like this, using Gabor patches instead of line segments, Hess and coworkers identified an *association field* (Fig. 45.2C), which identifies how distance and relative orientation between Gabor patches determine their grouping strength (Field et al., 1993). Remarkably, these same factors influence contextual modulation in V1 neurons. Line segments that are flanked by colinear ones elicit larger responses (Kapadia et al., 1995; Nelson and Frost, 1985). This depends on relative distance, angle, and axial offset. In fact, neural association fields (Fig. 45.2D,E; Kapadia et al., 2000) have been determined that look very much like the perceptual association fields. These neural association fields map the modulation that is evoked by stimuli surrounding an optimal and RF-centered stimulus. When a surrounding stimulus (with the same orientation) has no effect, the map is flat at that particular position, while excitatory or inhibitory influences are shown by different colors. At 10% to 20% contrast, there is strong facilitation by colinear line segments and weak inhibition by flanking line segments, while at 50% contrast the reverse is the case.

BOUNDARIES, SURFACES, AND FIGURE-GROUND SEGREGATION In Figure 45.3A, the more or less one-dimensional chain of lines of Figure 45.2A has been extended to two dimensions. The line segments, which are now grouped on the basis of orientation similarity, segregate from a background of line segments of another orientation. The stimulus is richer in

some aspect, however, than the one of figure 45.2A. We can distinguish a boundary and a surface of the segregating figure. Where line segments of one orientation juxtapose line segments of the orthogonal orientation, we observe a sharp boundary between the square figure and the background. The line segments within this boundary form a figure surface, which is perceived as if lying in front of the background, which is assumed to continue behind it. The boundary is asymmetrical in that it “belongs” to the figure and not to the background.

FIGURE 45.2. Colinear grouping and contextual modulation. *a*, An example of the grouping of line segments that lie on a colinear path. *b*, The display is the same as in *a*, except for the relative angles between the line segments that lie on the colinear path. The grouping is less strong. *c*, The relative grouping of neighboring Gabor elements depends on relative orientation, angle, and distance. This constitutes the association field. Strong grouping is depicted by solid lines, weak grouping by dashed lines. *d*, The effect of neighboring line segments on the response of a V1 neuron with a horizontally oriented RF at the center. Blue/white depicts facilitation and red/yellow depicts inhibition for neighboring lines at the given position. At 10% to 20% contrast (shown), the main effect is facilitation by colinear line segments. *e*, The same figure at 50% contrast, where the main effect is inhibition by flanking line segments. (*c* from Field et al., 1993, courtesy of Robert Hess) (*d*, *e* from Kapadia et al., 2000, courtesy of Charles Gilbert.) (See color plate 27.)

Are all these perceptual elements of the scene also reflected in the modulations of V1 responses to the line segments that make up the display? To study this, the responses of V1 neurons to line segments at various positions along the display had to be recorded (Fig. 45.3D). However, during this manipulation, the stimulus within the RF had to be maintained identical. Figure 43.3B shows how this was achieved for the line segments making up the figure surface: the response of a V1 neuron was recorded while it was stimulated either with a display containing a figure or with a display alone (Lamme, 1995; Zipser et al., 1996). The line segments covering the RF were identical in the two displays. Responses to figure and background elements were compared and were subtracted to obtain the modulation signal in isolation (Fig. 45.3C). This result shows that until about 100 msec after stimulus onset, V1 neurons responded identically to the two displays. After that, however, the response to figure elements was larger. The immediate context of the RF line segments was identical, yet still there was strong modulation. Apparently the more global perceptual context, being that of a figure overlying a background, influenced the V1 activity.

That these modulations reflect figure-ground segregation is corroborated by a further analysis in which modulation across the display was studied. In Figure 45.3D the contextual modulation recorded across the figure-ground display of Figure 45.3A is shown. To obtain this plot, responses from a neuron with its RF at different positions relative to the figure and the background were recorded, such that the line segments within the RF were the same for all conditions (Fig. 45.3B; Lamme et al., 1999). Subsequently, the response to a scene with identical line segments, but containing no figure, was subtracted (Fig. 45.3C). As a result, the initial feedforward activity (typically occurring at a latency of 40 to 50 msec) was no longer visible; only the modulation, evoked by recurrent interactions, remained (Lamme et al., 1998a). Positive modulation, that is, a response enhancement from about 80 msec after stimulus onset, is observed at the boundary between figure and ground (see also Nothdurft et al., 2000). After 100 msec, all line segments that belong to the figure uniformly evoke a stronger response than line segments of the background. Note the asymmetry across the figure-ground boundary; while the immediate context is almost identical for a neuron with its RF immediately inside or outside the figure, modulation is present only when the RF is within the figure's boundary. As soon as the RF is outside, modulation is absent. It is as if a neural image of the figure is stamped out of the neural image of the background, closely reflecting our figure-ground percept.

These data illustrate an important point about contextual modulation that is not observed in the results discussed in the previous section. Above (Fig. 45.2), we saw contextual

modulation reflecting local grouping and segregation criteria. But using stimuli such as those in Figure 45.3A, we see that these local criteria can be overridden: at the center of the figure, the line segments are surrounded by similar ones, but nevertheless contextual modulation is the same as it is close to the edge, where elements are flanked by orthogonal ones (although the modulation at the edge occurs at a shorter latency). Immediately outside the boundary between figure and ground, elements are flanked by orthogonal ones, but contextual modulation is absent (i.e., responses are identical to background positions farther away). Apparently, contextual modulation is not limited to reflecting local discontinuities, or differences between RF center and surround stimuli. Contextual modulation in these experiments reflects the figure-ground relationships of the surfaces in the scene.

With respect to this interpretation, it is important to note that the strength of modulation depends on the size of the figure. The results mentioned above were obtained with figures of 4 degrees of visual angle in diameter on a 24×16 degree background. Zipser et al. (1996) found modulation to be much bigger for smaller figures and to decline as figures grew larger. No significant modulation was found for figures larger than 10 degrees. Rossi et al. (2001) found a similar size tuning, but with a much earlier cutoff, with no modulation for figures larger than 3 degrees. The results of Marcus and Van Essen (2002) are in between. It has been argued that this dependence on figure size counters the interpretation of contextual modulation representing figure-ground segregation (Rossi et al., 2001). However, the essential component in the figure-ground interpretation is the finding of asymmetry of modulation across the figure-ground boundary, as explained above. The findings of Rossi et al. do not bear on that issue, as the dependence on figure size was measured only with the RF at the center of the figure. The authors interpreted their sharp size tuning as showing that V1 cells respond only to figure-ground boundaries and that V1 is involved only at a stage prior to figure-ground analysis. To support that claim, however, the authors should have recorded on both sides of the figure-ground boundary and should have found equal modulation in both cases. That was not the case. Of course, that leaves us with the question of why there is a discrepancy in the reported cutoffs in the size tuning curves (Zipser et al., 10 degrees; Rossi et al., 3 degrees; Marcus and Van Essen, 5 degrees). These quantitative differences are probably reconcilable within the domains of intersubject and intersession differences. Factors of importance here include the size of the background, as figure-ground assignment is very much determined by relative size, and stimulus contrast, as salience of the figure probably plays a role. In fact, an alternative interpretation of the figure-ground modulation could be that the neurons representing the perceptually most salient

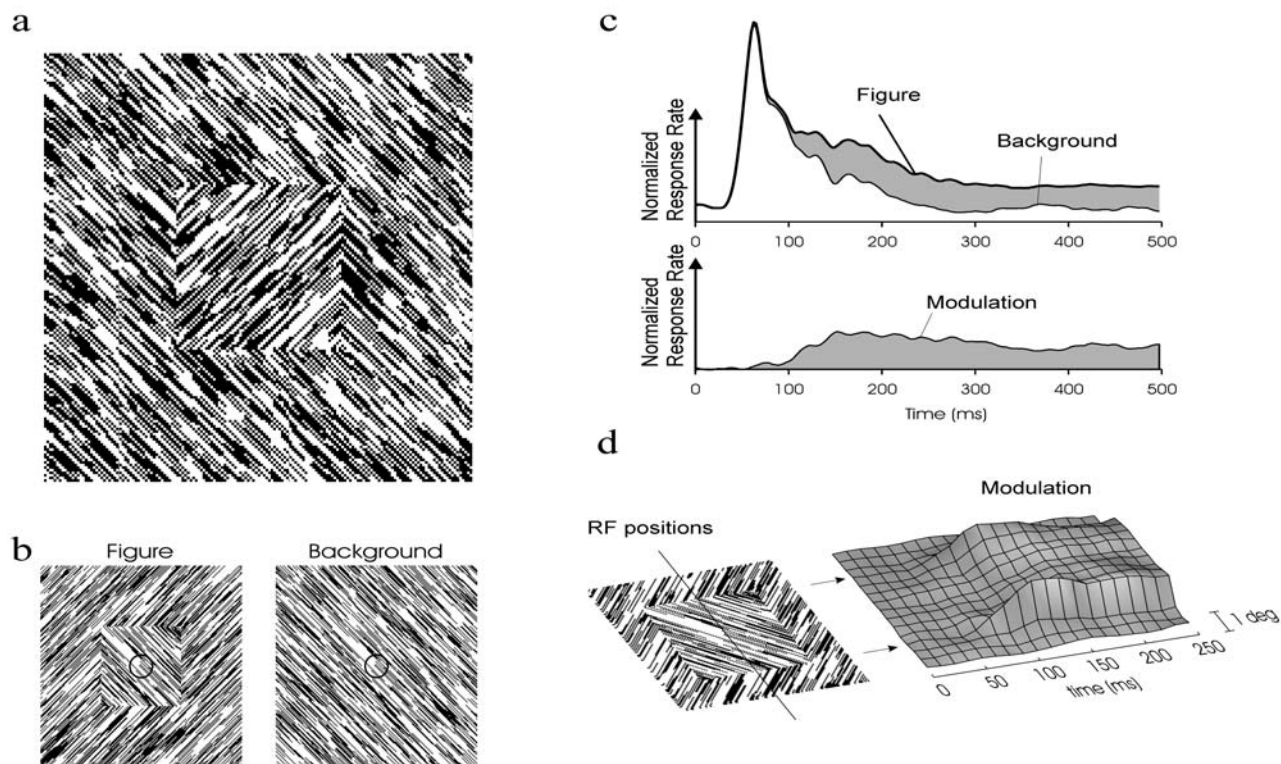

FIGURE 45.3. The neural correlate of figure-ground segregation in V1. *a*, Line segments of similar orientation perceptually group together and segregate from line segments of another orientation. The center square is considered a textured figure on a textured background that perceptually seems to continue behind it. The boundary between figure and ground belongs to the figure surface. *b*, Contextual modulation related to figure-ground segregation can be recorded by stimulation with the two displays shown, while the line segments within the RF are the same for both conditions. *c*, Responses from a population of V1 neurons to the two stimuli shown in *b*. The difference between the superimposed responses, contextual modulation, is shaded in gray and is shown separately

below. *d*, Modulation with the RF at 15 different positions relative to figure and ground, such that the contextual modulation is “scanned” across a line passing over and through the figure. The three-dimensional graph combines the modulation, such that the 15 positions are on the *x*-axis (side), time is on the *y*-axis (in front), and response strength is on the vertical axis. Responses are identical up to about 80 msec after stimulus onset, and no modulation is present. Then responses are “highlighted” at the boundary between figure and ground. This is followed by an equal response enhancement for all positions of the RF within the figure compared to responses for positions of the RF on the background.

elements of the scene, in this case the whole figure, are highlighted relative to the neurons representing less important elements.

Contextual modulation can be elicited by figure-ground displays defined by a variety of cues, such as differences in orientation, direction of motion, disparity, color, or luminance. At the population response level, contextual modulation is of the same magnitude for figures defined by these various cues, while at the single unit level, some cells show complete cue invariance (Lamme, 1995; Zipser et al., 1996). Surprisingly, figure-ground-related contextual modulation bears no relation to the RF properties of the neurons recorded from. For example, modulation for a motion-

defined figure can be recorded in cells without direction selectivity (Lamme, 1995). Also, when cues are combined, modulation is not additive, but instead is identical to the one-cue-alone situation (Zipser et al., 1996). This indicates that the modulation signals figure-ground relationships instead of feature-specific differences; a figure is a figure, no matter how it is defined. It also shows that contextual modulation is mediated by mechanisms far removed from those that shape and tune the local RF.

Also, when more complicated scenes are used, contextual modulation reflects the figure-ground arrangements of the surfaces in that scene. Particularly nice examples can be found in Zipser et al. (1996) and Lee et al. (1998) using sur-

faces containing holes, multiple overlying surfaces, and so on. Under specific conditions, it can sometimes be observed that there is a stronger modulation at the geometrical center of the figures in those scenes (Lee et al., 1998). It has been proposed that this plays a role in representing the medial axes of objects (Kovacs, 1996; Lee et al., 1998).

Mechanisms of contextual modulation

THE EXCITATION-INHIBITION BALANCE From the results discussed thus far, an important problem emerges: the presence of surround stimuli typically results in an inhibition of the response. However, depending on the nature of these surround stimuli, this inhibition can be reduced or sometimes can even revert to facilitation. What mechanisms control this delicate balance between excitation and inhibition? Perceptually, a similar paradox can be formulated: perceptual grouping depends on similar features enhancing each other's representation. Segregation, on the other hand, requires similar features to inhibit each other (Roelfsema et al., 2002). The figure-ground modulation discussed in the previous section is a good example of both processes operating at the same time.

The excitation-inhibition balance seems to depend critically on the contrast of stimuli. Manipulating the contrast of center and surround, such that the cell's RF is stimulated less or more strongly than the surround, may invert the sign of modulation from inhibition to facilitation (Levitt and Lund, 1997). Similarly, in cats, it was found that colinear Gabor patches facilitate the response to a low-contrast Gabor patch on the RF but suppress the response to a high-contrast patch (Mizobe et al., 2001; Polat et al., 1998). The neural association field shown in Figure 45.2D was recorded at 10% to 20% contrast. Figure 45.2E shows the neural association field recorded at 50% contrast (Kapadia et al., 2000). While at high contrast there is strong lateral inhibition and weak colinear facilitation, the opposite is true at low contrast. More generally, it appears that facilitation is stronger the weaker the stimulation of the RF.

The most extreme version of a low-contrast RF stimulus is, of course, no RF stimulus at all. By definition, there should be no response in that case and, consequently, no modulation either. When a cell is excited by such a configuration, the conclusion should simply be that the RF is bigger than it was believed to be. Still, there have been recent reports of cells in V1 being activated by stimuli outside the RF of a neuron, even when the RF itself was not stimulated (Li et al., 2001; Rossi et al., 2001). A possible reason to classify these responses as coming from beyond the RF is that they typically have a very long latency, ~100 msec, clearly in the range of the latency of modulatory effects. Also, they show little specificity for stimulus features such as orienta-

tion. These results might be placed in the context of what we know about the potency of contextual effects when the RF is stimulated at low contrast: What exactly is "no" stimulus on the RF? When a gray area is covering the RF, cells in V1 will still respond to it (after all, we see it; but see also Komatsu et al., 1996; MacEvoy et al., 1998). Perhaps this very faint stimulation is enough to enable modulation from distant sites that are strongly stimulated.

HORIZONTAL CONNECTIONS OR FEEDBACK? The functional properties of contextual modulation we have discussed depend strongly on the anatomical connections between the neuron recorded from (and whose RF is being stimulated) and other neurons. As already pointed out, contextual modulation is mediated by horizontal and feedback connections (Lamme and Roelfsema, 2000). It is difficult to disentangle the relative contributions of these two systems in a particular contextual effect. Some insight might be obtained by studying the latency of contextual effects.

Responses in area V1 have a minimal response onset latency of about 30 msec (Maunsell and Gibson, 1992; Nowak et al., 1995). This can be viewed as the time when processing in V1 begins. In relation to the question of what types of connections (feedforward, horizontal, or feedback) may mediate contextual modulation, it is important to know how long it takes for these modulations to occur once activity has started in V1. The suppressive effect that results from presenting a stimulus in the immediate surround of an RF (Fig. 45.1B) develops quickly. No latency difference (Müller et al., 1997), or a latency difference of only 7 msec, has been reported (Knierim and Van Essen, 1992). Orientation-specific effects, that is, comparing the effect of an identical background with that of an orthogonal background producing perceptual popout (Fig. 45.1B vs. Fig. 45.1C) takes about 20 msec (Knierim and Van Essen, 1992). Modulation related to figure-ground segregation of surfaces (Fig. 45.3) may start 30 to about 70 msec after response onset, depending on the cue that segregates figure from ground (Lamme, 1995; Zipser et al., 1996) and on the distance of the RF from the edge of the surface (Fig. 45.3D).

Once processing has started in V1, contextual modulation apparently occurs within a wide temporal range. The latency of the effects seems to depend on the complexity of the computations underlying the modulation and the spatial extent of the part of the scene that is considered. Short-latency contextual modulation effects are more likely to be generated by feedforward and horizontal connections than by feedback connections, since it is assumed that the latter take some time to exert their effect. However, for some extrastriate visual areas, minimal response latencies as short as those in V1 have been reported (Nowak and Bullier, 1997; Nowak et al., 1995), so even short-latency effects may be caused by feedback.

Insight into the roles of horizontal versus feedback connections also comes from studying the properties of these connections. Of the horizontal connections in V1, we know that (1) at a short range ($\sim 500\mu\text{m}$, i.e., a column's width), connections are excitatory and inhibitory, not very specific, and fall off rapidly with distance (Das and Gilbert, 1999; Kapadia et al., 2000); (2) at a longer range (several millimeters), connections are specific, that is, they preferentially link cells with similar orientation tuning (Malach et al., 1993); and (3) long-range connections between similarly oriented cells are even stronger when these cells have RFs along a colinear axis (Bosking et al., 1997; Schmidt et al., 1997). On the basis of these connections (excluding feedback), many contextual effects can be explained, such as those shown in Figures 45.1 and 45.2, but also the boundary enhancement at figure-ground edges (Fig. 45.3). Particularly striking is the correspondence between the association field (Fig. 45.2C) and what is known about horizontal connections.

There are also effects that cannot be explained by horizontal interactions alone. A good example is the modulation that can be recorded at the center of a figure overlying a background (Fig. 45.3). A model based on horizontal connections predicts enhancement at the figure-ground boundary but also predicts an equal level of activation at the center and at the background (Kapadia et al., 2000; Roelfsema et al., 2002; Fig. 45.4C). Center modulation (Fig. 45.3) can be explained, however, by adding feedback from higher areas. In this model, the higher areas perform the same analysis on their input (coming from lower areas) as the V1 cells, but at coarser spatial scales. Interactions between the horizontal connections at each level, and the feedback signals coming from higher levels, fully explain the asymmetrical figure-ground enhancement observed physiologically (Fig. 45.4A; Roelfsema et al., 2002). That feedback plays a role is further corroborated by lesion experiments. Figure 45.4B shows the results of recording figure-ground-related modulation in an animal that had sustained a large lesion to the extrastriate areas ipsilateral to the recording site. Contextual modulation is still evoked at the boundary between figure and ground, but it is no longer present for the surface elements of the figure (Lamme et al., 1998a). Others have confirmed that figure-ground-related modulation in V1 depends on the integrity of the extrastriate areas (Hupe et al., 1998), while simpler modulatory effects, such as those explained in Figure 45.1, do *not* depend on feedback (Hupe et al., 2000).

ANESTHETIZED VERSUS AWAKE ANIMALS It is crucial to record contextual modulation in awake animals. The effects described above have mostly been recorded in awake and perceiving animals. In anesthetized preparations, RF surround effects are present (Allman et al., 1985b; Kastner et al., 1997; Sillito et al., 1995). To what extent these

effects are similar to contextual modulation in the awake animal is not clear. Thus far, only one investigation has directly compared the awake and anesthetized conditions in the same animals and with the same stimuli. It was found that at the population response level, figure-ground-related contextual modulation is present only in the awake and perceiving animal. In the anesthetized condition, modulation is totally absent. Feedforward RF tuning properties, on the other hand, are not different in the anesthetized and awake conditions (Lamme et al., 1998b). In other studies recording contextual modulation from single units in the anesthetized monkey, effects were either found to be weak compared to those in the awake monkey (Nothdurft et al., 1999) or effects were both positively and negatively correlated with perceptual parameters, so that at the population level the net effect was close to zero (Jones et al., 2001). This could imply that subprocesses underlying normal contextual modulation are operational under anesthesia but fail to produce a coherent effect at the population response level.

Functions of contextual modulation

CONTEXTUAL MODULATION AND PERCEPTUAL GROUPING The computations performed within the separate cortical areas must be combined to produce a coherent output. The role of vision is to segregate objects from each other and to select particular ones for behavioral responses. Image elements and features of the objects that we encounter are processed by cells at different locations, and the results have to be combined so that we can manipulate them (the *binding problem*; Singer and Gray, 1995; Treisman, 1996). To some extent, this might be explained by the feedforward cascade of information processing. The increasingly complex RF tuning properties that one observes when going upstream through the hierarchy of visual areas suggest that low-level features are combined into complex constellations of features in higher areas (Barlow, 1995; Maunsell and Newsome, 1987). Strict feedforward processing, however, has its limitations—for example, in terms of the number of neurons that are needed to map every possible combination of features onto all possible outputs (the *combinatorial explosion*). In this context, many have advocated population coding as opposed to *grandmother* cell hypotheses (Abeles, 1982; Georgopoulos, 1991; Singer and Gray, 1995). In population coding, cells might be engaged in a processing task with one set of neurons (an assembly) at one time but, at another time, might be engaged in a different task with a different set of neurons. For this mechanism to work, cells have to be labeled as belonging to the same assembly, with a label that can rapidly be switched on and off. For example, in processing an image such as Figure 45.3A, the label should tag the neurons that code for the elements of the figure separately from the neurons that code for the background.

FIGURE 45.4. The relative contribution of horizontal and feedback connections to figure-ground modulation. *a*, Modulation (see Fig. 45.3*d*), “recorded” from V1 neurons of a neural network model. The model uses realistic horizontal interactions in four different “cortical areas” that interact via feedforward and feedback connections. The model mimics the figure-ground boundary enhancement to precede enhancement for the figure surface. *b*,

Modulation recorded from V1 neurons of a monkey that sustained a lesion to the extrastriate areas. Only boundary enhancement remains. *c*, Modulation from V1 model neurons (*a*) without feedback from higher “areas.” The model evokes boundary enhancement with V1 horizontal interactions only. (*a* and *c* from Roelfsema et al., 2002; *b* from Lamme et al., 1998a.)

Synchrony of firing between cells has been proposed to act as such a label (Singer and Gray, 1995). Neurons in V1 fire their action potentials in relative synchrony when their RFs are stimulated with a coherently moving bar, and this synchrony is reduced when the neurons are costimulated with separate bars (Freiwald et al., 1995; Gray et al., 1989). Based on the hypothesis that synchrony labels neurons belonging to the same assembly, one would predict that neurons whose RFs fall within the figure region of an image such as Figure 45.3*A*, fire in synchrony with other neurons whose RFs fall within the figure and do not fire in synchrony with neurons whose RFs fall on the background. We tested

this hypothesis by recording from multiple sites simultaneously in V1 but did not find it to be the case. Synchrony between neurons at considerable distance was found. However, this synchrony could be just as strong between neuron pairs whose RFs were within the figure as between pairs whose RFs were on either side of the boundary between figure and ground (Lamme and Spekreijse, 1998). The results suggested that synchrony reflects the interactions mediated by local and horizontal connections, but does not take into account more global (feedback) interactions that form the basis of the figure-ground percept. Apparently, synchrony in V1 does not operate as a label tagging neurons as

belonging to an assembly coding for the figure-ground percept.

An alternative binding tag could be an enhanced firing rate. In that case, cells engaged in processing features or elements of the same object would have an enhanced firing rate compared to other cells. The results discussed above provide evidence that the neural system might use an enhanced firing rate in this way. All neurons responding to elements of the same figure have an equal amount of response enhancement (Fig. 45.3*D*). Also, colinear line segments that group together share an enhanced firing rate (Kapadia et al., 1995; Sugita, 1999). A drawback of the firing rate as a binding tag is that it is difficult to separate several assemblies from each other, while this can easily be achieved with synchrony as a tag (Singer and Gray, 1995). It is, however, questionable whether the visual system is indeed capable of representing many objects simultaneously. Visual search and change blindness experiments indicate that no more than one to four objects are represented by the visual system at a time (Irwin, 1997; Rensink, 1997; Treisman, 1993; Wolfe and Bennet, 1997).

ATTENTION AND AWARENESS Line segments that group into a coherent object have higher salience than background elements and thus draw attention in bottom-up fashion (Egeth and Yantis, 1997). It is therefore conceivable that the contextual modulations of firing rate we observe are to a large extent attentional modulations or are at least contaminated by attentional effects. This seems all the more possible in light of the recent finding that effects of attention can be recorded in early areas including V1 (Desimone and Duncan, 1995; Ress et al., 2000; Roelfsema et al., 1998; Vidyasagar, 1998). However, in general, contextual modulation appears to be independent of focal spatial attention. For example, two separate and distant figures evoke the same amount of figure-ground-related modulation as one (Lamme et al., 1998b). Instructing the animal to attend to one of several objects does not modify figure-ground modulation very strongly (Landman et al., 2002). The benefits of colinear facilitation in the detection of low-contrast line segments are most pronounced when attention is distributed over the scene (Ito and Gilbert, 1999). The strongest evidence for the independence of contextual effects from attention comes from an Magneto Encephalo Graphy (MEG) study in human subjects. With appropriate paradigms, V1 contextual modulation related to scene segmentation can be recorded in human subjects using electroencephalography (EEG) or MEG (Bach and Meigen, 1992; Caputo and Casco, 1999; Lamme et al., 1992, 1993a, 1993b, 1994; Romani et al., 1999). In one study (Scholte et al., 2002), subjects were not told in advance about the presence of the segmenting stimuli, and their attention was diverted away from

their location. This resulted in the condition of *inattention blindness*, in which subjects reported that they did not see the segmenting objects. Nevertheless, figure-ground MEG modulation was still present, and was in fact just as strong as when subjects did see the objects. Since the condition of inattention blindness ensures that no attention whatsoever was directed to the segmenting stimuli, the finding proves that figure-ground modulation occurs in the absence of attention.

The study makes a second important point: the presence of contextual modulation is not sufficient for a conscious report about the stimulus configuration that evokes the modulation. The same was found in a study where the presence or absence of modulation was related to the behavior of monkeys that were trained to detect textured figures (like those in Fig. 45.3*A*) on a textured background. The figures varied in position and salience, and the animals had to make an eye movement toward that position to obtain a reward. Also, on some trials, no figures were present at all, and on those occasions the animals had to maintain fixation. Surprisingly, on some trials where a figure was presented, the animals still maintained fixation, as if indicating that they did not see the figure. On those trials, contextual modulation was absent or lower than on trials where the figures were correctly detected. Further analysis showed that the occurrence of modulation is *necessary* for the monkey to detect the figures but is not sufficient (Supér et al., 2001). The occurrence of modulation reflects a successful unrolling of perceptual organization, but an independent decision process that follows ultimately determines the animal's answer.

That contextual modulation is necessary for a figure-ground percept is corroborated by a masking study. Presenting a textured screen within 50 msec after presenting a textured figure-ground scene prevents the occurrence of contextual modulation related to the figure-ground segregation. That same manipulation renders the figure invisible (Lamme et al., 2002). A second manipulation that suppresses modulation is to present figure-ground displays of orthogonal orientation to either eye in a binocular setup. Either eye alone still receives (and can "see") a figure-ground display, but in the fused *cyclopean* percept the figure is no longer present (Fig. 45.5). Modulation is absent in this condition (Zipser et al., 1996).

Conclusions

In V1, receptive field properties are relatively simple. As the processing time after stimulus onset grows, however, the V1 responses incorporate information from more and more distant cortical regions. In doing so, they start to reflect perceptual grouping operations of wider and wider spatial

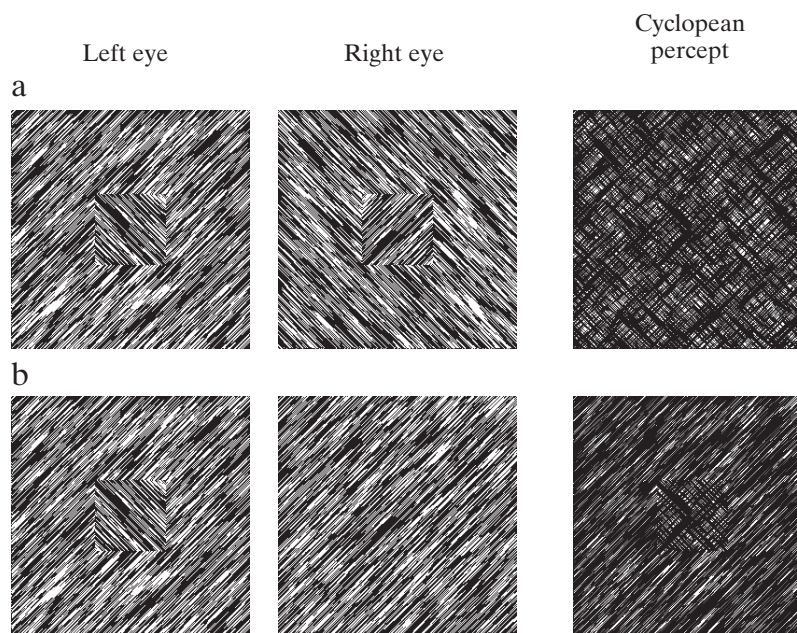

FIGURE 45.5. *a*, Orthogonal textures presented to the two eyes, each containing a figure on a background, yield a cyclopean percept of a homogeneous texture, with no visible figure (at eccentric fixation). *b*, When the figure is present in one eye only, the cyclopean percept is that of a figure on a background. The stimulus in *b* yields figure-ground-related contextual modulation; the stimulus in *a* does not.

range and increasing complexity. This process is mediated by horizontal and feedback corticocortical connections that modulate the feedforward-generated RF tuning properties. Contextual modulation was originally viewed as a relatively unimportant feature of cortical processing, providing the RF with an inhibitory surround, possibly related to gain control or constancy mechanisms. We now know that, instead, contextual modulation reflects potentially widespread corticocortical interactions related to perceptual organization (Lamme and Roelfsema, 2000). Furthermore, contextual modulation plays an important role in generating a coherent phenomenal experience of the visual scene (Lamme et al., 2000a; Lamme et al., 2000b).

46 Contributions of Vertical and Horizontal Circuits to the Response Properties of Neurons in Primary Visual Cortex

THOMAS R. TUCKER AND DAVID FITZPATRICK

ONE OF THE FUNDAMENTAL challenges of visual neuroscience is to unravel how distinct components of cortical circuits contribute to the responses of individual cortical neurons. The complexity of the task remains daunting, but significant progress has come from the recognition of two types of connections: (1) vertical connections, which run perpendicular to the cortical surface, extend for short distances, and interconnect neurons in different layers, and (2) horizontal connections, which run parallel to the cortical surface, extend for long distances, and link together neurons that lie in the same layer. The functional contributions of these two types of connections have been most thoroughly studied in the superficial layers (layers 2/3) of primary visual cortex. The principal source of vertical inputs to layer 2/3 arises from lateral geniculate recipient neurons of layer 4. These inputs have traditionally been regarded as the driving force for layer 2/3 neurons; they are the primary determinant of receptive field size and shape, as well as stimulus selectivity (orientation preference, direction preference, etc.). In contrast, horizontal connections are viewed as modulators, the source of both receptive field surround effects and the fine-scale temporal patterning that underlies neural synchrony. In this chapter, we consider the origin of these functional distinctions, evaluate the evidence upon which they are based, and consider recent results that challenge this strict functional dichotomy.

The identification of vertical and horizontal connections

The work of Mountcastle in somatosensory cortex (Mountcastle, 1957, 1997; Powell and Mountcastle, 1959) and Hubel and Wiesel in visual cortex (Hubel and Wiesel, 1962, 1968, 1977) established one of the fundamental principles of cortical organization: the orderly arrangement of cells with similar functional properties into vertically oriented columns traversing the cortex from pia to white matter. In visual cortex, the similarity in the response properties of neurons (e.g., orientation preference, ocular dominance, position in visual space) recorded along a vertical electrode

penetration and the regular progression in response properties recorded along tangential penetrations led to the view that the elements of cortical circuitry critical for setting up these specific response properties are confined to the column (Hubel and Wiesel, 1962, 1968, 1977). Although the exact dimensions of the column were subject to some debate, the idea that response properties were generated from interactions within a relatively localized cortical region was consistent with the evidence from Golgi studies of Ramon y Cajal (1911), Lorente de No (1938), and Lund (1973; Lund and Boothe, 1975) showing a predominantly cylindrical arrangement of intracortical connections. Neurons in layer 4 of the macaque visual cortex, for example, give rise to axon arbors that ascend and produce terminal arbors that cover less than 1 mm of surface area in layer 2/3.

Fisken and colleagues (1975) were the first to recognize that some connections identified by degeneration techniques following cortical lesions extended for more than 1 mm across the cortical surface, but it was the work of Rockland and Lund (1982; Rockland et al., 1982) that provided the first clear picture of just how far this horizontal network could extend. Following injections of retrograde tracers into visual cortex in the tree shrew, these investigators demonstrated patches of labeled cells and terminals that were distributed over distances 3 to 4 mm from the injection site in cortical layer 2/3, covering a substantial fraction of V1 in this species. These initial observations were subsequently confirmed in other species (Matsubara et al., 1985, 1987; Rockland and Lund, 1983), and the elegant intracellular injection experiments of Gilbert and Wiesel (1983) and Martin and Whitteridge (1984) demonstrated that the bulk of these long-range connections originate from pyramidal neurons. Ultrastructural analysis also demonstrated that horizontal connections terminate on the dendritic processes of other pyramidal cells as well as smooth dendritic GABAergic neurons (McGuire et al., 1991). These anatomical observations received support from intracellular recordings in tissue slice experiments showing that electrical stimulation of

horizontal connections can evoke both excitatory and inhibitory postsynaptic potentials (EPSPs and IPSPs) at more distant sites (Hirsch and Gilbert, 1991; Weliky et al., 1995).

Reconciling horizontal connectivity with cortical receptive field properties

The demonstration that intracortical connections extend for distances far beyond the local column raised the question of how the selectivity in response properties that characterizes the column could be maintained in the face of such extra-columnar interactions. The answer to this question depends on the degree of functional specificity exhibited by horizontal connections, an issue that has been examined extensively with respect to the property of orientation selectivity. There is general agreement that horizontal connections are biased in their distribution toward sites that have similar preferred orientations. Evidence in support of this conclusion comes from experiments in which the distribution of labeled cell bodies or axon terminals resulting from small tracer injections has been compared to functional maps of orientation preference generated by 2-deoxyglucose (Gilbert and Wiesel, 1989) or intrinsic signal imaging techniques (Bosking et al., 1997; Kisvarday et al., 1994; Malach et al., 1993). With optical imaging techniques it has been possible to provide a quantitative assessment of specificity, generating orientation tuning curves of labeled boutons or cell bodies by assigning each labeled element the orientation preference for its location in the cortex (Fig. 46.1). The distribution of horizontal connections from a given site has a tuning function that peaks on the preferred orientation of the injection site (Bosking et al., 1997) and, for some cases, the width of the bouton tuning curve is comparable to that of the physiologically derived tuning curve for multiunit activity at the injection site. Given that measures of bouton tuning have been made from bulk injections of tracers, and that the injection sites themselves occupy some range of orientation preferences, these values may underestimate the degree of tuning present in the horizontal network. At the least, these results demonstrate a strong bias in the distribution of horizontal connections for sites that have similar orientation preferences.

The other feature of horizontal connections that had to be reckoned with was how their extent across the map of visual space relates to the receptive field size of V1 neurons. Defining the limits of the receptive field of neurons in visual cortex has never been a simple issue, but a common approach is to determine the *minimum discharge field* by presenting a small stimulus (usually a light or dark bar at the appropriate orientation) and delimiting the area of visual space that consistently elicits spike discharges above some background level (Barlow et al., 1967; Hubel and Wiesel, 1962). Surprisingly, the extent of visual field encompassed by the spread of horizontal connections was found to be two to three times the

size of minimum discharge fields of V1 neurons (Gilbert, 1992, 1998; Gilbert and Wiesel, 1983, 1989). For this reason, horizontal connections have been viewed as a potential substrate for receptive field surround effects—alterations in the response to presentation of a stimulus within the minimum discharge field produced by the presentation of stimuli in surrounding areas of visual space (Fiorani et al., 1992; Gilbert and Wiesel, 1990; Kapadia et al., 1995; Knierim and Van Essen, 1992; Maffei and Fiorentini, 1976; Nelson and Frost, 1985; Polat et al., 1998; Fig. 46.2A). As has been made clear by more recent intracellular recording experiments in cat visual cortex, receptive field surround effects reflect the fact that a cortical minimal discharge field is just the tip of the iceberg of a much larger region of subthreshold responsiveness (Bringuier et al., 1999). Although cortical neurons are most sensitive to a restricted region of visual space, subthreshold depolarizing and hyperpolarizing inputs can be detected from regions of visual space that are two to three times the size of the spike discharge zone (Fig. 46.2B). Based on latency measures and conduction velocity estimates, it has been argued that these subthreshold regions are mediated by monosynaptic connections conveyed by horizontal connections (Bringuier et al., 1999). This view is also consistent with the observation that activation of horizontal connections in tissue slice experiments elicits subthreshold responses significantly smaller in magnitude than those elicited by stimulation in layer 4 (Hirsch and Gilbert, 1991; Yoshimura et al., 2000).

In retrospect, the proposed functional dichotomy between horizontal and vertical connections arose as a natural consequence of accommodating an unexpected result (long-range horizontal connections) in an existing architectural framework in which receptive field properties were ascribed to interactions that occurred within a local column of cortical tissue. The simplicity of this relationship between distinct elements of cortical circuitry and features of neuronal responsiveness has significant appeal; however, there are a number of reasons to question this hypothesis, starting with a consideration of the considerable spatial overlap of the two sets of connections.

Horizontal connections are not strictly long-range

Compared with the arrangement of layer 4 inputs, horizontal connections extend for long distances across the cortical surface. However, horizontal connections are not exclusively long-range; the density of horizontal connections is actually greatest locally and diminishes with distance (Bosking et al., 1997; Gilbert and Wiesel, 1989; Kisvarday et al., 1997; Malach et al., 1993; Rockland and Lund, 1982; Rockland et al., 1982; Fig. 46.3A). At least some of these proximal connections originate as collaterals from the axons of pyramidal neurons that continue to more distal targets

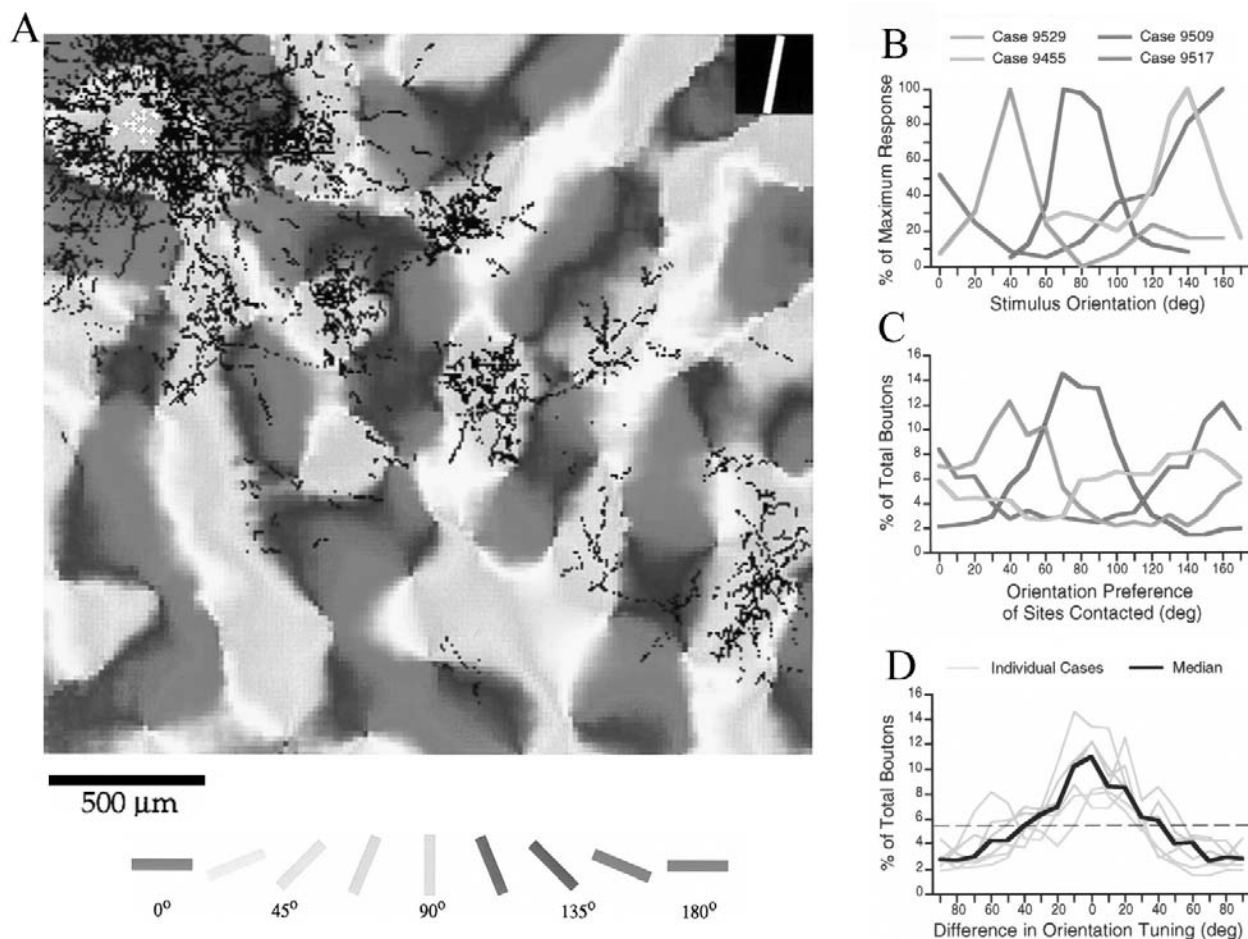

FIGURE 46.1. Relation of horizontal connections to maps of orientation preference derived with intrinsic signal optical imaging. *A*, Distribution of biocytin-labeled boutons (black dots) resulting from an injection of tracer into a site (white crosses) that responded preferentially to an 80 degree stimulus (just off vertical). Within 500 μm of the injection site the terminals are distributed over a wide range of orientations, while at longer distances the terminal patches are localized in regions that have orientation preferences similar to

that of the injection site. Orientation preference is color coded according to the key at the bottom of the panel. *B,C*, Comparison of the multiunit orientation tuning curves from four injection sites (*B*) with the bouton orientation tuning curves derived from the distribution of boutons on the optical maps (*C*). *D*, Summary of the orientation tuning of the bouton distribution relative to the preferred orientation of the injection site. within the horizontal network (Gilbert and Wiesel, 1983; Kisvarday and Eysel, 1992; Martin and Whitteridge, 1984; Yabuta and Callaway, 1998), suggesting that the same signal is propagated throughout the cortical region that contributes to the minimum discharge field and the surrounding sub-threshold region. Thus, no parts of the receptive field escape the influence of the horizontal network; indeed, assuming a smooth and continuous mapping of visual space (see below), the impact of the horizontal network is likely to be as strong or stronger in the cortical region that contributes to the minimal discharge field.

Furthermore, the functional specificity that is a characteristic feature of long-range horizontal connections may not apply to the interactions mediated by these shorter-range horizontal connections. Although extracellular tracer injections reveal the modular specificity of long-range connec-

tions, with such connections terminating primarily in regions of orientation preference similar to that of the injection site, the pattern of termination within 500 μm of the injection site is diffuse and nonspecific, lacking the patchiness which is characteristic of the long-range horizontal connections (Bosking et al., 1997; Gilbert and Wiesel, 1989; Kisvarday et al., 1997; Malach et al., 1993). This pattern, suggestive of interconnections between cortical sites with a broad range of orientation preferences, is supported by the results of several recent physiological studies. For example, cross-correlation analysis suggests that there is a high degree of connectivity between pairs of neurons that are separated by distances of less than 500 μm , regardless of the orientation preference of the individual neurons (Das and Gilbert, 1999; DeAngelis et al., 1999; Hata et al., 1991; Michalski et al., 1983; Fig. 46.3*B*). Likewise, recent intracellular

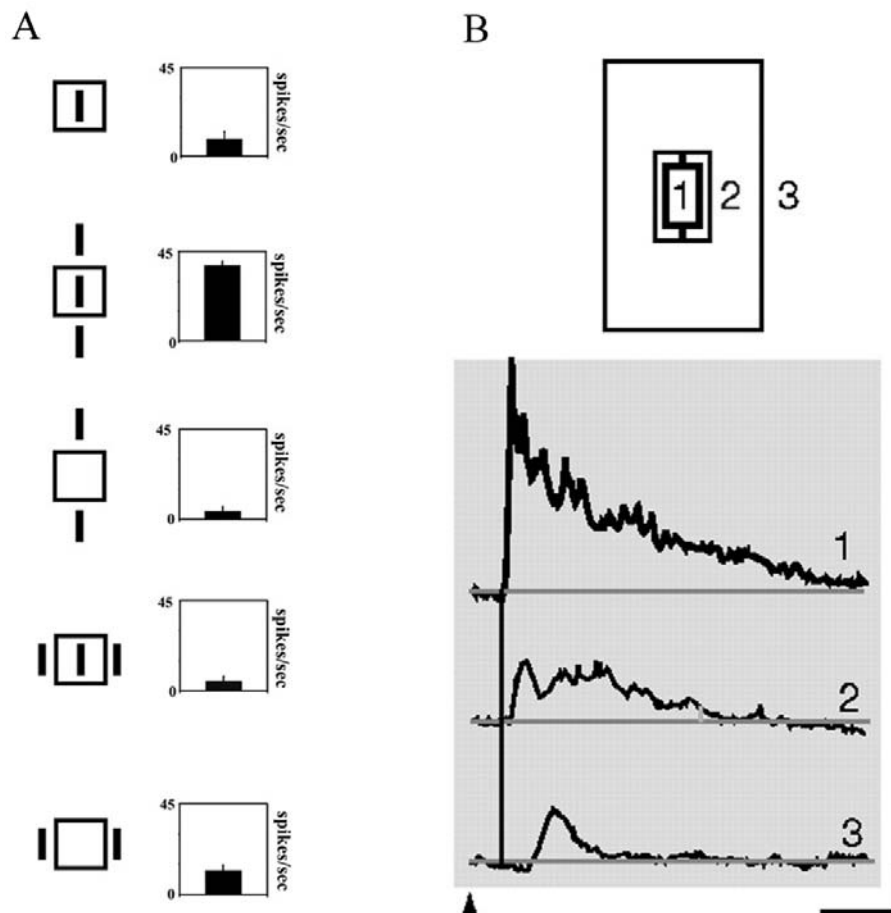

FIGURE 46.2. Receptive field center and surround. *A*, The black square indicates the boundaries of the minimum discharge field assessed by using a small bar the size of the receptive field to delimit the area of visual space that evokes spike discharge. Although presentation of stimuli in the region around the minimum discharge field does not evoke spikes, placement of stimuli in these regions can alter the response to stimuli presented in the minimum discharge field. In this case, a colinear arrangement of surround stimuli enhances the spike rate, while the noncolinear arrangement decreases the spike rate over that found with center stimulation

recording experiments show effects consistent with a uniform pattern of local connections whose tuning can be broad or narrow, depending on the properties of the orientation map. The subthreshold responses of neurons near pinwheel centers (regions where orientation preference changes rapidly across the cortical surface) are considerably broader in their orientation tuning than those that lie in regions where orientation is changing at a slower rate (Schummers et al., 2001).

Short-range horizontal interactions also include a significant contribution from the population of smooth dendritic, GABAergic neurons within layer 2/3. This is an extremely diverse class of neurons that differ in morphology and synaptic properties (Gupta et al., 2000; Miles, 2000). Most have axon arbors that do not extend over more than 500 μm , although one distinct class (the basket cell) spreads its axon

alone. *B*, Subthreshold responses from regions that surround the minimum discharge field. Intracellular records showing responses from flashed grating stimulation of the minimum discharge field (1) and annular stimulation with the minimum discharge field blocked by masks of different sizes (2, 3). Even stimulation with the largest mask several times the size of the minimum discharge field still evokes a significant subthreshold response. (*A* from Kapadia et al., 2000; *B* reprinted with permission from Bringuier et al., *Science* 283, 695, 1999. Copyright 2000 American Association for the Advancement of Science.)

arbor for distances that rival those of pyramidal cells (Kisvarday and Eysel, 1993; Kisvarday et al., 1993). Analysis of the distribution of boutons from inhibitory neurons (both short- and long-range) suggests that they are more broadly tuned than those of more distant pyramidal cell terminations (Kisvarday et al., 1994, 1997), and this observation is consistent with the results of photostimulation experiments in tissue slices (Roerig and Kao, 1999).

The functional significance of this dense system of local horizontal connections remains unclear, but two distinct hypotheses have been offered. One possibility is that these connections contribute to the minimum discharge field by adjusting response gain to match the range of contrasts that are present in the visual scene. Contrast-dependent shifts in the responsiveness of V1 neurons play a critical role in optimizing the representation of a wide range of stimulus

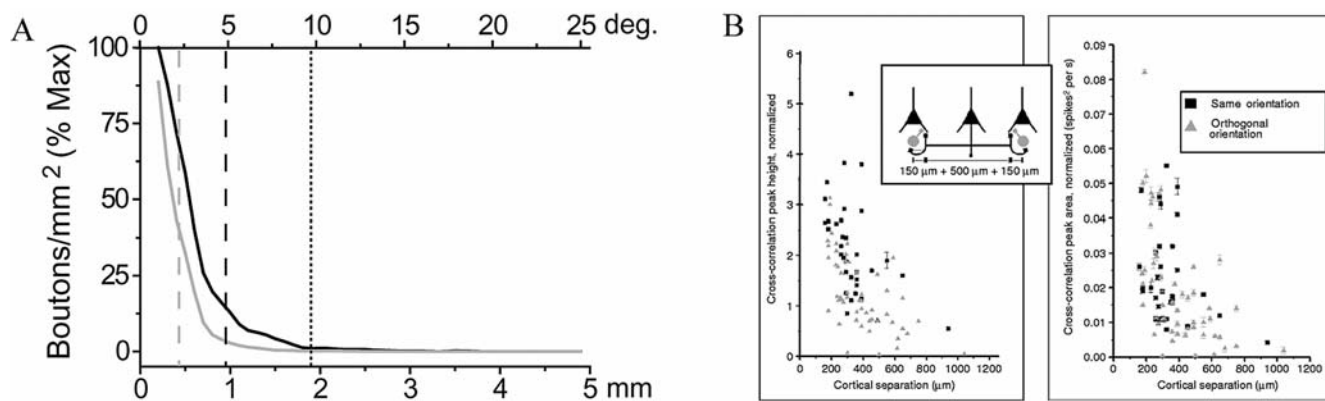

FIGURE 46.3. The properties of short-range horizontal connections. *A*, Number of boutons versus cortical distance along the axis of preferred orientation in the map of visual space (*black*) and along the orthogonal axis (*gray*). Horizontal connections are actually most dense locally, decreasing by an order of magnitude within a millimeter of the injection site center. Note greater extent and density of boutons along the axis of preferred orientation. *B*, Quantification of the degree of cross-correlation between neurons with different preferred orientations at short separation distances. *B*, Whether

using measures of peak height (*left*) or peak area (*right*), correlations are high regardless of whether the sampled pair have the same or orthogonal orientation preferences. These results are consistent with the view that short-range horizontal connections link cells with less specificity than their long-distance counterparts. (*A* from Chisum et al., 2003. Copyright 2003 by the Society for Neuroscience; *B*, reprinted by permission from *Nature* (Das and Gilbert, 1999, *Nature*, 399:655–661). Copyright 1999 Macmillan Publishers Ltd.)

contrasts within the limited range of cortical neuron spike discharge rates. Consistent with the nonspecific nature of local horizontal connections, the signal responsible for contrast gain control is thought to arise from a pool of neurons that respond to a wide range of stimulus orientations and whose receptive fields are limited to regions of visual space that correspond to the target neuron's receptive field (Bonds, 1989; DeAngelis et al., 1992; Heeger, 1992).

A second possibility is that a subset of these connections, though short-range, may link neurons with largely nonoverlapping receptive fields due to inhomogeneities in the mapping of visual space (Das and Gilbert, 1997). In cat visual cortex, localized jumps in the otherwise smooth mapping of visual space have been demonstrated to occur in association with discontinuities in the mapping of orientation preference known as *orientation pinwheel centers* (Das and Gilbert, 1999). As a result, for neurons that lie near pinwheel centers, local horizontal connections could mediate receptive field surround effects, linking cells with nonoverlapping receptive fields and different orientation preferences. Evidence in support of a contribution of short-range connections to receptive field surround effects comes from observations on the suppression of V1 responses that is induced by simultaneously presenting a line segment of the preferred orientation in the minimum discharge field and an orthogonally oriented line segment outside the minimum discharge field. These suppressive effects are most prominent for neurons located near pinwheel centers, where the stimulus configuration would be expected to activate nearby populations of cortical neurons linked by local horizontal connections. Although additional work needs to be done to confirm these results (Bosking et al., 2002; Fitzpatrick, 2000),

they suggest that local horizontal connections could contribute to either the minimum discharge field or the surround, depending on their location relative to orientation pinwheel centers.

Stimulation confined to the minimum discharge field activates a distributed population of layer 2/3 neurons linked by horizontal connections

The view that horizontal connections are responsible for the properties of the receptive field surround and not those of the minimum discharge field is also difficult to sustain if one considers the amount of cortical surface area that is activated by stimuli confined to the minimum discharge field. Stimuli confined to a receptive field activate a region of cortex that is large enough to include a significant fraction of a neuron's horizontal network (Fig. 46.4*A*). The relationship between the population of cortical neurons that is predicted to be activated by a stimulus filling the minimum discharge field of a layer 2/3 neuron in tree shrew visual cortex and the distribution of horizontal connections is illustrated in Figure 46.4*B*. In this example, the size of the receptive field has been convolved with the cortical map of visual space and with the point image size (the spread of activity expected for stimulation of a point in space) to arrive at an estimate of the area that would contain spiking neurons (Bosking et al., 2002). A similar estimate (without inclusion of point spread) is shown for results from the squirrel monkey visual cortex in Figure 46.4*C* (Sincich and Blasdel, 2001). These results indicate that stimulation of a neuron's minimum discharge field will be accompanied by spiking activity in a distributed population of layer 2/3 cortical

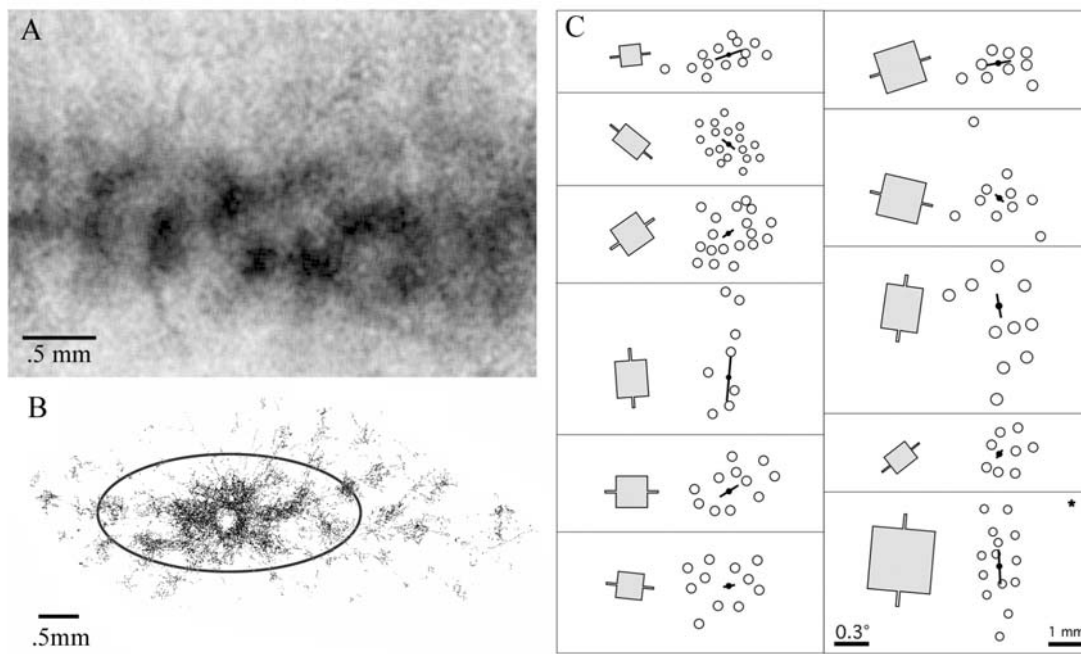

FIGURE 46.4. Horizontal connections and the minimum discharge field. *A*, Distribution of active neurons in V1 of the tree shrew resulting from the presentation of a single line $\frac{1}{4}$ degree in width (20 degrees in length) oscillating over 1 degrees of visual space. This stimulus results in a broad line of activated neurons (dark regions), with hot spots centered on regions that respond preferentially to the orientation of the stimulus. The average full width at half height of the active zone for such a stimulus is 1 mm. Movement of the stimulus to a new location 1 degree away results in systematic shifts of the activation peak of $200\mu\text{m}/\text{degree}$. Given that the average width of layer 2/3 cell receptive fields is 5 degrees, stimuli confined to the receptive field will activate a region of cortex

that includes a significant fraction of the neuron's horizontal network. *B*, Comparison of the region of cortex that would be activated by a stimulus that fills the receptive field of a layer 2/3 neuron (black oval) and the distribution of horizontal connections (black dots) in the tree shrew. *C*, Comparison of minimum discharge field size (gray squares) and horizontal connection extent (circles represent bouton patches in layer 2/3) in monkey visual cortex for 11 cases. Comparison of the receptive field plots and the anatomical plots (that have been scaled by the appropriate cortical magnification) reveals the potential contribution of horizontal connections to the minimum discharge field. (*C* from Sincich and Blasdel, 2001, Copyright 2001 by the Society for Neuroscience.)

neurons, neurons that are linked by the more proximal parts of the patchy horizontal network.

If the horizontal network contributes to the properties of the minimum discharge field, then anisotropies in the spatial arrangement of horizontal connections should be reflected in the shape of the minimum discharge field as well as the subthreshold surround. Horizontal connections in the superficial layers of tree shrew visual cortex exhibit striking anisotropy, extending preferentially along one axis of the cortical map of visual space. Furthermore, the axis of elongation is orientation specific, distributing so as to link cells whose receptive fields prefer similar orientations and are aligned along the axis of preferred orientation in visual space (Bosking et al., 1997). In the tree shrew, these connections extend roughly twice as far along the axis of preferred orientation (up to 20 degrees in the map of visual space) as along the orthogonal axis (Fig. 46.3*A*), and give rise to four times as many terminal boutons (Bosking et al., 1997; Chisum et al., 2003; Figs. 46.1*A*, 46.4*B*). This bias in the distribution of horizontal connections is consistent with the average shape of the minimum discharge field of layer

2/3 neurons (roughly 2:1) and with the size and shape of the subthreshold facilitatory zones that extend beyond the minimum discharge field for distances of up to 20 degrees (Chisum et al., 2003). These features appear to emerge in layer 2/3; layer 4 neurons in this species have receptive fields that are radially symmetric, poorly tuned for orientation, and either exhibit no sign of summation or show suppression for increases in stimulus length (Chisum et al., 2003). An orientation-specific anisotropy of horizontal connections also has been described in the cat and in squirrel and owl monkey visual cortex; however, the magnitude of elongation is less than that described in the tree shrew (Schmidt et al., 1997; Sincich and Blasdel, 2001), and this may reflect the less pronounced (or less homogeneous) elongation of layer 2/3 cell receptive fields in these species (Angelucci et al., 2002).

What is clear from these considerations is that the strict allocation of the minimum discharge field and subthreshold regions to the functions of vertical and horizontal circuits, respectively, must be tempered by the recognition of significant overlap in the spatial extent of these two types of con-

nections, as well as by the amount of the horizontal network that is activated by stimulation of the minimum discharge field. Indeed, based on the fact that their density falls with distance, the contribution of horizontal connections should be significant over the entire receptive field (supra- and subthreshold) and should be greatest in the region of the minimum discharge field. Furthermore, as the following sections indicate, the functional interactions between the minimum discharge field and the subthreshold regions that surround it are far from simple: they vary in sign (facilitatory or inhibitory) and in magnitude based on the nature of the visual stimulus and the context in which it is presented.

Intracortical circuits and receptive field dynamics: stimulus contrast and summation

The dynamics of receptive field center-surround interactions are well illustrated by considering the effects of varying stimulus contrast on the responses of V1 neurons to bars of varying lengths. Some of the earliest studies of the receptive fields of V1 neurons noted that many cells appeared to be tuned to the length of a bar moving through the receptive field. Increasing the length of a bar stimulus results in an increased neuronal response rate (*summation*) until an optimal bar length is reached, after which further increasing the bar length leads to a decrement in response often referred to as *endstopping*. More recently, it has become clear that the para-

meters of length tuning are highly dependent on stimulus contrast. For many cells in primate and cat V1, the length tuning curve for high-contrast stimuli plateaus at relatively short stimulus lengths, and many (but not all) tuning curves exhibit a reduction in response to the presentation of longer-length stimuli. At low-contrast values, however, the stimulus length over which summation occurs can be increased by two to four times over that found with high-contrast stimuli, and there is no sign of a reduced response to longer stimuli (Kapadia et al., 1999; Sceniak et al., 1999; Sengpiel et al., 1997; Fig. 46.5A). Thus, stimuli presented in the same region of visual space can exert a facilitatory effect, a suppressive effect, or have no effect, depending on stimulus contrast.

A similar contrast dependence is evident in center-surround interactions that have been probed with multiple discrete stimuli (Fig. 46.5B). For example, the effect produced by presentation of a colinear stimulus outside the minimum discharge field can often be changed from facilitation to suppression by increasing the contrast of the stimulus in the receptive field center (Henry et al., 1978; Kapadia et al., 2000; Levitt and Lund, 1997; Polat, 1999; Polat et al., 1998; Sengpiel et al., 1997). It is worth noting that there is considerable disagreement in the literature over the presence of facilitatory regions beyond the classical receptive field (DeAngelis et al., 1992, 1994; Kapadia et al., 1995, 1999; Levitt and Lund, 1997; Mizobe et al., 2001; Maffei and Fiorentini, 1976; Nelson and Frost, 1985; Polat et al., 1998;

FIGURE 46.5. Dynamics of receptive field surround effects. *A*, Comparison of average length summation curves for a population of neurons in monkey visual cortex generated with stimuli of low and high contrast. For high-contrast stimuli, the length summation curve peaks at short stimulus lengths, and there is a decrease in response to longer stimulus lengths. For low-contrast stimuli, the peak of the length summation curve occurs at significantly longer lengths, and the reduction (endstopping) is often absent. *B*, Responses to arrays of Gabor stimuli exhibit contrast-dependent

facilitatory and suppressive effects. The neuronal response to Gabor stimuli centered in the minimum discharge field increases with increasing stimulus contrast (*filled circles*). The addition of colinear flanks (*open circles*) results in facilitation over single Gabor response at low contrast and suppression at high contrast. (*A* from Kapadia et al., 1999, Proc. Natl. Acad. Sci., USA, 96:12073–12078. Copyright 1999 National Academy of Sciences, USA. *B* reprinted by permission from *Nature* (Polat et al., 1998, *Nature*, 391:580–584). Sceniak et al., 1999; Sengpiel et al., 1997; Walker et al., 1999). Much of the discrepancy can be attributed to how the receptive field center is defined; facilitatory surround effects are likely to result from placement of discrete stimuli outside the minimum discharge field but within the regions that contribute to length summation with continuous stimuli (see Fitzpatrick, 2000 for discussion).

Length summation and surround facilitation are generally thought to arise from an increase in the activity of excitatory inputs, but endstopping and surround suppression have been attributed to a number of mechanisms, including recruitment of inhibition (Kapadia et al., 1999; Somers et al., 1998; Stemmler et al., 1995), withdrawal of excitation (Sceniak et al., 1999), or a combination of these factors (Anderson et al., 2001). In support of recruitment of inhibition, recordings from cortical slices show that weak electrical stimulation of intracortical circuits elicits purely EPSPs, while stronger stimulation elicits compound EPSP/IPSPs (Hirsch and Gilbert, 1991). Thus, by analogy, low-contrast stimuli which might be expected to evoke a relatively low level of activity in cortical circuits result in summation, while higher-contrast stimuli which reach the threshold for recruiting inhibitory inputs lead to endstopping. An alternative explanation suggests that endstopped responses are better explained by withdrawal of excitation than by increased inhibition. By quantifying the responses of cortical neurons to stimuli of different lengths at different contrasts and fitting the data with a difference of Gaussians model, Sceniak et al. (1999) found that length summation was relatively insensitive to changes in surround suppression but was well fit by changes in facilitation. Recent *in vivo* intracellular recordings provide evidence that supports both withdrawal of excitation and increased inhibition as contributors to the suppression: endstopping evoked during measurements of length tuning with high-contrast stimuli is associated with both increased inhibitory conductance and large decreases in excitatory conductance (Anderson et al., 2001).

In principle, the changes in excitatory and inhibitory currents that underlie the dynamics of length tuning could be explained solely by interactions between the network of long-range horizontal connections and short-range GABAergic neurons (Douglas and Martin, 1991; Douglas et al., 1995; Somers et al., 1998; Stemmler et al., 1995; Fig. 46.6). For low-contrast stimuli, the level of activity in the horizontal network is likely to be low; given that weak stimulation elicits only EPSPs (Hirsch and Gilbert, 1991), inhibition may not be recruited under these conditions. Increases in stimulus length recruit more and more of the horizontal network, leading to an increase in the average discharge rate of the neurons (Fig. 46.6*A*). This facilitation saturates at stimulus lengths that correspond to the cortical extent of horizontal connections. Indeed, recent analysis in macaque V1 shows that horizontal connections extend over

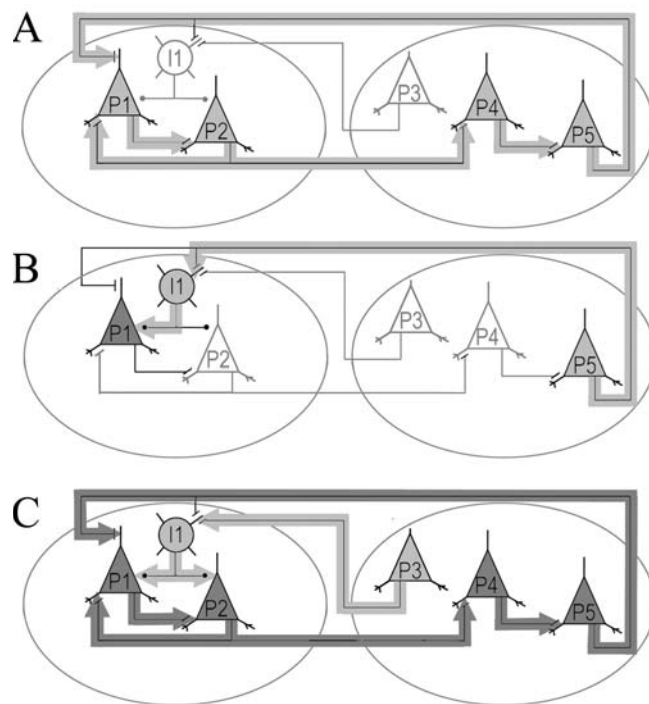

FIGURE 46.6. Changes in the level of activity of the horizontal network that may underlie length summation and endstopping. Populations of pyramidal cells are indicated by triangular symbols; networks of inhibitory cells are represented by a circular symbol with a smooth contour. Increases in activity are depicted by light gray, decreases by dark gray. Increases in the length of low-contrast stimuli recruit more of the excitatory horizontal network that synapses with P1 (*A*). Increases in the length of high-contrast stimuli lead to levels of activity in the horizontal network that are sufficient to recruit local inhibitory neurons, reducing the activity of P1 (*B*); concomitantly, the amount of excitatory activity in the horizontal network is reduced (*C*). (See color plate 29).

a distance that is in accord with the low-contrast measures of length summation (Angelucci et al., 2002; Cavanaugh et al., 2002). During presentation of high-contrast stimuli, in contrast, the high level of activity in the horizontal network permits the recruitment of inhibition. Thus, although increases in stimulus length still lead to recruitment of additional horizontal connections, at some point the level of activity in the horizontal network reaches the threshold of inhibitory neurons (Fig. 46.6*B*). At this point, the activity of local inhibitory neurons results in increased inhibitory conductances and, due to net reduction in the activity of the horizontal network, a concomitant decrease in excitatory conductances (Fig. 46.6*C*).

However, it seems likely that changes in the activity of vertical circuits could also play a significant role in the dynamics of length summation and endstopping, as layer 4 neurons themselves are known to exhibit summation. In addition, at low contrast, longer bars will recruit a larger percentage of the population of layer 4 neurons that converge onto a given layer 2/3 neuron, contributing to summation. Increasing the

length of high-contrast bars has a different effect: because layer 4 neurons are a significant source of the excitatory inputs to inhibitory neurons in layer 2/3, an increase in the length of a high-contrast bar produces more vigorous responses in layer 4 neurons and recruits GABAergic neurons in layer 2/3, contributing to endstopping in layer 2/3. Finally, because some layer 4 neurons in cat and monkey visual cortex exhibit endstopping themselves, increasing stimulus length can result in a decrease in the activity of vertical inputs, which is likely to contribute to the decrease in excitatory currents that accompanies the endstopped responses of layer 2/3 neurons. It has been suggested that a circuit involving either direct projections from a subpopulation of layer 6 neurons to layer 4 or projections from layer 6 neurons to the visual claustrum (a thin sheet of neurons in the rostral forebrain that projects back to cortical layer 4) may be the source of the endstopping of layer 4 neurons (Bolz and Gilbert, 1986; Sherk and LeVay, 1983). Indeed, inactivation of layer 6 neurons or lesions of the visual claustrum result in a reduction of endstopped responses in V1. Thus, while it is tempting to explain the dynamics of length summation as the result of interactions mediated largely by horizontal connections, a more complete explanation of these phenomena will require understanding how alterations in the activity of vertical inputs and inputs from extrinsic sources interact with horizontal interactions in shaping the responses of layer 2/3 neurons.

Intracortical circuits and receptive field dynamics: artificial scotoma

The response to presentation of stimuli within and outside the minimal discharge field is also sensitive to the neuron's stimulation history. Masking a limited region of the visual field for several minutes while stimulating the surrounding regions of visual space causes the receptive fields of cortical neurons in this *artificial scotoma* to expand to several times their original size (Gilbert and Wiesel, 1992; Kapadia et al., 1994; Pettet and Gilbert, 1992). The effect can be reversed by presenting visual stimuli within the masked region, causing the receptive fields to shrink to their original size.

It seems likely that an increase in the effectiveness of horizontal connections contributes to the expansion of the receptive field. During the creation of an artificial scotoma, the activity of pairs of layer 2/3 neurons that are separated by several millimeters across the cortical surface becomes more strongly correlated, consistent with an increase in the effective strength of horizontal connections (Das and Gilbert, 1995a). Although the precise synaptic basis for such an alteration in efficacy remains unclear, one possibility is that the change is largely a product of network dynamics—

alterations in the balance of excitation and inhibition that increase the responsiveness of layer 2/3 neurons to weaker, more distant inputs. For example, the local inhibitory network in layer 2/3 may be the source of tonic inhibition that regulates the sensitivity of layer 2/3 neurons to excitatory inputs. During the artificial scotoma paradigm, the local inhibitory network in the region of the cortex that represents the scotoma is less active than it would be if a stimulus was present, and the neurons are relatively more sensitive to horizontal inputs from the surrounding areas, resulting in an expanded receptive field. Changes in network excitability could be accompanied by potentiation of the synapses associated with horizontal connections during the masking period. In support of this proposal, *in vitro* experiments provide evidence that the strength of synapses in the horizontal network can be modified by stimulation (Hirsch and Gilbert, 1993).

An alternative possibility is that scotoma-induced changes in receptive field size depend less on network dynamics than on activity-dependent changes in intrinsic conductances, a possibility raised by studies of contrast gain control (Ohzawa et al., 1985). During sustained presentations of high-contrast visual stimuli, neuronal activity is high, but neuronal responsivity decreases due to the activation of intrinsic conductances which hyperpolarize the membrane potential (Carandini and Ferster, 1997; Sanchez-Vives et al., 2000a, 2000b). Conversely, during low-contrast visual stimulation, neuronal activity is low but responsivity increases due to the deactivation of intrinsic currents. The nature of these effects suggests that the efficacy of horizontal connections may be modulated, during changes in mean level of neuronal activation, through the control of membrane potential by intrinsic conductances. For example, during periods of full-field visual stimulation, the local inhibitory network receives direct activation through ascending afferents from layer 4 and local pyramidal cells receive tonic inhibition, rendering long-range horizontal connections relatively ineffective and shrinking receptive field area. However, during generation of an artificial scotoma, neuronal activity within the affected area is low, so the local inhibitory network is less active as afferents ascending from layer 4 are silenced. As a result, local pyramidal cells are released from tonic inhibition and neurons may depolarize enough to bring membrane potentials close to threshold, enabling horizontal connections to become more effective in driving spikes and yielding receptive field expansion. In this conception, activity-dependent changes in intrinsic conductance regulate the efficacy of horizontal inputs and establish the size of the minimum discharge field.

Although this discussion has focused on the impact of changes in the efficacy of horizontal connections, it is worth emphasizing that both network and conductance-induced changes in membrane potential operate simultaneously on

all of the inputs that a neuron receives, altering the efficacy of vertical as well as horizontal and feedback connections from extrastriate areas. The observation that artificial scotoma-induced changes in receptive field size are frequently accompanied by changes in the magnitude of response to the presentation of stimuli in the center of the receptive field, where vertical connections would be expected to be strongest, is consistent with an overall increase in responsiveness to the full spectrum of inputs that are centered on the cell's receptive field (Pettet and Gilbert, 1992). Furthermore, at least some of the increase in receptive field size following the artificial scotoma is likely to reflect the increased efficacy of those layer 4 inputs that lie most distant from the layer 2/3 neuron and contribute the fewest synaptic terminals. In addition, the proposed changes in intrinsic conductance would be expected to occur in layer 4 neurons themselves, altering the sizes of their receptive fields and thereby contributing to the changes of their targets in layer 2/3.

Intracortical circuits and neuronal synchrony

A prominent feature of neurons in visual cortex is their tendency to fire synchronously despite large cortical separation distances (Singer, 1999; Usrey and Reid, 1999). Most efforts to explain neuronal synchrony emphasize a prominent role for horizontal connections, and the orientation selectivity of long-range synchrony is certainly consistent with the properties of the horizontal network (Das and Gilbert, 1999; Gray et al., 1989; Hata et al., 1991; Toyama et al., 1981a, 1981b; Ts'o et al., 1986). However, two different synaptic mechanisms have been proposed to explain their involvement.

One possibility is that synchrony is largely the result of oscillations in the activity of a distinct class of pyramidal cells in superficial layers of cortex, termed *chattering cells*, that generates rhythmic bursts of action potentials at 20 to 70 Hz. The excitatory drive in this cell class is proposed to synchronize neuronal spiking, entrain neuronal populations, and generate gamma wave oscillations (Gray and McCormick, 1996). Supporting this theory, models show that neurons are most likely to fire action potentials when they receive multiple, coincident EPSPs (Softky and Koch, 1993; Stevens and Zador, 1998). Thus, concerted neuronal activation may arise from the ability of chattering cells to deliver bursts of EPSPs simultaneously to large neuronal populations (Fig. 46.7A). Although at least some chattering cells appear to give rise to horizontal connections, they represent only a small percentage of superficial pyramidal cells, raising the question of how this small number of cells could be the source of a signal that entrains large populations of neurons in widely separated orientation domains (Gray and McCormick, 1996). Some regular-spiking cells have intrinsic

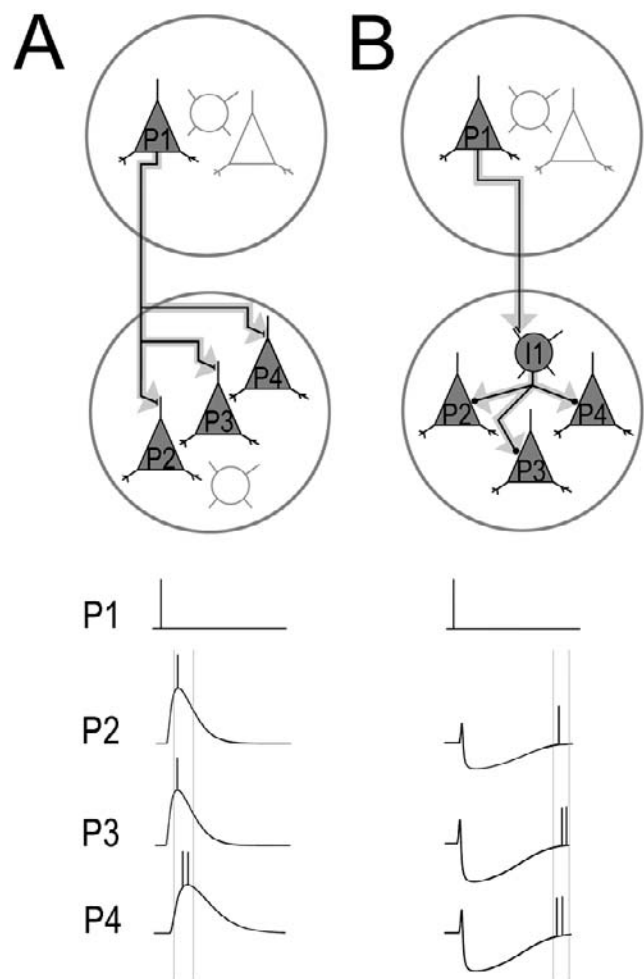

FIGURE 46.7. Horizontal connections and the generation of neuronal synchrony. *A*, Neuronal synchronization based on excitation driven by chattering cells. A chattering cell (P1) generates bursts of action potentials that are carried through long-range horizontal connections to pyramidal cells in neighboring orientation domains (P2 to P4); as shown below the circuit diagram, activity in P1 generates synchronous EPSPs in P2 to P4, resulting in synchronized firing patterns. *B*, Inhibition-based mechanism for generating neuronal synchrony. Through its horizontal connections, a regular-spiking pyramidal cell (P1) strongly activates the local inhibitory network (I1) in a neighboring domain, resulting in the generation of simultaneous IPSPs in local pyramidal cells (P2 to P4). As shown below the circuit diagram, as these pyramidal cells recover together from hyperpolarization, they fire synchronous action potentials, having a precise temporal relationship to P1.

sic membrane properties enabling them, when depolarized, to switch to a chattering mode (Brumberg et al., 2000), suggesting that an initially small group of chattering cells may recruit additional members; however, whether this is sufficient to produce temporal correlations over long distances remains to be shown.

An alternative view suggests that excitatory connections may be insufficient for generating synchronous activity, because EPSPs have relatively long durations and do not

constrain spike timing as effectively as does inhibition (Van Vreeswijk et al., 1994). Instead, synchronization may rely on the ability of inhibitory cells to control spike timing in pyramidal cells, as has been demonstrated in cortical slices (Cobb et al., 1995). By delivering IPSPs to numerous pyramidal cells, inhibitory cells cause pyramidal cells to hyperpolarize simultaneously and fire synchronous spikes during the rebound (Fig. 46.7*B*). While most inhibitory cell axons extend only several hundred microns, perhaps sufficient to synchronize activity within an orientation domain, there are two mechanisms by which they might evoke synchronization over longer cortical distances. First, large basket cells represent a small percentage of inhibitory cells in superficial layers, but they have arbors extending several millimeters (Kisvarday and Eysel, 1993; Kisvarday et al., 1993), raising the possibility that this cell type may contribute to synchronizing activity across long distances. Second, an alternative possibility is that the long axons of large basket cells are not required for long-range synchrony, because horizontal connections are very effective in driving inhibition (Hirsch and Gilbert, 1991). This possibility has received support from realistic neuronal models showing that the axons of pyramidal cells may generate synchrony over long distances by interconnecting the local inhibitory networks and driving inhibition in multiple orientation domains (Bush and Sejnowski, 1996; Traub et al., 1996).

While horizontally mediated synaptic interactions are no doubt critical to long-range synchronization (Wilson and Bower, 1991), the amplitude and timing of vertical inputs from layer 4 are also likely to play a significant role in these interactions. Neuronal synchrony originates at the earliest stages of visual processing, being evident in the retina and in the lateral geniculate nucleus, and may be further refined by corticothalamic feedback (Sillito et al., 1994; Singer, 1999; Usrey and Reid, 1999). The correlation in the activity of thalamic inputs to layer 4 neurons may serve as a seed for the coarse temporal patterning of responses in layer 2/3 that are then further refined by the actions of the horizontal network. Thus, the interplay between the timing and the amplitude of vertical and horizontal inputs is likely to be the source of the precise temporal synchrony that characterizes the responses of layer 2/3 neurons.

Summary and conclusion

We hope that this review has served to emphasize the continuing evolution of our conceptions of the cortical receptive field and the circuitry that underlies it. The cortical receptive field has become a dynamic entity, one in which context and history play significant roles in shaping its boundaries and altering its properties. With this has come the recognition that even small, simple stimuli activate large populations of cortical neurons whose interactions via

vertical and horizontal circuits are complex and whose functions are not so easily parsed into traditional functional categories such as center and surround. Understanding the neural basis for the response properties of layer 2/3 neurons will require a better understanding of the dynamic interplay between vertical and horizontal inputs that converge onto individual neurons, and how this interplay is altered by GABAergic inputs, intrinsic membrane properties, and the state of the cortical network. Perhaps it should come as no surprise that the properties of the neurons that mediate visual perception cannot be attributed to individual components of the network in which they are embedded. Like perception itself, the behavior of the circuit would appear to be more than the sum of its parts.

47 Nonlinear Properties of Visual Cortex Neurons: Temporal Dynamics, Stimulus Selectivity, Neural Performance

DUANE G. ALBRECHT, WILSON S. GEISLER, AND ALISON M. CRANE

Introduction

ANALYSIS OF VISUAL CORTX NEURONS The primary visual cortex plays a very important role in vision and visual perception. To begin with, consider the fact that without area V1, all of the many visual cortical areas (which constitute approximately half of the cerebral cortex in the macaque monkey) are deprived of the visual information relayed through the thalamus from the retina. It has been known for more than a century that damage to this area produces almost total blindness. However, area V1 is not merely a relay station between the thalamus and the other cortical regions. On the contrary, V1 clearly transforms the lateral geniculate nucleus input: in comparison to the relatively simple center-surround receptive fields of geniculate cells, the receptive fields of V1 neurons are considerably more complex and, as will be emphasized in this chapter, the cells are considerably more selective for specific visual features. Finally, consider the anatomical size of the region and the complexity of the neural tissue. In the macaque monkey, V1 constitutes approximately 10% of the entire cerebral cortex, and in comparison to all of the other cortical areas, the primary visual cortex has about twice as many neurons per unit volume, with perhaps half a billion neurons per hemisphere. Given all of these facts, analysis of both the structures and the functions of the primary visual cortex stands as an important challenge to visual neuroscientists in their quest to understand vision and visual perception.

Beginning with the work of Hubel and Wiesel (1962), measurements of the responses of V1 neurons (in the form of action potentials) have provided a wealth of information concerning both the potential biophysical and biochemical mechanisms as well as the ultimate visual information processing functions of these neurons. Nonetheless, in spite of this wealth of scientific information that has accumulated over the decades, in many respects we have taken only a very small step toward a complete understanding of how the visual cortex contributes to visual perception.

In an attempt to analyze the structures and the functions of visual cortex neurons, many researchers have used the well-developed conceptual and mathematical techniques of what can be termed a *systems analysis*. This quantitative approach was introduced to visual neuroscience in principle by Hartline, who was studying the *Limulus* visual system (e.g., Ratliff et al., 1974); it has since been used to study the retina, lateral geniculate nucleus, and visual cortex of the primate and related species (e.g., De Valois et al., 1982; Enroth-Cugell and Robson, 1966; Movshon et al., 1978; Ohzawa et al., 1985; Shapley and Victor, 1979; for reviews see Carandini et al., 1999; De Valois and De Valois, 1988; Ferster and Miller, 2000; Geisler and Albrecht, 2000; Palmer et al., 1991; Robson, 1975; Shapley and Lennie, 1985).

Over the past several decades, much research has been devoted to describing both the linear and the nonlinear properties of V1 neurons using a systems analysis. Within this framework, one begins by assessing what aspects of the behavior can be accounted for by simple linear equations and what aspects require nonlinear equations. In this chapter, we describe linear and nonlinear response properties that have been measured within V1 neurons. We then discuss these measurements (and others) within the context of functional transformations of the visual information that ultimately produce high degrees of reliable stimulus selectivity. Finally, we consider several models, at different levels of analysis, of the neural operations that can potentially account for the linear and nonlinear behaviors that have been measured.

STIMULUS SELECTIVITY: FEATURES, FILTERS, AND FUNCTIONS Research over the past several decades indicates that stimulus selectivity plays a fundamental role in the analysis of visual information within the visual systems of humans, primates, and related species. Within the visual cortex, each neuron is quite selective for a specific *visual feature*. Currently, there is no agreed-upon intuitive name that adequately captures the presumed function associated with this selectivity

(e.g., *edge detector*, *line detector*, *spatial frequency detector*, and so forth). Nonetheless, it is possible to summarize and quantify the selectivity by measuring the responses as a function of many different stimulus dimensions that describe visual stimuli: for example, spatial position, spatial orientation, spatial frequency, temporal frequency, direction of motion, contrast, color, and so forth. These stimulus dimensions are relatively easy to manipulate within the laboratory to measure stimulus selectivity in a systematic, quantitative, and replicable fashion. Further, it is possible to develop descriptive mathematical equations that can adequately describe and summarize the measured responses along these various dimensions. Finally, these descriptive equations can be combined with other equations and analyses to assess the performance characteristics of visual cortex neurons within this multidimensional space and to investigate the ultimate functional consequences of the measured stimulus selectivity.

Rather than attempting to characterize the function of visual cortex neurons using simple intuitive visual feature detection (e.g., edge detection), it is possible to conceptualize the function of each neuron, in a somewhat more neutral fashion by thinking of the function as a filtering operation. A neuron in the primary visual cortex only responds to a specific range of values within a complex (and not necessarily intuitive) multidimensional feature space. In so doing, the neuron filters out the overwhelming majority of unique subsets within the total set and only passes (or signals) the presence of a very small and unique subset. It seems reasonable to assume that whatever this particular type of stimulus selectivity might be, it will probably be closely related to the statistics of natural images (Barlow, 1961).

The observation that cortical neurons are selective for a specific subset of possible visual stimuli has important implications for the overall performance capabilities of cortical neurons: because of this stimulus selectivity, the response of each neuron contains specific information about the presence or absence of a particular feature within the visual stimulus that could be used by a subsequent brain mechanism to detect, discriminate, and identify that specific visual feature. For example, the response magnitude could be used to identify, with a high level of confidence, a specific oriented spatial contour, demarcated by a specific color contrast, moving across a particular location in space, at a particular rate, in a particular direction, and so forth.

This high degree of stimulus selectivity at the level of the visual cortex has led to several different hypotheses regarding the ultimate functional significance of the selectivity. One hypothesis is that the selectivity reflects a sparse code that is well matched to the statistics of natural images (Field, 1987; Olshausen and Field, 1987). A second hypothesis is that the selectivity for local image feature/attributes is a critical step toward the goal of object segregation (Geisler and

Albrecht, 2000). A third hypothesis is that the selectivity reflects the sequential hierarchical progression toward neurons within higher cortical regions that are selective for real-world objects (Barlow, 1995). As noted some time ago, sequential filtering is functionally equivalent to pattern recognition (Craik, 1966).

Regardless of whether one, or all, of these hypotheses proves to be accurate, it seems clear that the stimulus selectivity of cortical neurons plays an important role in visual information processing. With this observation in mind, the major focus of this chapter will be those linear and nonlinear properties (and mechanisms) that could potentially have a beneficial influence, or a deleterious influence on stimulus selectivity.

SPATIOTEMPORAL FILTERS AND SYSTEMS ANALYSIS In an attempt to characterize both the structures and the functions of visual cortex neurons, from the subcellular level to the behavioral level, many neuroscientists have used the well-developed techniques of systems analysis. The basic principles of this analytical approach have been fully described for the physical sciences as well as the life sciences (e.g., Marmarelis and Marmarelis, 1978; Schwarz and Friedland, 1965) and need not be formally described in this chapter. Stated simply, one attempts to identify and characterize the linear as well as the nonlinear properties of a complex system with the goal of developing a quantitative model that can potentially describe the behavior of the system under a wide range of diverse circumstances. Within this framework, visual cortex neurons can be conceptualized as spatiotemporal filters that respond selectively along several different stimulus dimensions.

There are different methodologies that can be used to investigate a physical system of interest: for example, one can use a frequency domain analysis, a space and/or time domain analysis, a white noise domain analysis, and so forth (see Marmarelis and Marmarelis, 1978). All of these methods have been applied to visual cortex neurons. As noted above, this quantitative systems approach was initially introduced to visual neuroscience by Hartline (and colleagues), but over the past three decades many different laboratories have adopted this approach, and as a consequence we have a rich understanding of both the linear and nonlinear properties of visual cortex neurons (for recent reviews of this literature, see Carandini et al., 1999; Ferster and Miller, 2000; Geisler and Albrecht, 2000).

To simplify this chapter, the frequency domain analysis will be the major focus, although other analyses will be discussed when appropriate. In a frequency domain analysis of visual cortex neurons, the visual stimulus is a spatiotemporal sine wave grating pattern, which can be systematically varied along many different stimulus dimensions. These measurements, and the equations that can be used to

describe the responses along the various stimulus dimensions, have provided a quantitative description of the stimulus-response characteristics of visual cortex neurons across a wide and diverse set of circumstances.

LINEAR SYSTEMS ANALYSIS CAN REVEAL BOTH LINEAR AND NONLINEAR PROPERTIES Over the past half century, linear systems analysis has played a major role in the quantitative analysis of the visual system. As will be described in this chapter, there is overwhelming evidence that visual cortex neurons exhibit a variety of nonlinear properties. Although specific mathematical methods have been developed to study nonlinear systems (e.g., Victor and Knight, 1979; Victor et al., 1977; see also Marmarelis and Marmarelis, 1978), we have learned a great deal about the nonlinear properties of visual cortex neurons by applying linear systems techniques and analyzing the deviations from what would be expected from a linear system.

In a linear system, the response to the sum of several inputs is equal to the sum of the responses to each input individually, and as the amplitude of the stimulus increases the response increases proportionately. There are many standard techniques for characterizing a linear system that could be applied (see Schwarz and Friedland, 1965), and have been applied, to characterize visual cortex neurons. For example, one could measure either the spatiotemporal receptive field or the spatiotemporal transfer function (e.g., DeAngelis et al., 1993; Palmer et al., 1991). If a system is linear, then all of the different techniques give equivalent results and the measurements made with any one of the techniques can be used to predict the responses of the system to arbitrary inputs. However, when a system is nonlinear, two different techniques may give different results; in this case, it becomes essential to use several different techniques and then compare what is similar and what is not. For example, in the case of visual cortex neurons (as will be described below), the spatiotemporal receptive field and the spatiotemporal transfer function are not exactly equivalent. Finally, note that oftentimes, a specific nonlinear mechanism can only be revealed, isolated, and studied using a specific technique. In the case of visual cortex neurons, different nonlinear properties have been discovered and characterized by using different linear systems techniques.

TEMPORAL DYNAMICS, STIMULUS SELECTIVITY, NEURAL PERFORMANCE During natural viewing, eye movements create a rapid progression of diverse images, and because of this, the spatiotemporal contrast can change rapidly over the course of a few hundred milliseconds (for a comprehensive review see Carpenter, 1991). The average duration of a single fixation (during normal saccadic inspection of a visual scene) is approximately 200 msec. This is an important observation to keep in mind when considering the potential

effects of a specific linear or nonlinear mechanism on stimulus selectivity and neural performance. If the temporal dynamics of the mechanism are relatively fast, then the mechanism might be able to influence selectivity and performance during a single fixation, based on the spatiotemporal contrast contained within that single fixation. On the other hand, if the temporal dynamics are relatively slow, then the mechanism will not be able to influence stimulus selectivity during a single fixation, based on the spatiotemporal contrast within that fixation.

Over the past several decades, many different laboratories have measured the responses of V1 neurons using drifting spatial frequency gratings, across a wide array of stimulus dimensions, using stimulus durations that are relatively long, to approximate a steady-state condition. These measurements, along with other measurements, have revealed some of the fundamental linear and nonlinear properties of V1 neurons (e.g., De Valois et al., 1982; Movshon et al., 1978; for recent reviews see Carandini et al., 1999; Ferster and Miller, 2000; Geisler and Albrecht, 2000).

The drifting steady-state measurements can be supplemented by measurements of the responses to transient stationary stimuli, where the stimulus durations approximate the fixation durations during natural viewing. Consider using a stationary grating that is presented for a brief interval (200 msec) to measure the responses as a function of some stimulus dimension of interest (e.g., contrast). The measured poststimulus time histograms offer a unique opportunity to examine the temporal dynamics of specific linear and nonlinear properties on a fine time scale. With such a set of measurements, one can ask a wide range of different experimental questions and compare the results of the experiments to what we have learned from the steady-state experiments. Consider the following, somewhat overlapping, subset of possible questions:

- In general, are the basic response properties that have been measured using drifting steady-state stimuli similar under transient stationary conditions?
- What is the temporal onset of the stimulus selectivity along each of the fundamental stimulus dimensions?
- Do the selectivities change over the course of the brief interval?
- How long does it take for the nonlinear properties (e.g., contrast-set gain control) to build up through time?
- How do the temporal dynamics compare to the average fixation duration during natural viewing?
- Does the well-established relationship between the mean and the variance of the responses of cortical neurons hold under these transient stationary conditions?
- Does the discrimination performance change?

Recently, several different laboratories have measured the responses to brief stimuli and analyzed the time course of

some of the fundamental properties (e.g., Albrecht et al., 2002; Frazor et al., 1997; Gillespie et al., 2001; Muller et al., 2001; Ringach et al., 1997). Within this chapter, we will consider measurements using drifting steady-state stimuli and measurements using stationary transient stimuli. The results of both types of measurements will be discussed within the context of the effects of the various nonlinearities on stimulus selectivity within a time frame that is comparable to natural viewing.

Linear and nonlinear properties

SOME LINEAR PROPERTIES OF SIMPLE CELLS Hubel and Wiesel (1962) described two basic types of neurons in the visual cortex: *simple cells* and *complex cells*. Since then, some investigators have elaborated the original binary classification with subsidiary and supplementary subclassifications (e.g., Henry, 1977) and others have argued that simple and complex cells reflect opposite ends of a virtual continuum (Chance et al., 1998; Geisler and Albrecht, 2000; Mechler and Ringach, 2002). However, the basic distinction between simple and complex cells remains an important part of the published literature. Stated simply, simple cells have a variety of linear properties that are not generally seen in most complex cells. Specifically, in their original report, Hubel and Wiesel (1962) described four basic linear properties of simple cells:

- Distinct excitatory and inhibitory subregions within the receptive field
- Spatial summation within a given subregion
- Mutual antagonism between subregions
- Responses to novel stimuli can be predicted (qualitatively) on the basis of the arrangement of the subregions

These four properties are what one would expect from a linear spatiotemporal filter. Complex cells, on the other hand, failed to display these properties and were therefore defined by exclusion. For example, a typical complex cell will produce excitatory responses to both white and black stimuli in the same spatial location. This is clearly not what one would expect from a linear spatiotemporal filter. Nonetheless, it is important to emphasize that notwithstanding the various linear and nonlinear properties of simple and complex cells, both types of neurons are highly selective for specific stimulus attributes (e.g., orientation).

Many different laboratories have measured a variety of properties of simple cells using many different types of stimulus protocols. On the basis of this research, it is possible to list a set of linear properties that have been reported in simple cells. Note that in each case, the implied comparison is between (1) the measured neural response behavior of simple cells and (2) the known theoretical behavior of a linear spatiotemporal filter. Finally, bear in mind that the

comparison between the measured behavior of the neurons and the known behavior of a linear filter is always approximate, and never exact.

The receptive field and the optimal stimulus. The receptive field can be mapped using flashing white and black spots (or bars/lines). This map (which is analogous to the impulse response of a linear spatial filter) provides one characterization of the stimulus selectivity for the dimension of space. Thus, for example, one can qualitatively predict the optimal spatial position (say, 2 degrees above the optic axis), spatial orientation (say, horizontal), and spatial configuration of the contrast (say, one narrow white line flanked by two narrow black lines). This observation suggests that the spatial variations in luminance contrast are summed in a linear fashion.

Responses to drifting gratings. When a linear spatiotemporal filter is stimulated with a drifting sine wave, the response is a sinusoidal modulation in synchrony with the temporal frequency of the stimulus. Similarly, when a simple cell is stimulated with a drifting sine wave, the response of the cell modulates in synchrony with the temporal frequency of the input. However, the shape of the temporal response (i.e., the poststimulus time histogram) is not sinusoidal. Specifically, all of the negative values of the sine wave are absent. This observation is not particularly surprising given that simple cells generally have little or no maintained activity (and, of course, there are no *negative action potentials*). In sum, the responses of simple cells to drifting sine waves are similar to what one would expect from a linear filter followed by half-wave rectification.

Responses as a function of spatial phase. Using a stationary spatial frequency sine wave grating whose contrast is modulated in time (i.e., a counterphase flickering grating), it is possible to measure the responses as a function of spatial phase. If this measurement is performed on a linear spatiotemporal filter, the response is a sinusoidal function of spatial phase. Similarly, if this measurement is performed on a simple cell, the response (i.e., the poststimulus time histogram) is approximately a sinusoidal function of spatial phase. There is a specific relationship between the direction selectivity of a linear filter and the responses as a function of spatial phase. The responses of simple cells follow these linear expectations to a first approximation (Albrecht and Geisler, 1991; Reid et al., 1991; Tolhurst and Dean, 1991).

Spatiotemporal transfer function. There are several strong constraints that are implied by the linear model for the spatiotemporal receptive field (e.g., amplitude symmetry and phase additivity), and many of these constraints hold, to a

first approximation, for simple cells. Because these constraints hold, it is possible to describe the spatiotemporal phase transfer function using a simple four-parameter linear equation (Albrecht, 1995; Dawis et al., 1984; Hamilton et al., 1989).

Null phase position. Enroth-Cugell and Robson (1966) introduced a clever method to test for linear spatial summation in retinal ganglion cells whose center-surround receptive fields are approximately circularly symmetric. The logic of this test is simple. A white-black edge is positioned on the center of the receptive field and then flashed on and off. If the cell sums its inputs in a linear fashion, then the response of the cell should be unaffected by the flashing edge because the increased luminance over half of the receptive field is canceled by an equivalent decrease in the luminance over the other half. The method is clever for the following reason: No response is evoked, and hence the linearity of spatial summation can be tested even if there are response nonlinearities. This method for testing the linearity of spatial summation has been applied to simple cells, and the linear prediction holds to a first approximation (e.g., De Valois et al., 1982; Movshon et al., 1978).

Receptive field and spatial frequency tuning. It is possible to characterize the properties of a complex unknown system by measuring either the *impulse response* or the *frequency response*. If the system is linear, either set of measurements would provide a complete description of the system, and further, one would be able to predict the impulse response from the frequency response (and vice versa). Measurements of the spatial receptive field and the spatial frequency tuning are analogous to the impulse response and frequency response. Movshon et al. (1978) have demonstrated that it is possible to predict the shape of the spatial receptive field profile on the basis of the measured spatial frequency response function to a first approximation.

Spatiotemporal receptive field and motion. If the receptive field is measured as a function of both space and time using stationary flashed bars or spots, and if the cell behaves in a linear fashion, it is possible to use the resulting spatiotemporal receptive field to determine (1) whether the cell is direction selective, (2) the optimal direction of motion, and (3) the degree of direction selectivity.

It has been demonstrated that these linear expectations hold for simple cells to a first approximation (DeAngelis et al., 1993; McLean and Palmer, 1989).

SOME NONLINEAR PROPERTIES OF BOTH SIMPLE AND COMPLEX CELLS

Response refractory period. As the firing rate of a given neuron increases, the absolute and relative refractory periods will

produce response saturation that is solely determined by the magnitude of the firing rate, regardless of what particular stimulus produced the high rate of firing. The temporal dynamics for this nonlinearity are on the order of a few milliseconds or less. It is worth noting that from the perspective of neural performance there are potential costs and benefits associated with this nonlinearity. In particular, response saturation that is caused by the absolute or relative refractory period is deleterious on stimulus selectivity because it makes the neuron less selective at high firing rates. Interestingly, however, the regularization in the spike trains that occurs during this type of saturation has beneficial consequences for detection, discrimination, and identification performance because, for most cells, the regularization decreases the variance in the firing pattern relative to the mean (Geisler et al., 1991). One might speculate that these two factors could potentially offset each other to some extent.

Response rectification. Hubel and Wiesel (1962) were the first to observe the effects of rectification: they reported that many complex cells responded in an excitatory fashion to both white and black lines (or bars) in the same spatial location throughout all positions of the receptive field. Similarly, as illustrated in Figure 47.1A, when stimulated with a counterphase flickering sine wave grating pattern, excitatory responses are observed regardless of whether the luminance is increasing or decreasing over a particular spatial region (e.g., De Valois et al., 1982; Movshon et al., 1978). This type

FIGURE 47.1. Responses (poststimulus time histograms) of two monkey cells to a counterphase flickering sine wave grating pattern, to illustrate response rectification in complex cells (A) and simple cells (B). (Adapted from De Valois et al., 1982.)

of behavior can be described as full-wave rectification. When a sine wave is passed through a linear filter followed by full-wave rectification, the output is the absolute value of the input.

In comparison, as illustrated in Figure 47.1B, when simple cells are stimulated with a drifting or flickering sine wave grating, only half of the modulation appears in the response waveform (e.g., Albrecht and De Valois, 1981; Movshon et al., 1978). This type of nonlinear behavior can be described as half-wave rectification: when a linear filter, followed by half-wave rectification, is stimulated with a sine wave, the output does not contain any of the values of the sine wave that are below zero. As will be described below, rectification, in both simple and complex cells, appears to be fully operational within 200 msec, and thus it can exert its influence within the time frame of a single fixation.

Half-wave rectification could, in part, be a simple consequence of the fact that cortical cells tend to have little or no maintained spontaneous discharge; the net result can be thought of as a threshold nonlinearity. Although half-wave rectification forces a doubling of the number of elements that are required to transmit both the positive and the negative values, it does have beneficial consequences. First, it conserves metabolic energy within the cortex by reducing the number of action potentials produced, the amount of neurotransmitter substance released, and so forth. Second, it increases the stimulus-specific identification performance of a neuron: given that the cell produces no action potentials unless a very specific stimulus is present at a very specific location within the visual field, just a few action potentials can strongly constrain the most likely set of potential visual features at that location (Barlow et al., 1987; Geisler and Albrecht, 1995, 1997). Third, full-wave rectification can be useful for computing *motion energy* (Adelson and Bergen, 1985; Watson and Ahumada, 1985) and *texture energy* in the stimulus (Bergen, 1991).

Response expansion. Measurements of the responses as a function of luminance contrast using drifting gratings have shown that, in general, as the contrast increases from zero, the response increases in an accelerating fashion (e.g., Albrecht and Hamilton, 1982; Sclar et al., 1990). Figure 47.2 shows measurements of the contrast response function from a representative cell to illustrate the response expansion that can be seen at the lower values of contrast. The smooth curve shows the fit of a Naka-Rushton equation:

$$r_i(c) = \frac{c^n}{c^n + c_{50}^n}$$

where n is the response exponent, c_{50} is the half-saturation contrast, and c is luminance contrast. Many studies have shown that this function provides a good fit to the contrast response function of striate cortex neurons (e.g., Albrecht

FIGURE 47.2. Responses (mean firing rate) as a function of contrast for a representative neuron to illustrate the response expansion that can be seen in the contrast response function at lower contrasts, prior to the compression and saturation that are induced by the contrast-set gain control. (D. G. Albrecht and W. S. Geisler, unpublished observations.)

and Hamilton, 1982; Albrecht et al., 1984; DeAngelis et al., 1993; Geisler and Albrecht, 1997; McLean and Palmer, 1996; Sclar et al., 1990; Tolhurst and Heeger, 1997). The exponent of this equation can be used to quantify the response expansion. The average value in the primary visual cortex is approximately 2.5.

Note that in measurements of the contrast response function, the acceleration is most easy to visualize at the lower values of contrast (prior to any compression and saturation). However, it would be incorrect to conclude that the effects of the accelerating nonlinearity are expressed only at low contrasts. Indeed, there are many other types of experimental observations, which demonstrate that the response acceleration operates across the full range of contrast and response, even after the response is fully saturated. For example, as noted above, the responses of simple cells as a function of spatial phase are approximately sinusoidal, but not exactly. Specifically, the responses as a function of spatial position appear more narrow and peaked than a sine wave across the full range of contrasts, even contrasts that evoke fully saturated responses. A linear filter that is followed by an accelerating nonlinearity produces exactly this sort of behavior. Interestingly, if the value of the expansive exponent, determined from the measured contrast response function for a given cell, is taken into consideration (i.e., by applying the acceleration to a sinusoidal function), the predicted responses provide a reasonably good fit to the measured responses of that cell.

There are other observations that cannot be predicted by a linear filter alone, but can be accounted for reasonably well if a linear filter is followed by an accelerating nonlinearity. Several of these observations are listed below. In each case, the accelerating nonlinearity diminishes the discrepancy between the linear prediction and the measured properties.

- The measured spatial frequency selectivity is narrower than expected, based on the measured receptive field (e.g., De Valois et al., 1985; Tadmor and Tolhurst, 1989).
- The measured direction selectivity is greater than expected, based on the responses as a function of spatial phase (Albrecht and Geisler, 1991; Murthy et al., 1998; Reid et al., 1991; Tolhurst and Dean, 1991).
- The measured direction selectivity is greater than expected, based on the spatiotemporal receptive field (DeAngelis et al., 1993; McLean and Palmer, 1994).
- The measured orientation selectivity is greater than expected, based on the measured receptive field (Gardner et al., 1999).
- Vernier acuity is greater than expected, based on measurements of length summation (Swindale and Cynader, 1989).
- Direction selectivity is greater when action potentials are measured and compared to intracellular synaptic potentials (Jagadeesh et al., 1997).

Response saturation. Measurements of the contrast response function have shown that cortical neurons generally have a limited dynamic response range followed by response saturation. Figure 47.3 plots the responses as a function of contrast to illustrate response saturation. Measurements illustrated below (Figs. 47.7 to 47.10) have demonstrated that the saturation can occur well within the time frame of a single fixation. In a later section (“Contrast Response Nonlinearities”) we will consider the potential effects of saturation on stimulus selectivity.

Contrast-set gain control. As shown in Figure 47.3, the responses of cortical cells saturate as the contrast increases, oftentimes at very low contrasts. This saturation could be determined by either (1) the magnitude of the response or (2) the magnitude of the contrast. Measurements performed over the past several decades have shown that this saturation is only one manifestation of a scaling of the response based on the magnitude of the contrast: a contrast-set gain control. Recent measurements (e.g., the section “Contrast Response Nonlinearities”) have shown that this nonlinearity is operational well within the time frame of a single fixation. Interestingly, this contrast-set gain control affords the maintenance of stimulus selectivity and high differential sensitivity along many dimensions; however, this beneficial consequence comes at the expense of differential sensitivity along the dimension of contrast.

Consider the effect of response-set saturation determined by the absolute and relative refractory periods: in this case, the saturation would diminish stimulus selectivity because at contrasts that produce response saturation, optimal and nonoptimal stimuli could produce equivalent responses. However, measurements of the contrast response function

FIGURE 47.3. Responses (mean firing rate) as a function of contrast for a representative neuron recorded from the monkey cortex to illustrate response saturation. (D. G. Albrecht and W. S. Geisler, unpublished observations.)

FIGURE 47.4. Contrast response functions measured at five different spatial frequencies to illustrate contrast-set gain control. The smooth curves through the measured responses show the fit of a single, scaled Naka-Rushton equation (with the same half-saturation contrast and the same expansive exponent). The fact that the shape of the contrast response function remains invariant with spatial frequency indicates that the scaling (including the saturation) is determined by the magnitude of the contrast and not the magnitude of the response. (D. G. Albrecht and W. S. Geisler, unpublished observations.)

using optimal and nonoptimal stimuli have shown that the saturation is not determined by the magnitude of the response (e.g., Fig 47.4); instead, the saturation is determined by the magnitude of the contrast (Albrecht and Hamilton, 1982; Sclar and Freeman, 1982; for a review see Carandini et al., 1999; Geisler and Albrecht, 2000). Further, the saturation is just one manifestation of an overall scaling of the entire contrast response function by the magnitude of the contrast.

Latency shift. As contrast increases and the response magnitude increases, there is a decrease in the latency of the response. This latency shift could be determined by either

(1) the magnitude of the response or (2) the magnitude of the contrast. Measurements have demonstrated that the shift is determined by the contrast, and not the response (Albrecht, 1995; Carandini and Heeger, 1994; Carandini et al., 1997; Dean and Tolhurst, 1986; Gawne et al., 1996; Reich et al., 2001). Figure 47.5 shows the shift for a representative cell at an optimal and a nonoptimal spatial frequency. The magnitude of the response to the optimal stimulus was approximately three times the magnitude of the response to the nonoptimal stimulus. Therefore, if the latency was determined by the magnitude of the response, then the latency shift should be greater for the optimal stimulus. However, as can be seen, the shift appears to be equivalent for both the optimal and the nonoptimal stimulus.

Contrast adaptation. When a V1 neuron is presented with a high-contrast grating for an extended period of time (e.g., 30 seconds), the response magnitude decreases, as illustrated in Figure 47.6 (Albrecht et al., 1984; McLean and Palmer, 1996; Movshon and Lennie, 1979; Saul and Cynader, 1989). The temporal dynamics of this nonlinearity are too slow to have an influence on stimulus selectivity within a single fix-

FIGURE 47.5. Response amplitude (*A*) and response latency (*B*) plotted as a function of contrast, to illustrate that the latency shift is determined by the magnitude of the contrast and not the magnitude of the response. (D. G. Albrecht and W. S. Geisler, unpublished observations.)

ation, based on the level of stimulus contrast within that single fixation. To the extent that there is some degree of contrast adaptation during a single fixation, this adaptation has been induced over the course of many fixations.

Other types of nonlinear behaviors

- Nonlinear spatial summation (Movshon et al., 1978)
- Spatial frequency inhibition (De Valois and Tootell, 1983)
- Surround effects, outside the classic receptive field (Cavanaugh et al., 2002a, 2002b; De Valois et al., 1985)
- Non-Fourier envelope responses (Zhou and Baker, 1994)
- Supersaturation (Bonds, 1991; Li and Creutzfeldt, 1984)
- Cross-orientation inhibition (Bonds, 1989)
- Nonspecific suppression (e.g., Carandini et al., 1997; DeAngelis et al., 1992; Nelson, 1991).

Temporal dynamics

It is worthwhile to consider the temporal dynamics of the various nonlinear properties, described above, within the context of the potential effects upon stimulus selectivity and neural performance during natural viewing. For example, if the onset of a specific nonlinear mechanism is slow relative to the duration of a single fixation, then it will not affect the selectivity and neural performance within a single fixation based on the spatiotemporal contrast within that fixation.

RAPID AND SLOW NONLINEARITIES It is clear that some of the nonlinearities operate rapidly enough to exert their influence on stimulus selectivity and performance based on the response to a stimulus during a single fixation. It is equally

FIGURE 47.6. Responses (mean firing rate) of a cortical cell to a high-contrast spatial frequency grating drifting over the course of 30 sec, to illustrate contrast adaptation. (Adapted from Albrecht et al., 1984.)

clear that other nonlinearities could not have a significant influence on the selectivity and performance, based on the stimulus within a single fixation, because the onset occurs over the course of many seconds. Consider the temporal dynamics of the absolute refractory period, half-wave rectification, the latency shift, and contrast adaptation.

- *Response refractory period:* Any refractory effects on selectivity and performance would surely be fully expressed within the time frame of a single fixation, given that they would operate on the order of a few milliseconds.

- *Response rectification:* To the extent that rectification is based on the transduction from the voltage within the neuron to the production of action potentials, any rectification effects would also be fully expressed within a single fixation.

- *Latency shift:* The average value of the contrast-induced latency shift is approximately 45 msec (Albrecht, 1995; Carandini and Heeger, 1994; Carandini et al., 1997; Dean and Tolhurst, 1986). Therefore, the effects of the latency shift can be expressed within the time frame of a single fixation, and the shift will be based on the contrast within that fixation.

- *Contrast adaptation:* It takes approximately 15 seconds for contrast adaptation to achieve two-thirds of its full strength (e.g., Albrecht et al., 1984). Therefore, the effects of contrast adaptation cannot be expressed within the time frame of a single fixation.

CONTRAST RESPONSE NONLINEARITIES Most of the nonlinear properties described above can be seen in the steady-state measurements of the contrast response function. However, the steady-state measurements are not well suited for analysis of the temporal dynamics that occur on the time frame of a single fixation. As described in the preceding section “Temporal Dynamics, Stimulus Selectivity, Neural Performance,” the responses to transient stationary gratings are useful for examining the temporal dynamics of linear and nonlinear properties. Recently, several different laboratories have been measuring the responses to brief stimuli and analyzing the time course of some of the fundamental properties (e.g., Albrecht et al., 2002; Frazor et al., 1997; Gillespie et al., 2001; Muller et al., 2001; Ringach et al., 1997).

In this section we show the responses as a function of contrast when the stimulus is a stationary grating, presented for a brief interval (200 msec), in order to illustrate how the contrast response function develops over the course of the first 200 msec after stimulus onset. Further, we consider some of the general questions posed in the Introduction, within the context of this specific set of transient stationary measurements. For example, one can ask: How long does it take for the two nonlinearities, response expansion and contrast-set gain control, to build up? If the expansion and

gain control take more than a few hundred milliseconds, they will have little or no influence on the responses during a single fixation, based on the level of contrast within that fixation. Therefore, these two nonlinearities will have little or no influence on stimulus selectivity during a single fixation.

Poststimulus time histogram as a function of contrast. Figure 47.7 shows the responses of a neuron recorded from within the monkey visual cortex to stationary gratings that were presented for a 200 msec interval at 10 different levels of contrast. Each set of data points plots the responses as a function of time, every 4 msec (i.e., the poststimulus time histogram), for 10 different levels of contrast (from 0% to 90% in linear increments). The smooth curves through the data points plot the average poststimulus time histogram that has been scaled for the amplitude of the response at a given level of contrast and shifted for the latency of the response at a given level of contrast. For ease of viewing the rapid variations across time and contrast, only 100 msec of the responses are plotted and the contrast-induced latency shift has been removed, such that the responses at each level of contrast are optimally aligned (i.e., they begin at the same time, peak at the same time, and so forth). There are several trends that are easy to see when the responses are plotted in this fashion:

- The magnitude of the response increases rapidly from the base rate to the maximum firing rate in approximately 20 msec and then declines to approximately one-third of the maximum firing rate within approximately 30 msec after the peak.
- The overall shape of the poststimulus time histogram appears to be relatively similar across the different levels of contrast.
- Simply scaling and shifting the average temporal response profile accounts for much of the variation in the data (over 95% on average across a population of cells).

FIGURE 47.7. Responses (poststimulus time histograms) of a neuron recorded from the monkey visual cortex as a function of time and contrast. (Adapted from Albrecht et al., 2002.)

- Although the stimulus remains on for 200msec, the response is considerably more transient.

It is important to note that there is a great deal of heterogeneity from cell to cell (Albrecht et al., 2002).

Responses as a function of contrast through time. Figure 47.8 plots the responses as a function of contrast for six different times during the course of the responses shown in Figure 47.7: 58 (◆), 62 (■), 70 (▲), 78 (●), 86 (▼), and 102msec (✱). The smooth curves through each set of data points plot the parameter-optimized fits of a single, scaled Naka-Rushton equation, with the same half-saturation contrast (29.6%) and the same expansive response exponent (3.1); the equation was simply scaled in amplitude for the different time intervals. There are several trends that are easy to see when the responses are plotted in this fashion:

- A single, scaled Naka-Rushton equation accounts for a large percentage of the variation in the data (over 95% across a population of cells).

- The expansive response exponent and the contrast-set gain control appear to be present in every time interval, even the first interval, which occurs only 8msec after the onset of the response.

- The saturation does not appear to be determined by the magnitude of the response given that the saturation occurs at the same contrast, independent of the magnitude of the response.

Responses during the first 16msec. Figure 47.9 plots the responses as a function of contrast during the first 16msec after the onset of the response to a transient stationary grating. Each set of data points plots the responses in sequential 2msec time bins after the onset of the response. The sequential order of the symbols is as follows: (■), (▲), (◆), and (●), with dashed lines, and (■), (▲), (◆), and (●),

FIGURE 47.8. Responses (from the poststimulus time histograms shown in Figure 47.7) as a function of contrast during the first 50msec after the onset of the response to a stationary grating. (Adapted from Albrecht et al., 2002.)

with solid lines. The curves through each set of points show the parameter-optimized fit of a single, scaled Naka-Rushton equation, with the same expansive response exponent (3.1) and half-saturation contrast (31.0). There are several trends that are easy to see in this plot:

- The responses are quite systematic and appear to be qualitatively similar across the different time intervals.

- A single, scaled Naka-Rushton equation accounts for a large percentage of the variation in the responses across contrast and through time (over 95%); this demonstrates quantitatively that the shape of the contrast response function is relatively invariant through time.

- The two important nonlinearities (expansive response exponent and contrast-set gain control) appear to be fully operational at the onset of the response (well within 10msec after the onset of the response).

Responses to optimal and nonoptimal stimuli during the first 20msec. Figure 47.10 plots the responses as a function of contrast

FIGURE 47.9. Responses (mean firing rate) as a function of contrast during the first 16msec after the onset of the response to a stationary grating. (Adapted from Albrecht et al., 2002.)

FIGURE 47.10. Responses (mean firing rate) as a function of contrast during the first 20msec of the response for an optimal (▲) and a nonoptimal (●) spatial phase. (Adapted from Albrecht et al., 2002.)

during the first 20 msec after the onset of the response for an optimal and a nonoptimal spatial position. The smooth curves through the data points plot the fit of a single Naka-Rushton equation that is simply scaled for each spatial position (i.e., the same exponent and half-saturation contrast). The single, scaled equation indicates that the scaling is determined by the magnitude of the contrast and not the magnitude of the response.

Response expansion and contrast-set gain control. In summary, using transient stationary gratings, it is possible to track the temporal dynamics of various linear and nonlinear properties to assess whether these properties could, or could not, play a role in shaping stimulus selectivity and performance on the time frame of single fixations during natural viewing. Based on the measurements illustrated in Figures 47.7 to 47.10, it appears as though the two nonlinearities revealed within the measurements of the contrast response function operate rapidly enough to have a significant impact on stimulus selectivity and neural performance. The functional implications of these virtually instantaneous nonlinearities are discussed in greater detail below.

TEMPORAL NONLINEARITIES The temporal properties of V1 neurons have been measured using drifting gratings as well as stationary gratings; in addition, the stimuli have been presented for relatively prolonged durations (several seconds, to approximate a steady-state condition) as well as for relatively brief durations (to approximate natural viewing more closely). The results of these different types of measurements do not always conform to what would be expected within the framework of a linear system. Further, these discrepancies are not easily explained, even when the other known nonlinearities are taken into consideration.

Steady-state stimuli versus impulsive stimuli. Consider several discrepancies between the properties that are measured using drifting steady-state stimuli as opposed to transient stationary stimuli:

- The responses to transient stationary stimuli decay more rapidly than expected from the steady-state temporal frequency transfer function (Muller et al., 2001; Tolhurst et al., 1980).
- The steady-state temporal frequency tuning changes substantially as contrast increases (e.g., Albrecht, 1995; Hawken et al., 1992; Holub and Morton-Gibson, 1981), whereas the temporal response profile for transient stationary gratings is relatively invariant as contrast increases (Albrecht et al., 2002).
- Under steady-state conditions, the variability of cortical neurons is approximately proportional to the mean firing rate (e.g., Geisler and Albrecht, 1997; Softky and Koch, 1993; Tolhurst et al., 1983), whereas this relationship does

not hold for the initial transient response to stationary gratings (Muller et al., 2001).

Transient stationary stimuli versus transient drifting stimuli. There are several discrepancies between the responses measured for transient drifting stimuli versus transient stationary stimuli (Albrecht et al., 2002; Frazor et al., 1997; Muller et al., 2001):

- Responses to stationary gratings are more transient than responses to drifting gratings.
- Both detectability and discriminability are better for drifting gratings than for stationary gratings.
- Transient stationary gratings generally produce large off-responses, whereas transient drifting gratings generally do not.
- Transient stationary gratings often evoke complex secondary oscillations, whereas transient drifting gratings generally do not.

SELECTIVITY ALONG OTHER DIMENSIONS Figures 47.7 to 47.10 indicate that the properties of the contrast response function are fully established at the very onset of the response and remain relatively invariant throughout the entire time course of the response, during an interval comparable to natural fixation (i.e., a 200 msec interval). These findings lead one to ask whether the response properties along other stimulus dimensions are similar. For example, is the stimulus selectivity along other stimulus dimensions fully established at the onset of the response? Similarly, is the stimulus selectivity along other stimulus dimensions relatively invariant throughout the entire time course of the response during an interval comparable to natural fixation?

With these questions in mind, it is important to note that several different lines of evidence appear to indicate that this type of behavior (i.e., rapid development and invariance through time) may not generalize to other stimulus dimensions. However, it is equally important to note that this is an emerging line of research and that the results across laboratories are not yet entirely reconcilable. In brief, it appears as though some important aspects of stimulus selectivity develop over the course of the first 50 msec after the onset of the response.

Spatial frequency and orientation selectivity measured with a reverse correlation procedure. Ringach et al. (1997) have measured the temporal dynamics of orientation tuning using a new *reverse correlation* procedure (where gratings are presented for very brief intervals: 20 msec). Their measurements indicate that orientation tuning changes through time for some V1 neurons: specifically, the preferred orientation changes and the selectivity increases (however, see Gillespie et al., 2001; Mazer et al., 2002; Muller et al., 2001).

Bredfeldt and Ringach (2002) used a similar procedure to measure the temporal dynamics of spatial frequency selectivity. Their measurements indicate that spatial frequency selectivity also changes through time. Specifically, the measurements indicate that (1) the preferred spatial frequency shifts from low frequencies to high frequencies and (2) the selectivity increases (however, see Albrecht et al., submitted).

Spatial frequency and orientation selectivity measured in an awake, behaving monkey. Mazer et al. (2002) have measured the responses of V1 neurons using the awake, behaving preparation, in which a monkey is trained to fixate while visual stimuli are presented (for a duration longer than 20 msec). Unlike the measurements of Ringach et al. (1997), their measurements indicate that orientation selectivity is relatively invariant through time. However, similar to Bredfeldt and Ringach (2002), the measurements of Mazer et al. indicate that the preferred spatial frequency increases through time.

Spatial frequency selectivity measured with transient stationary stimuli. We have measured spatial frequency selectivity using stationary gratings that are turned on for 200 msec and off for 300 msec (Albrecht et al., submitted). In agreement with Bredfeldt and Ringach (2002) and Mazer et al. (2002), we find that spatial frequency selectivity changes through time. Specifically, our measurements indicate that the latency of the response increases as spatial frequency increases. This latency shift causes the peak of the spatial frequency response function to shift through time, and it also causes the spatial frequency selectivity to decrease as the responses are integrated over the course of 200 msec: the spatial frequency peak and the bandwidth change as the responses are integrated over the first 50 msec, and then they both become relatively stable and remain invariant thereafter.

Spatial frequency, spatial phase, and direction selectivity during natural fixation. Given that all three laboratories discussed in the preceding sections, using very different measurement techniques, have reported that spatial frequency tuning changes through the course of an interval comparable to natural fixation, it is important to consider the functional consequences of these changes. Although these changes may help us understand the underlying structural components that produce high degrees of stimulus selectivity, it seems unlikely that these changes will have important functional consequences for the discrimination and identification performance, if one assumes that subsequent neurons integrate the responses over more than just a few milliseconds. Specifically, if the response to a given stimulus is integrated through time following the onset of the response, the stimulus selectivity should become relatively stable within 50 msec.

In addition, it is important to keep in mind the effect of the integration interval on the signal-to-noise ratio when

considering neural discrimination and identification performance. We know from signal detection theory that performance should improve as the integration interval increases. In the case of V1 neurons, as the integration interval increases, the number of action potentials increases, and because the variance is proportional to the mean of the response, the longer the integration interval the larger the signal-to-noise ratio. We have found that, on average, it takes approximately 50 msec to reach 50% of the total number of action potentials when a stationary grating is presented for 200 msec (Albrecht et al., 2002, submitted). Thus, for example, integrating over the entire 200 msec would, on average, double the number of action potentials, which would increase the signal-to-noise ratio by approximately 50% (assuming a variance proportionality constant of 1.3).

Even if stimulus selectivity is dynamic over the first 50 msec of the response, measurements indicate that if the integration interval is extended to 200 msec (comparable to natural fixation), the selectivity for many stimulus dimensions is stable and essentially equivalent to the selectivity that is measured with steady-state stimuli (Frazor, 2002; Frazor et al., 1997). This observation holds not only for spatial frequency, but also for direction selectivity and spatial position selectivity. Figure 47.11 illustrates the responses as a function of spatial frequency and the direction of stimulus

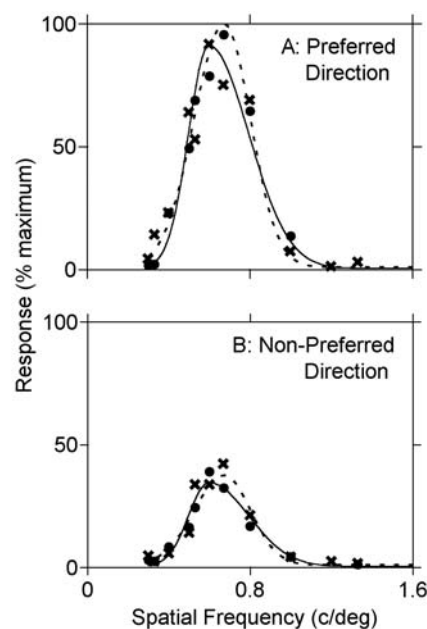

FIGURE 47.11. Responses (mean firing rate per 200 msec) as a function of spatial frequency for the preferred direction of motion (A) and the nonpreferred direction of motion (B). The responses and fitted curve for steady-state stimuli are shown with the \times and solid curve; the responses and fitted curve for transient stimuli are shown with the \bullet and dashed curve. (Adapted from Frazor, 2002.)

FIGURE 47.12. Responses (mean firing rate per 200msec) as a function of spatial position. The responses and fitted curve for steady-state stimuli are shown with the \times and solid curve; the responses and fitted curve for transient stimuli are shown with the \bullet and dashed curve. (Adapted from Frazor, 2002.)

motion for transient and steady-state methods of stimulus presentation; Figure 47.12 illustrates the responses of the selectivity for spatial position. In sum, the stimulus selectivity for these three dimensions for integration over 200msec is very similar to the stimulus selectivity that has been measured using steady-state stimuli.

Conclusion

MODELS AT DIFFERENT LEVELS OF ANALYSIS There are many different laboratories measuring the properties of visual cortex neurons and developing models at many different levels of analysis. In preparation for writing this chapter, we searched the literature to learn more about the different types of models that have been proposed for neurons in the visual cortex. We tried to be as inclusive as possible. As one might expect, there are hundreds of unique types of models that have been proposed over the past several decades to account for a variety of different linear and nonlinear properties of visual cortex neurons, at many different levels of analysis. In order to organize this vast literature (which cannot be reviewed here), we have found that it is useful to distinguish three different levels of models: *descriptive models*, *functional models*, and *structural models*.

Descriptive models. Consider performing systematic measurements of the responses across a large population of visual cortex neurons as a function of some important stimulus dimension; say, for example, the dimension of contrast. At this stage of the investigation (i.e., after performing the measurements), it is useful to have a *descriptive model*. The goal of a *descriptive model* is to summarize and interpolate the measured responses using an atheoretical mathematical equation. For example, the Naka-Rushton equation provides a reasonably accurate description of the contrast response function for the overwhelming majority of visual cortex neurons using only three free parameters.

If the *descriptive model* provides an accurate description of the trends in the data across the entire sample of neurons, it becomes a very powerful tool that can be used in many different applications. To begin with, the function can be used to describe important characteristics of the responses across the entire sample of cells in a unified and quantitative fashion. Oftentimes, the parameters of the equation directly quantify the property of interest (e.g., the exponent of the Naka-Rushton equation). Even if the parameters themselves are not useful, it is easy to use the equation to solve for the value of interest, as long as the equation provides an accurate description.

In addition to providing this initial summary of the data, a *descriptive model* can be used in many other applications. Consider the following applications of the Naka-Rushton equation:

- To test quantitatively the hypothesis that response saturation is determined by the magnitude of the response or the magnitude of the contrast (see above).
- To test quantitatively the hypothesis that the contrast-set gain control and the expansive response exponent are present virtually instantaneously (see above).
- To test quantitatively the hypothesis that the latency shift is determined by the magnitude of the contrast or the magnitude of the response (see above).
- To assess the degree to which the variation in the measured responses is more likely a result of systematic variation, as opposed to the inherent stochastic variation of cortical neurons, by performing randomization tests of specific null hypotheses (e.g., Albrecht et al., 2002).
- As one final example, the equation has been effectively incorporated into many different higher-level models, at both the functional level and the structural level (e.g., Albrecht and Geisler, 1991; Carandini et al., 1999; Heeger, 1991, 1992a, 1992b).

Several examples of *descriptive models* are given in Albrecht et al. (2002).

Functional models. Upon completing systematic measurements and the quantitative description and summary using a *descriptive model* (or models), it then becomes useful, at this stage of the investigation, to consider analyzing the systematic trends within a functional context and to develop a *functional model*. The goal of a *functional model* is to characterize the response properties within the context of a visual information processing algorithm.

Consider, for example, systematic measurements of the responses of a simple cell as a function of contrast (in both directions of motion) and spatial position. The responses can be summarized using the Naka-Rushton equation. Then, as trends are observed, analyzed, and quantified, one can begin to speculate about possible functions that are revealed within

a given set of measurements. Given the measurements described in this example, several important trends reveal possible functions.

- The contrast response function reveals an accelerating nonlinearity.
- The contrast response function reveals a saturating nonlinearity.
- The responses scale and saturate at the same contrasts for both optimal and nonoptimal spatial positions, even though the response magnitude is very different for these two positions.
- The cell is direction selective.
- The responses as a function of contrast saturate at the same contrast for the two directions of motion, even though the response amplitudes are very different for the optimal versus nonoptimal direction of motion.
- The degree of direction selectivity is related to the responses as a function of spatial phase, but the selectivity is much larger than would be expected.
- The phase response function is approximately sinusoidal.
- There is a null phase position even though the cell is direction selective.
- The phase response function is more narrow and peaked than a sine wave.

Within the context of the *descriptive model*, these are all separate facts that are quantified with the Naka-Rushton equation. However, these apparently disparate facts can be unified within the context of a relatively simple *functional model*: a linear spatial filter, whose gain is set by the overall magnitude of the contrast, followed by an expansive response exponent (e.g., Albrecht and Geisler, 1991; Carandini and Heeger, 1994; Ferster, 1994; Heeger, 1991, 1992a, 1992b; for reviews see Carandini et al., 1999; Geisler and Albrecht, 2000). The linear filter accounts for (1) the sinusoidal responses as a function of spatial position, (2) the direction selectivity, and (3) the relationship between the two. The contrast-set gain control accounts for the saturation at the same contrast, independent of response amplitude. The expansive exponent accounts for (1) the mismatch between the direction selectivity and the responses as a function of spatial phase as well as (2) the narrow and peaked pattern. Several examples of *functional models* are given in Albrecht et al. (2002).

Structural models. Upon completing systematic measurements and analyzing the systematic trends within a functional context, it is then useful to develop a *structural model*. The goal of a *structural model* is to characterize the biophysical and biochemical neural mechanisms that are responsible for some specific property. Consider, for example, two of the nonlinear properties that have been identified in many

different laboratories in many different stimulus situations: contrast-set gain control and the expansive response exponent. Many different laboratories are currently working to understand these nonlinearities within the context of various structural models.

Structural models for response expansion and contrast-set gain control include: expansive voltage-spike transduction, noisy membrane potential, recurrent excitation, intracortical inhibition, correlation-based inhibition, synaptic depression, nonspecific suppression, shunting inhibition, tonic hyperpolarization, strong push-pull inhibition, and changes in membrane conductance. Some models rely on feed-forward inputs, others rely on feedback inputs, and still others rely on lateral inputs through local connections and through the far-reaching interconnectivity among cortical neurons. For recent discussions and reviews of this literature, and related issues, see the sources listed in Table 47.1.

CONTRAST-SET GAIN CONTROL

Gain control, amplifiers, light adaptation. The gain control that occurs within electrical systems in general, and electronic amplifiers in particular, has provided a useful analogy for the type of gain control that occurs at various levels of the visual system. Consider, for example, the ammeter analogy discussed by Craik (1938), or consider a simple amplifier. The purpose of a traditional amplifier is to take a small input voltage and make it larger by multiplying the input by a con-

stant factor. The *gain* of an amplifier refers to this multiplicative factor: it relates the magnitude of the output to the magnitude of the input. To optimize the limited dynamic response range of the amplifier, across a wide range of input values (while attempting to minimize distortions), *gain control* systems can be introduced to adjust the magnitude of the multiplicative factor based on the magnitude of the input, the output, or both: if the input values are small, the gain is adjusted to be large, whereas if the input values are large, the gain is adjusted to be small.

The amplifier analogy and terminology have been applied to the light adaptation characteristics of the visual system (e.g., Hood, 1998; Shapley and Enroth-Cugell, 1984). Conceptually, within this analogy, the gain of the system is adjusted based on the prevailing, ambient range of luminance intensities available within the visual stimulus at any point in time. The gain control in this case shifts the sensitivity to light, based on the average amount of light available. The goal is to use effectively the limited response range so as to optimize high differential sensitivity (to luminance increments and decrements) and other such performance characteristics. The amplifier analogy and terminology have also been applied to the contrast response characteristics of visual cortex neurons.

Cortical contrast-set gain control. It seems reasonable to take the traditional notions of gain control that have been applied to light adaptation and brightness discrimination and apply the same basic concepts to the virtually instantaneous type of contrast-set gain control that occurs within the visual cortex. However, one must apply the analogy carefully because the direct application to the dimension of contrast and contrast discrimination performance is not particularly useful. It may lead one to think that the contrast-set gain control has the beneficial consequence of improving contrast discrimination. It does not. In fact, it is deleterious in the sense that the responses as a function of contrast saturate at low contrasts (due to the contrast-set gain control).

In the light adaptation analogy, one might suppose that the gain control in the cortex is designed to position the limited dynamic response range of V1 neurons around the ambient level of contrast for optimal contrast discrimination performance. If one attempts to apply the analogy, as formulated above, one is immediately confronted with a number of properties of the gain control that are to some extent counterintuitive. Specifically, the gain control produces response saturation that is virtually instantaneous, oftentimes at very low levels of contrast, for both optimal and nonoptimal stimuli, even though the latter do not produce large amplitude responses. These properties have a deleterious effect on contrast discrimination: obviously, when the cell saturates, contrast discrimination is eliminated.

Gain control in a multidimensional feature space. As emphasized many times within this chapter, one hallmark of cortical neurons is stimulus selectivity. To characterize this selectivity, visual neuroscientists measure the responses along many different stimulus dimensions. Although these measurements are fundamental in our analysis of V1 neurons, it is important not to lose sight of the fact that the stimulus selectivity of any given neuron reflects many stimulus dimensions simultaneously. We study the selectivity within the multidimensional feature space, varying each stimulus dimension individually, but the visual feature itself is the simultaneous combination along all of the dimensions.

The traditional notions of gain control can be applied to cortical contrast-set gain control; however, it is necessary to consider more than the single stimulus dimension of contrast. Specifically, one must consider all of the *other* stimulus dimensions. Within this framework, the gain control does improve discrimination performance, but not along the dimension of contrast. Instead, the gain control improves performance within a multidimensional feature space. The contrast gain of the cell's dynamic response range is set such that the optimal stimulus (within this feature space) will always produce the maximum response, and the nonoptimal stimuli will simply scale down accordingly, independent of the overall ambient prevailing level of contrast. In so doing, the discrimination performance is optimized along all of the stimulus dimensions within this feature space, with the exception of contrast, and deviations from the optimum will produce maximum discriminability. Further, when the cell produces saturated responses, it identifies the presence of a specific feature with a high degree of certainty.

In sum, for the traditional analogy of gain control to be useful, the dimension of luminance needs to be compared to a multidimensional feature space: the contrast-set gain control scales the responses, based on the average prevailing contrast, such that differential sensitivity is optimized within the multidimensional feature space.

48 Binocular Interaction in the Visual Cortex

RALPH D. FREEMAN

THERE ARE TWO MAJOR physiological transformations that occur in central pathways in the primary visual cortex. The first is that the receptive field (RF) structure, which consists of concentric center-surround patterns for ganglion and lateral geniculate nucleus (LGN) cells, becomes elongated, rectangular, and orientation specific in striate cortex. The second transformation is that input from left and right eyes, which is essentially segregated in peripheral pathways, becomes integrated at the level of V1, which is therefore the first stage of binocular visual processing.

This review provides selected coverage of the physiological elements of binocular vision. An attempt is made to identify central areas that have been addressed and to consider certain problems with some experimental approaches. For the most part, theoretical investigations are not covered. The most functionally relevant application of binocular function, that is, stereoscopic depth discrimination, is not dealt with here except in a cursory fashion. These topics are covered in other chapters in this volume (e.g., Chapters 49, 87, and 88).

Finally, it should be stated at the outset that this review is heavily influenced by the work on this subject that has been conducted in my laboratory. No attempt is made to give equal weight to all reports in the literature. An attempt is made to discuss work that is directly relevant to the topics that are covered here.

Background

The mixing of inputs from left and right eyes in the visual cortex is not complete, but it does provide the basis for the physiological fusion of monocular images. There are minor species differences in this regard since the population of cells in input layers of the primate is more monocular than that of the cat (Hubel and Wiesel, 1962, 1968). Monocular pathways clearly support a two-dimensional analysis of the visual world. The image from each eye projects to regions that produce two-dimensional maps of object space. These maps are interpreted in monocular pathways. Because the two eyes have slightly different views of visual space, their respective images are displaced on the retinas. This retinal disparity is the necessary and sufficient condition for stereoscopic depth discrimination. It allows the two-dimensional projection of visual space to become a three-dimensional percept.

Disparity-based stereopsis was demonstrated in early psychophysical studies (Wheatstone, 1838).

Details of the anatomical pathways that subserve binocular vision are covered in other chapters (see Chapter 37). The primary relevant physiological finding is that neurons in the striate cortex or V1 are responsive binocularly. The original demonstration of this, from studies of area 17 in the cat, was mainly by procedures in which tests were conducted alternately between left and right eyes. In other words, conclusions about binocular function were made from monocular tests. This is problematic because, as shown below, monocular tests can produce faulty assessments of the degree of binocularity of a cell. To be fair, the landmark study of binocular interaction in the cat (Hubel and Wiesel, 1962) included tests of both eyes simultaneously. It was also noted that some cells responded only when both eyes were activated simultaneously. However, subsequent to the early study, most experiments in which binocularity has been assessed have used only monocular tests (see below).

One other factor should be noted in connection with the physiological study of binocular vision. In the early investigations, the suggestion was made that binocular interaction in the visual cortex could be connected to the physiological basis of stereoscopic depth discrimination (Hubel and Wiesel, 1962). However, the way in which this might be accomplished was not specified. In subsequent investigations, direct attempts were made to identify neurons that responded to stimuli positioned at different depths. The factor referred to above is that essentially all the early work was conducted under the assumption that cortical neurons are depth detectors. This is, of course, a reasonable approach, and it follows the work of a long line of investigators who were interested in *trigger features* as they applied to a particular animal (for example, Lettvin et al., 1959). One limitation of this approach is that a given experiment and the main results are linked to a specific interpretation. In the case of *depth-detecting* neurons, it is possible that the disparity selectivity of cortical cells is a result of RF organization. There may be no direct linkage to a perceptual process. It is very important to establish this link, and recent work on alert, behaving monkeys enables a firm connection to be made between RF response characteristics and behavioral performance (Cumming and Parker, 2000; DeAngelis and Newsome, 1999).

It is possible to approach the physiological study of binocular vision without the assumption that neurons in the primary visual cortex are depth detectors. In this case, the question addressed is: how do binocular cells combine inputs from right and left eyes? The approaches used to answer this question are similar to those that have been undertaken for investigations of monocular pathways. In the most general sense, the purpose is to establish how a cell integrates light within its RF. This approach offers the potential of establishing the mechanisms of monocular and binocular processing in a unified manner.

Before describing the studies in which this approach has been applied, it is useful to summarize the classical work on the physiological basis of stereoscopic depth discrimination. The first direct study was performed in anesthetized paralyzed cats (Barlow et al., 1967). Neurons in area 17 were found to be selectively responsive to different retinal disparities corresponding to spatial depth ranges from near to far distances, as depicted in Figure 48.1. Preferences were found for a large range of both crossed and uncrossed disparities. However, the reported range of disparities was three times larger for horizontal compared to vertical disparities. This has a functional advantage because the horizontal displacement of the two eyes means that this orientation is required for stereopsis. Subsequent studies did not confirm this observation (Ferster, 1981; LeVay and Voigt, 1988; Nikara et al., 1968), but some hint of this asymmetry was found in other work (Joshua and Bishop, 1970; von der Heydt et al., 1978). By analysis of phase (shape) differences between the RFs of left and right eyes (to be described below), it has been shown that there are clear disparity-processing dissimilarities between horizontal and vertical orientations (DeAngelis et al., 1991).

Following the initial results of studies on disparity-sensitive cells in the cat's visual cortex, an attempt was made to replicate these findings in monkey striate cortex. The first

FIGURE 48.1. In this conventional view of disparity-selective neurons, the cat fixates a position on an arc tangent screen which traces the locus of contrast disparity. The data points represent cells tuned to relative retinal disparities corresponding to different depths in space.

result of this attempt was remarkable because the claim was made that there were no disparity-sensitive cells in V1 but there were in V2 (Hubel and Wiesel, 1970). This conclusion was wrong, of course, but it took studies in the awake, behaving monkey to sort out the issue. A series of experiments by Poggio and collaborators established conclusively that neurons in V1 and V2 are sensitive to relative changes in stereoscopic depth (Poggio and Talbot, 1981; Poggio and Fischer, 1977; Poggio et al., 1988).

The awake, behaving monkey setup is illustrated in Figure 48.2. An animal is trained to fixate a location on a screen that can be positioned at different depths. During fixation, individual cortical cells are recorded. In the initial study, four types of depth-sensitive neurons were identified: tuned excitatory, tuned inhibitory, near, and far cells. Response curves for these categories are shown in Figure 48.3. This scheme was modified subsequently (Poggio et al., 1988). However, it is reasonably clear from other work (LeVay and Voigt, 1988) that a four- or six- or n -category system is not adequate and not correct. The reasons for this inadequate classification system are explained in detail in a previous review (Freeman and Ohzawa, 1990).

In none of the early studies was an attempt made to develop a functional mechanism within which a disparity encoding and detecting system might fit. The problems with a disparity processing system based on four or six categories of cell types may be solved by the use of an encoding scheme that is scaled to the size or spatial frequency selectivity of cortical neurons. To do this, we need to analyze RF shape (phase) as well as relative position. In this way, we can determine if binocular disparity information is coded and represented in the visual cortex by phase-disparity selective neurons at different size or spatial frequency scales. The basis of this approach is detailed below.

FIGURE 48.2. An experimental arrangement is shown for behavioral and neurophysiological testing of a primate. The monkey views a fixation point on a stimulus display and, through a beam splitter, on a second screen. The stimulus display may be moved fore and aft to change the relative depth. RFs of cortical cells are projected onto the stimulus display. The monkey presses a key when the fixation spot is illuminated. Visual targets used to explore neural activity are projected to the monkey's eye via the beam splitter.

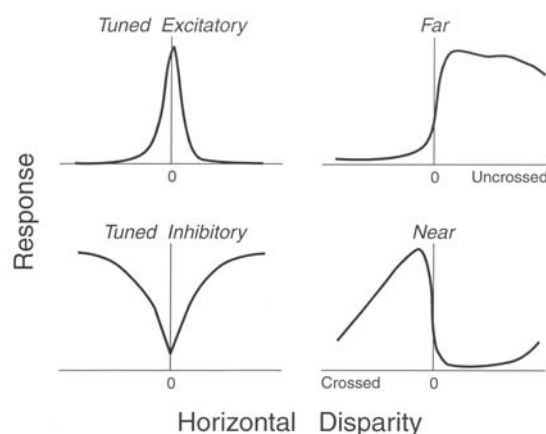

FIGURE 48.3. Four cortical cell types are illustrated according to their response patterns. Horizontal disparity is indicated on the abscissas, and response is represented on the ordinates. Crossed and uncrossed disparities are located to the left and right, respectively, of the zero position. Tuned excitatory and inhibitory cells respond or are suppressed, respectively, at zero disparity. Near and far cells respond to close or far distances, respectively.

Ocular dominance: the wrong way to assess binocularity

As mentioned above, the early studies of binocular interaction in the visual cortex resulted in a subjective ranking scale of ocular dominance (Hubel and Wiesel, 1962). This scale includes seven categories: groups 1 and 7 represent neurons that are entirely monocular, group 4 denotes equally balanced input from left and right eyes, and groups 2, 3, 5, and 6 indicate binocular cells with varying degrees of contralateral or ipsilateral dominance. In the original description of these categories, there is a footnote for groups 2 and 6 which states that for these cells, the non-dominant eye may be ineffective in activating the cell but it could influence the response to stimulation of the dominant eye (Hubel and Wiesel, 1962). No data were given to substantiate this statement, and no further mention is made of it in the original paper or in subsequent work.

In studies that followed, other investigators were apparently unaware of the footnote. An entire literature resulted in which binocular status was measured and assessed using monocular tests to derive ocular dominance histograms. Most of the experiments in the study of development and plasticity of vision use ocular dominance histograms, subjectively obtained, to draw conclusions concerning the effects of a given protocol. In the examples described below, it is shown that the reliance on subjective ocular dominance histograms can underestimate the degree of binocularity of a population of cells in the visual cortex. It seems unlikely that the conclusions of many studies in which this was the sole basis of assessment are incorrect. However, it is possible that for some investigations, especially those concerning the effects of monoc-

ular deprivation, there may have been more binocularity than was reported.

As noted above, estimation of this parameter is the primary measurement of a very large body of literature. In nearly every study, subjective measurements have been made of ocular dominance by using tests of response strength through each eye and then assigning an ocular dominance rating. This rating is then taken as a statement about the binocular status of the cell even though, in nearly every case, no binocular tests were performed. There are many studies on the development and plasticity of vision in which ocular dominance histograms, for different conditions of rearing, are derived for a sample of cells. Different protocols, mainly of a phenomenological nature, have been used to make inferences about mechanisms. In most of these studies, the shape of the ocular dominance histogram is the sole basis for conclusions about how a given rearing condition interferes with the development of normal binocular vision. Brief descriptions of these studies are presented below and in other reviews (e.g., Mitchell and Timney, 1984).

The main problem with this experimental process is that the method of estimating ocular dominance histograms is not entirely accurate. Specifically, it tends to make the cell under study appear to be more monocular than it actually is if tested binocularly. This is because of a threshold non-linearity in which a subthreshold input from an eye that appears to be silent can be expressed under binocular viewing and testing conditions. In other words, cells may appear to be monocular when each eye is tested individually, but they exhibit clear binocular interaction when tested dichoptically (Freeman and Ohzawa, 1988, 1992; Ohzawa et al., 1996). This interaction may be phase specific or it may be a general suppressive effect. In any case, these considerations make it clear that the use of subjective estimates of ocular dominance designations is not the correct way to determine binocular status. Instead, dichoptic tests should be run by which one may derive a binocular interaction index, such as that described below which specifies depth of modulation (Freeman and Ohzawa, 1992).

Binocular interaction measured by phase-shifted gratings

In a classical study of the retina, gratings with sinusoidal luminance profiles were used to determine spatial summation characteristics of RFs of ganglion cells (Enroth-Cugell and Robson, 1966). A number of similar investigations were then carried out at different levels of central and peripheral visual pathways. We used a related approach to study the binocular system and sought to determine the rules by which signals from left and right eyes are combined (Freeman and Robson, 1982; Ohzawa and Freeman, 1986a, 1986b). To do this, we used dichoptically presented, phased-varying gratings with sinusoidal luminance distributions. The stimuli are

depicted in Figure 48.4. In Figure 48.4A, a relative phase shift between two sinusoidal gratings is represented on the left. On the right, phase shifts in actual gratings are shown in a dichoptic presentation. In Figure 48.4B, RFs of simple cells are represented by Gabor functions. The abscissas for these curves denote retinal position, and the ordinate gives sensitivity to a luminance increment. In this case, negative positions of each curve represent OFF (dark-excitatory) subregions and positive positions denote ON (bright-excitatory) subregions. Dashed curves represent Gaussian envelopes of the idealized RFs. The curves give a full range of RF shape representations for phase shifts around the clock. Figure 48.4C depicts how relative dichoptic phase shifts appear to a viewer.

Before describing specific results, it is worthwhile to consider how signals from left and right eyes may be combined in the visual cortex. Inputs, which may be symmetrical, could be combined in a linear manner. This is represented in Figure 48.5A. Inclusion of a threshold mechanism, which follows binocular convergence, may be added to this rule of combination. In Figure 48.5B, multiplicative convergence is depicted. A good example of this is when a cortical cell is unresponsive to input through either eye but responds to stimulation of both eyes simultaneously (Hubel and Wiesel, 1962; Barlow et al., 1967). Figures 48.5C and 48.5D depict conditions in which there are symmetrical inputs that are modified by postsynaptic (C) or presynaptic (D) inhibition. For a great deal of the data that we and others have collected, results may be accounted for by a process of linear summation combined with a threshold mechanism. For other data, multiplicative binocular interaction is a major component both for simple and for complex cells (Anzai et al., 1999a, 1999b).

The unique characteristic of simple cells in the visual cortex is that they have discrete ON and OFF adjacent regions in their RFs. Therefore, dichoptic presentation of phase-varying gratings should result in regular increments and decrements of a neuron's response corresponding to the relative stimulation of ON and OFF areas of the RF. This is in fact what occurs for nearly all cells. Data from the detailed study of cortical cells, using this technique, are shown in Figures 48.7, 48.8, and 48.9. For comparison, results from tests of an LGN cell are shown first (Fig. 48.6).

To do these tests, qualitative estimates are made initially of the preferred stimulus parameters of each cell. For cortical

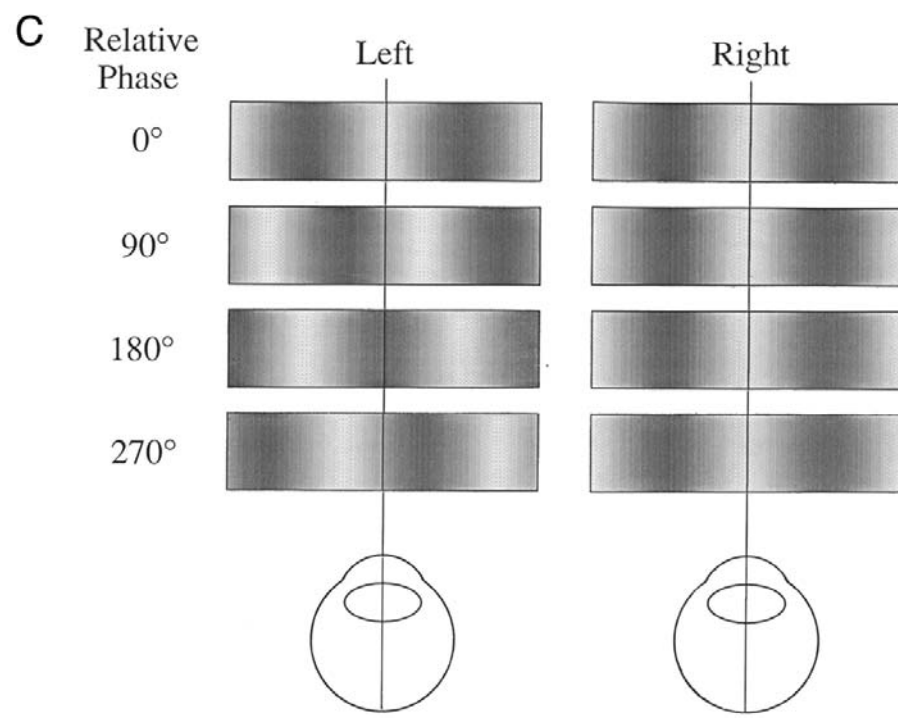

cells, this includes orientation and spatial frequency preferences. Since cortical cells are broadly tuned temporally, nearly all tests are run at 2 Hz. Contrast is arbitrarily set to elicit strong responses without causing excessive saturation. Generally, values of 50% are used. After each eye is tested monoptically, dichoptic presentations are made with relative interocular phase varied randomly, generally in 30-degree or 45-degree steps.

Responses from an LGN cell are illustrated in Figure 48.6. Results of monocular tests are shown in Figures 48.6A and 48.6B for orientation and spatial frequency, respectively. A typical pattern is seen, that is, responses are monocular (left eye driven in this case) and nonorientation specific. Clear spatial frequency selectivity is exhibited by the responsive eye. Phase-specific responses are shown in Figure 48.6C for randomly interleaved steps of 45 degrees. Monocular and blank (null) conditions are interleaved with the dichoptic tests. As expected, dichoptic tests elicit clearly modulated bursts corresponding to ON areas and silent sections in which ON and OFF regions counterbalance each other. The null condition shows a substantial level of spontaneous activity, and this is also observed in the monocular run of the nonresponsive right eye. Since binocular interaction at the level of the LGN is minimal, with the exception of a very mild suppressive influence from the nonresponsive eye, presumably mediated through intralaminar connections (Xue et al., 1987), dichoptic relative phase shifts are not expected to alter response levels. As seen in Figure 48.6D, there are minimal changes in response for the LGN cell illustrated. Response amplitudes shown in Figure 48.6D are obtained by harmonic analysis of each histogram in Figure 48.6C at the temporal frequency of the grating drift. The average spontaneous level is shown by the dashed line at the bottom of Figure 48.6D.

Data for a simple cell, in the same format as those for the LGN unit described above, are shown in Figure 48.7. Clear orientation and spatial frequency tuning functions are seen in Figure 48.7A and 48.7B, respectively, for monoptic runs. The PSTH histogram of Figure 48.7C shows a typical modulated discharge with bursts of firing at the first harmonic of the temporal frequency of the stimulus grating. Responses from right eye stimulation are stronger than those from the left eye. Note that at a relative interocular phase of 180 degrees, the neuron is silent. Phase positions on either side yield increased response levels. This is shown clearly in the harmonic analysis of Figure 48.7D. This

FIGURE 48.4. Phase shift grating conditions are illustrated. In *A*, a relative phase shift between an upper and a lower sinusoidal grating pair is depicted on the left. On the right, a fixed phase position is maintained for the right eye. For the left eye, the grating phase is varied. In *B*, various phase angles are indicated for Gabor functions that represent receptive field profiles for simple cells. The

abscissa for each curve gives retinal position, and the ordinate represents sensitivity. Dashed curves are Gaussian envelopes of the model receptive fields. In *C*, the appearance of phase-shifted, dichoptically viewed gratings is illustrated with fixed phase positions for the right eye.

FIGURE 48.5. Four schematic models are illustrated that might underlie the rules of combination of signals from left and right eyes. L and R represent left and right eyes, respectively. Inhibitory interneurons are labeled I.

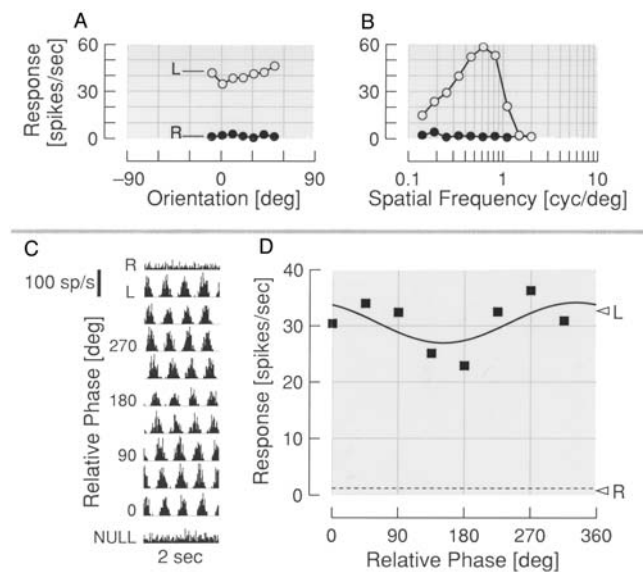

FIGURE 48.6. Responses are shown for an LGN neuron stimulated with drifting sinusoidal gratings. *A* and *B* represent orientation and spatial frequency tuning curves, respectively, for monocular tests. Dichoptic tests, run with phase-varying gratings, result in the PSTH data of *C*. The null condition is for a luminance screen with no pattern. Harmonic analysis is performed on the histograms of *C*, resulting in the function of *D*, in which responses are indicated for different relative phases.

phase-varying function is equivalent to a retinal disparity tuning curve.

An example of a typical complex cell response is represented in Figure 48.8. Once again there is clear, although relatively broad, tuning for orientation and spatial frequency

FIGURE 48.7. Responses are shown for monoptic and dichoptic tests of a cortical simple cell. The same format as that in Figure 48.7 is used.

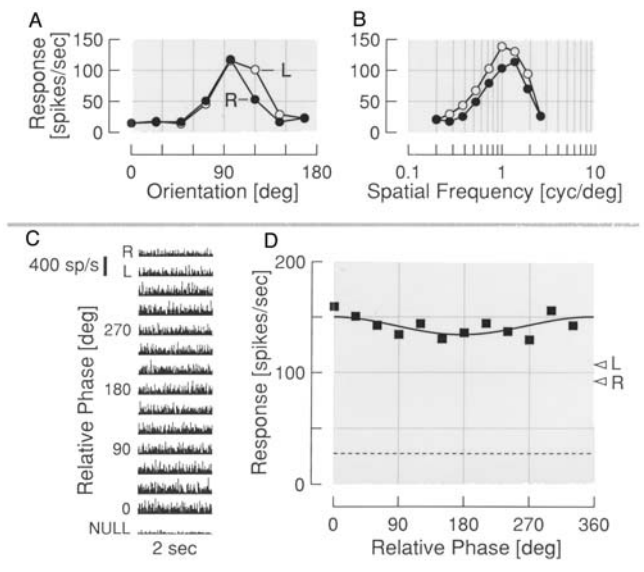

FIGURE 48.8. Responses are shown for monoptic and dichoptic tests of a cortical complex cell for which responses are phase insensitive. The same format as that in Figure 48.7 is used.

in the monoptic testing mode. The PSTH histograms shown in Figure 48.8C exhibit typical uniform discharge rates across the entire range of relative phase. As a result, the harmonic analysis yields a relatively flat response function, as presented in Figure 48.8D.

What is unexpected, however, is the other example of responses from a complex cell, as shown in Figure 48.9. As in the previous case, monoptic tuning functions for orientation and spatial frequency are clear and fairly broad. The PSTH histograms in Figure 48.9C exhibit nonmodulated

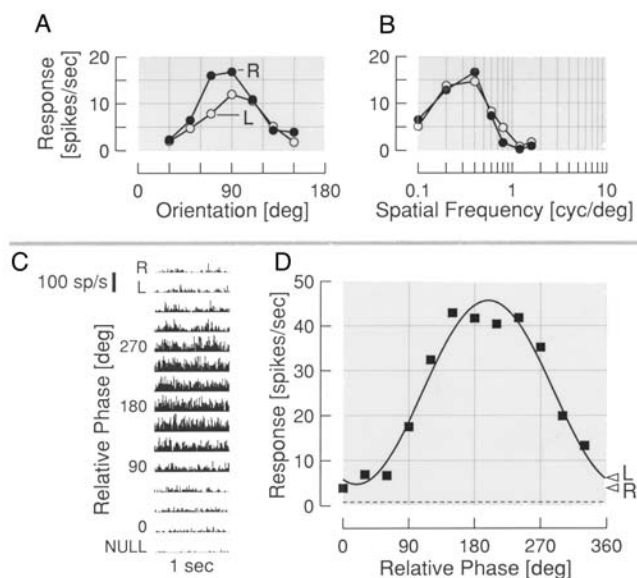

FIGURE 48.9. Responses are shown for monoptic and dichoptic tests of a cortical complex cell for which responses are phase specific. The same format as that in Figure 48.7 is used.

discharge patterns, but there are prominent differences for relative phase values. Monocular responses are relatively weak, and relative phases around 210 degrees are very strong. Phase values near 0 degrees are also weak. The result, as shown in the harmonic analysis of Figure 48.9D, is a clear phase-tuned response function. Since ON and OFF regions of complex cells are mixed so that the position of a stimulus in the monocular mode is not critical, relative phase tuning is not expected to be found in the dichoptic condition.

A possible explanation of this type of response is that the subunits of complex cells which exhibit phase-sensitive binocular interaction are either simple cells or are organized

like simple cell RFs. One prediction of this arrangement is that the subunits, which are phase specific, retain this characteristic at the output level of the neuron which would account for the pattern seen in Figure 48.9. It is possible to probe this conjecture by creating a special testing protocol, as illustrated in Figure 48.10. In each case illustrated (A, B, and C), a complex cell is depicted from which PSTH histograms are being collected in response to different stimulus protocols. In Figure 48.10A, a sinusoidal grating with optimal parameters of orientation, spatial frequency, and temporal frequency is drifted in a given direction across the RF. Stimulation in this case is monoptic, and the right eye is occluded. The resulting PSTH data at the bottom depict a typical mean discharge elevation without modulation. Figure 48.10B represents the result of another monoptic stimulation protocol with a grating of optimal parameters. In this case, the grating is not drifted. Instead, it is counterphased in place, that is, it flickers, with dark and bright components exchanging places sinusoidally. The typical response of a complex cell to this stimulus is different from the maintained discharge represented in Figure 48.10A. A flickering grating stimulus causes a modulated discharge at twice the temporal frequency of the counterphase, that is, there are two bursts of discharge per cycle of flicker (Movshon et al., 1978). The PSTH in Figure 48.10B represents a frequency-doubled response in accordance with previous results.

An interesting test concerning the organization of the subunit may be conducted by noting a relationship in wave theory. Traveling and standing sine waves are related to each other as follows. If two identical sine waves are drifted in opposite directions at the same drift rate, the combination results in a single flickering sine wave with twice the peak amplitude of each drifting wave.

With this relationship in mind, the question of subunit organization may be addressed in the following manner. A

FIGURE 48.10. A schematic illustration is shown of predicted responses of a complex cell according to different stimulus configurations. In A, a drifting grating is presented to the left eye only, resulting in an average increase in mean discharge. In B, a counterphase grating is shown to the left eye only, resulting in a modu-

lated, frequency-doubled response. In C, gratings are drifted in opposite directions in front of each eye, resulting in either a frequency-doubled (linear combination) response or an average increase in mean discharge (nonlinear combination).

FIGURE 48.11. PSTH histograms are presented for two complex cells stimulated by sinusoidal gratings of optimal parameters drifting at the same rate in opposite directions before left and right eyes. The right eye dominates in each case. The drift rate of 2 Hz yields four bursts of discharge per second, that is, the response is frequency doubled.

sinusoidal grating of optimal parameters is drifted across the RF of each eye in opposite directions, as depicted in the upper part of Figure 48.10C. If the drifting gratings are combined neurally, then the cells' response would be equivalent to that for a counterphased grating, that is, the discharge would be modulated bursts at twice the drift frequency. This would occur if the subunits of the complex cell carried out a linear summation of the inputs from each eye. The alternative is for a nonlinear combination to occur in which the response to a drift pattern is the dominant factor. In this case, the response of the complex cell would be a mean discharge with no modulation. These alternative possibilities are depicted in Figure 48.10C.

Examples of responses to the stimulus configuration shown in Figure 48.10C are given for two complex cells in Figure 48.11. Monocular responses are indicated in the top two histograms. For both cells, stimulation of the right eye causes an increase in mean discharge. The left eye does not respond in either case, that is, both cells are almost completely direction selective. Again in both cases, there is a striking modulated discharge pattern at virtually all relative phase values dichoptically tested. The temporal scale shows 1 second of response time, and the drift rate of each moving grating is 2 Hz. Therefore, the response of each cell is a frequency-doubled discharge, as predicted for a linear combination of signals from left and right eyes. In these cases, and in many others we have observed, the silent eye during monoptic testing exerts a clear influence on the cell's response during dichoptic activation (Ohzawa and Freeman, 1986a, 1986b; Freeman and Ohzawa, 1988, 1992).

Binocular processing of contrast

How do the above findings apply to standard variables of a visual stimulus? Of all the parameters of visual processing,

contrast is one of the most fundamental. It is perhaps the most straightforward variable to observe with respect to changes of response strength in central visual pathways. This is because alterations in contrast levels presumably affect a relatively uniform population of neurons. Many investigations have been carried out regarding the advantages in sensitivity of binocular compared to monocular vision. Most of these are psychophysical studies. In some of this work, it is suggested that binocular summation is not simply a statistical effect by which there are two chances to observe a given stimulus. Instead, it is thought to involve an active process in which there is neuronal interaction between signals from left and right eyes (e.g., Blake and Fox, 1973; Blake et al., 1981).

Although most of the work in this area has been done from a behavioral perspective, there are relevant physiological data on binocular summation. There has also been an attempt to relate directly the behavioral and physiological approaches. The neural basis of binocular summation in behaviorally determined contrast detection may be studied by measuring contrast response functions of cells in central visual pathways. By comparing results of tests from monoptic and dichoptic stimulation and applying receiver operating characteristic (ROC) analysis to the data, it is possible to derive monocular and binocular neurometric functions for each cell (Bradley et al., 1985). From this analysis, contrast thresholds and slopes for each neurometric function may be determined. Taken together, these data provide a bridge between behavioral and physiological studies.

Examples of responses from cells tested over a wide range of contrasts from 1% to $\approx 30\%$ are presented in Figure 48.12. In Figure 48.12A, data are shown for a simple cell for which left and right eye response strengths are approximately equal. The response rates for the left eye, right eye, and both eyes (*open circles*, *filled circles*, and *open triangles*, respectively) increase almost linearly with log contrast above an apparent contrast threshold level. There is some evidence of saturation in the binocular run at the higher contrast levels. Response strengths of the binocular tests are substantially stronger than the monocular counterparts at all but the lowest contrast levels. For the complex cell, whose data are shown in Figure 48.12B, right eye responses are stronger than those of the left eye, and binocular tests yield higher discharge rates than either. Monocular runs have steeper slopes than those for the simple cell of Figure 48.12A, and there is only a slight hint of saturation in the binocular function. Although these examples are representative of a relatively large population, there is considerable variability in response functions among the cells.

There are a number of aspects to the analysis of these data. Two elements are presented in Figure 48.13. Contrast thresholds are estimated by analysis of neurometric functions and ROC curves by which estimates are made of slope

FIGURE 48.12. Contrast response functions are shown for a cortical simple cell (A) and a complex cell (B). Open circles, filled circles, and open triangles represent mean discharge rates for the left eye, right eye, and binocular stimulation, respectively. Dashed lines indicate spontaneous levels.

intercepts. In this case, contrast threshold is defined as the contrast which gives a response probability of 0.75. This is an operational criterion response probability of a neuro-metric function. Details of the procedures used to drive these estimates are given elsewhere (Anzai et al., 1995). Distributions of estimated contrast thresholds for a population of cortical cells are given in Figure 48.13A. Values for the left eye, right eye, and both eyes are given, respectively, in the histograms from top to bottom. The geometric means, indicated by arrows above each histogram, are 6.8%, 6.2%, and 4.2%, respectively, for the left, right, and both eyes. Mean monocular thresholds of left and right eyes are significantly greater than that for both eyes together.

If the ratio of monocular contrast threshold to binocular contrast threshold is computed for each cell, it is possible to derive an index of binocular advantage for the population of cells under study. This commodity, which may be called a *binocular advantage ratio*, is plotted in Figure 48.13B. Open and filled arrows indicate geometric means of the binocular advantage ratios for left/binocular and right/binocular distributions, respectively. The values for left and right eyes are very similar (1.86 and 1.82, respectively). These values are significantly greater than a ratio of 1, indicating that individual neurons have a clear binocular advantage in processing visual information.

Contrast differences between left and right eyes

Just as the retina adapts to prevailing absolute luminance levels (Kuffler, 1953), the visual cortex adjusts its response range according to ambient contrast. This adaptive mechanism, contrast gain control (Ohzawa et al., 1985; Sclar et al., 1985), is a very effective way of maintaining high sensitivity over a large range of contrasts. Although this mechanism is transferable from one eye to the other (Sclar et al., 1985), interocular contrast mismatches suggest independent control of monocular pathways. Direct comparisons of monocular and binocular contrast encoding indicate that the primary mechanism occurs at a monocular site (Truchard et al., 2000).

Suppose that the contrast of a visual stimulus is relatively weak in one eye and strong in the other. This may happen in cases of anisometropia, amblyopia, or strabismus in which one eye has reduced function. It may also occur in rare cases in individuals with normal binocular vision when specular reflection from a surface effectively reduces the contrast of one eye's view more than the other. In any case, it is reasonable to assume that the eye through which a weak signal is generated will have little overall influence on the visual process. The results of psychophysical studies are consistent with this conjecture (Halpern and Blake, 1988; Legge and Gu, 1989; Schor and Heckmann, 1989; Westheimer and McKee, 1980). These studies show that relatively small

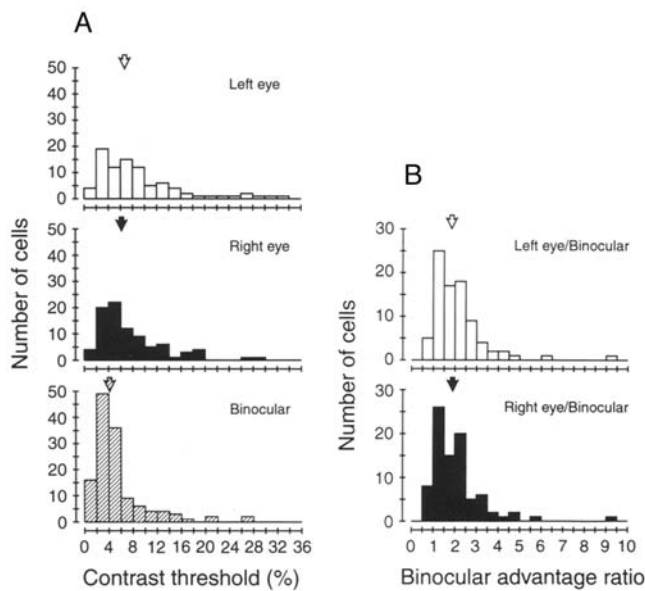

FIGURE 48.13. In *A*, contrast thresholds are shown for left eye, right eye, and binocular stimulation. Arrows indicate geometric means of contrast thresholds. The mean binocular threshold is significantly lower than either monocular value. In *B*, binocular advantage ratios are shown for left and right eyes. Arrows indicate geometric means of the binocular advantage ratios. Considered together, these data indicate that individual neurons have a significant binocular advantage.

contrast mismatches between the two eyes result in severely reduced stereo acuities. However, physiological investigations of interocular contrast differences yield different results. In particular, binocular interaction studies in which interocular phase is varied between gratings with different contrast values for each eye, demonstrate a compensation mechanism which acts to effectively boost the signal from the weak eye.

Examples of results from this physiological test are given in Figure 48.14. In Figure 48.14*A*, data are shown for a vigorously responding phase-specific complex cell tested with 50% contrast gratings presented to left and right eyes. The clear phase-specific response is typical of about half the population of complex cells (Ohzawa and Freeman, 1986a, 1986b). The same test was run again, but in this case, grating contrast to one eye was reduced by nearly a log unit to 6.3%. The result, shown in Figure 48.14*B*, is remarkably similar to the previous finding, that is, there is a clear phase-specific response pattern, with only a slightly reduced peak discharge rate around a relative phase of 180 degrees. A second complete run was made with another set of contrasts, that is, 50% to one eye and 12% to the other, and a very similar result was obtained. To quantify the degree of binocular interaction, one cycle of a sinusoid is fit to the phase-specific response curve. Using this fit, a *depth of modulation* index is derived allowing quantification of the degree of binocular interaction. The depth of modulation is equal to the ratio of amplitude of the fitted sinusoid over the mean of the binocular responses. In general, the larger the index,

the stronger the degree of binocular interaction. The flatter the interaction curve, the closer the index is to zero. In this case, stimuli presented to a given eye has no effect on the other eye's response pattern. In other words, the depth of modulation index provides a quantified assessment of the effect one eye has on a cell. Excitation through the other eye is used as the reference for this index.

In Figure 48.14*C*, depth of modulation is plotted on the left vertical axis and the response of the neuron to different contrasts is plotted for one eye (the left) on the right vertical axis. For the two contrast difference levels, depth of modulation is nearly the same as that for the identical contrast runs (50% for each eye). The contrast response curve for the left eye is standard and has a steep slope, that is, it is a monotonically increasing function. A second example, this time for a simple cell, is illustrated in Figure 48.14*D–F*. The same format as for the preceding example is used, and the data show a very similar pattern. Once again, the depth of modulation is essentially flat and the contrast response function for the left eye is also a steep, monotonically increasing curve, as in the previous example. For both of the cells shown in Figure 48.14, there is essentially no reduction in the depth of modulation even with relatively enormous differences in contrast levels between left and right eyes. This pattern may be compared with the monocularly elicited responses to stimulation of one eye (the left in both cases). In both monoptic cases, there is a sharp decline in response as contrast is reduced. These examples are clearly representative of a larger sample. For 21 cells tested in similar ways, mean depth of modulation values are given in Figure 48.14*G*. Once again, contrast differences between left and right eyes appear to have little effect on depth of modulation. These results may be interpreted in the context of a contrast gain reduction system that is mainly operational at monocular sites in the visual pathway (Truchard et al., 2000).

The compensatory mechanism for unequal signal strength in right and left eyes

What is the main implication of the results from the dichoptic experiments employing a strong stimulus to one eye and a weak one to the other? The data presented above for dichoptic stimulation with phase-varying gratings having different contrast levels for left and right eyes show clearly that a compensatory mechanism provides relative constancy of interaction. Since the use of a low-contrast grating implies a raised threshold, there must be a synaptic gain of signals from the eye receiving weak input. The gain must be high when input contrast is low and relatively low when input contrast is high. This suggests two mechanisms in the compensatory process. The first is a threshold mechanism that follows the convergence of inputs from both eyes. Strong inputs from either or both eyes raise the threshold level for spike discharge. Because monocular input can raise the threshold, and both eyes are affected, this may account for

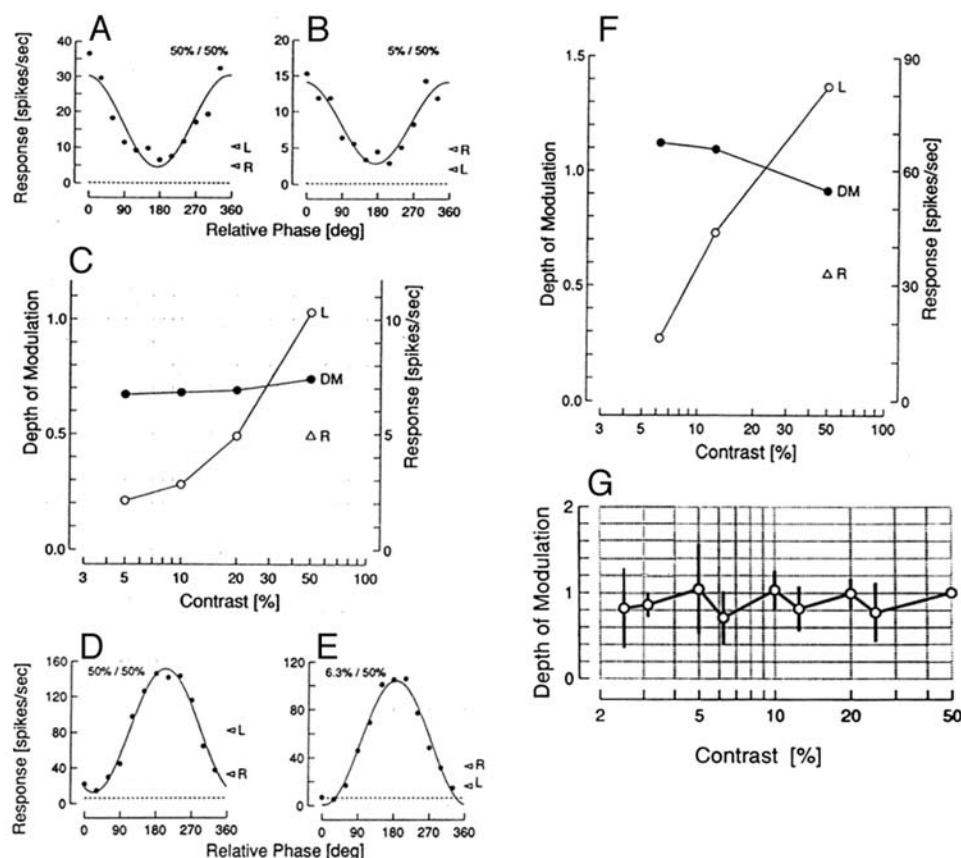

FIGURE 48.14. Data are shown for dichoptic tests in which the contrast of the grating presented to one eye is considerably lower than that for the other eye. Results are given for equal right and left eye contrasts (*A*) and unequal contrasts (*B*). In *C*, depth of modulation is shown for four contrast difference values (filled symbols).

the interocular transfer of contrast gain control. The second mechanism is also a type of contrast gain control. In this case it is a monocular function, and it operates at the synaptic contact between a given eye and a cortical target cell. This second mechanism can account for the observed constancy of binocular interaction when low- and high-contrast gratings are used for left and right eyes, respectively.

Interocular contrast differences create artificial changes in ocular dominance

We have considered how the assessment of binocular status should not be made. It is now possible to address ocular dominance from a different perspective. Note that the binocular presentation of unequal contrast gratings is a way to alter ocular dominance artificially. This is because contrast is a stimulus variable that directly affects the input strength that cortical cells receive. Ocular dominance is determined by the relative gain of inputs to a given cell from left and right eyes. Although the gain control mechanism is not readily available for experimental manipulation, net input to a given cortical cell from each eye may be altered by changes in input strength. This, in effect, changes the ocular dominance of

The same graph contains a contrast response function for the left eye with the discharge rate on the right. *D*, *E*, and *F* contain the same type of data for another cell. *G* is a summary graph for a population of cells showing that contrast differences between left and right eyes do not change the depth of modulation.

the neuron. This change is, of course, an artificial one and temporary. It should not be confused with previous attempts to change the intrinsic ocular dominance of a neuron as it is studied (Tsumoto and Freeman, 1981).

With the artificial changes in ocular dominance, instituted by the unequal contrast experiments, there is a somewhat surprising constancy in binocular response. This constancy occurs over a very wide range of input strength variation between the eyes. An eye with relatively reduced strength, by as much as a full log unit, still modulates the response of a given neuron. How does this apply to the case of actual variations in ocular dominance, as expressed in the full range of values that are reported in histograms? A gain imbalance in a normal visual cortex may be compensated for by mechanisms such as those discussed above. The wide range of ocular dominance values that are observed may be the result of a genetic compromise because it may be relatively difficult to program every cortical cell so that it has exactly balanced input from left and right eyes. However, because of the compensatory mechanisms described here, ocular dominance variability may not be important for binocular visual function under real conditions. Therefore, the subject of

ocular dominance of cortical cells may be of interest in laboratories but of little consequence in the real world of binocular vision.

Development and plasticity of binocular vision

Quantitative investigations of development of binocular vision have shown that the physiological apparatus that underlies this function is operational as early as one can effectively measure it. This applies to the kitten's visual system (Freeman and Ohzawa, 1992) as well as that of the primate (Chino et al., 1997). Although the subject of development and plasticity of vision is not part of the topic of this chapter, it is of interest here because it provides an opportunity to emphasize how estimates of binocular function can differ, depending on how measurements are made. Two examples are instructive, and they are illustrated in Figure 48.15.

The first example is for a cortical neuron recorded from a normally reared kitten at 3 weeks' postnatal. Note the standard tuning curves for orientation and spatial frequency for the left eye (Figs. 48.15*A* and 48.15*B*). For the right eye the curves are completely flat because there is no response for orientation and spatial frequency runs. In the dichoptic mode in which gratings are presented at various relative interocular phases, there are clear modulated responses (Fig. 48.15*C*). The monoptic response, for the left eye, is slightly modulated and the discharge is vigorous. Once again, in this sequence, the right eye is completely silent. What is striking is that harmonic analysis (Fig. 48.15*D*) reveals a clear overall suppressive effect. The eye which is silent when tested monoptically exerts a clear and substantial overall suppression of the response. There are two functions in Figure 48.15*D*. Data for one curve (*filled symbols*) were obtained 20 minutes after completion of the first run. Data from the second run are nearly superimposed on those from the first, so the overall suppression is clear and consistent. The conclusion here is that an eye that appears completely silent in the monocular mode is clearly connected to the neuron under study when tests are conducted dichoptically. The point is that an inaccurate picture is presented if only monocular tests are performed.

A similar situation applies for the other cell for which data are presented in Figure 48.15*E–H*. In this case, the neuron was recorded from a cat that had been monocularly deprived for nearly 3 years starting at the age of 3 weeks' postnatal. As the data in Figures 48.15*E* and 48.15*F* show, the nondeprived (left) eye drives the cell vigorously and the deprived (right) eye is completely ineffective. The PSTH data in Figure 48.15*G* again show a strong discharge from the nondeprived eye and greatly reduced responses for the dichoptic relative phase runs. Plots of the response amplitude (DC

component) obtained from harmonic analyses of the histograms in Figure 48.15*G* are presented as a function of relative phase in Figure 48.15*H* (*open symbols*). As the graph shows, there is a very strong non-phase-specific, uniform depression of responses compared to response levels for the nondeprived (left) eye alone. The neuron's activity is nearly shut off. A second curve (*filled symbols*) is also shown. These data, nearly superimposed on the first curve, are for a second interocular relative phase run in which the grating for the deprived (right) eye is rotated by 90 degrees so that it is orthogonal to the optimal grating orientation. As the data show, the suppressive influence of the deprived (right) eye is nonoriented. Once again, monocular tests alone do not capture the response characteristics of this neuron. There are many similar examples, and these have been documented elsewhere (e.g., Freeman and Ohzawa, 1988, 1992). Considered together, these data demonstrate that binocular tests are required to establish complete characteristics of neuronal responses in the visual cortex.

Conclusions

This review considers some of the essential factors in the physiological combination of signals from left and right eyes. The integration of monocular pathways in striate cortex produces the neural substrate for stereoscopic depth discrimination. This function is considered only briefly here. The focus instead is on the underlying features of the neural elements of binocular function. One of the key points is that the long-standing use of monocular tests to estimate binocular function in the form of ocular dominance measurements is not adequate. Instead, dichoptic techniques should be employed. Standard parameters and results of dichoptic tests involving phase-varying sinusoidal gratings are considered. The binocular processing of contrast information is dealt with in order to consider the physiological advantage of binocular compared to monocular vision. For gratings presented dichoptically, differences in contrast between left and right eye gratings result in surprisingly constant binocular interaction profiles. Gain control mechanisms, primarily at monocular sites, are responsible for this effect. Differences in left and right eye grating contrast also permit artificial manipulation of effective ocular dominance. The findings from these experiments suggest that ocular dominance differences among a population of cortical cells may be of laboratory interest only. It is possible that compensatory mechanisms offset ocular dominance variability in perceptual vision. Finally, brief consideration is given to the development and plasticity of vision to illustrate that monocular tests do not expose subthreshold input from an eye. In this case, binocular function is not adequately determined.

FIGURE 48.15. Results of monoptic and dichoptic tests are presented for a kitten at 3 weeks postnatal (A–D) and for an adult reared with right eye monocular deprivation (E–H). The format is the same as that in Figures 48.7 to 48.10. The second curve in D (filled symbols) is from a complete dichoptic test, identical to the first,

run 20 minutes after completion of the initial sequence. There are also two sets of data in H. One curve (filled symbols) is for a condition in which the grating presented to the deprived eye is rotated 90 degrees during the dichoptic test.

49 From Binocular Disparity to the Perception of Stereoscopic Depth

ANDREW J. PARKER

THE AIM OF THIS CHAPTER is to give a modern neurobiological account of the perception of stereoscopic depth. *Stereopsis* is understood here in its present-day usage as being the sense of depth created by binocular disparities. There are two main components to the chapter. First, there is a review of the role of V1 neurons in the initial registration and processing of binocular disparities. It is concluded that V1 has an important role but falls short in several respects in providing a full account of stereopsis. Second, there is a shift in focus to extrastriate cortex in a search for neuronal activity that can better explain some of the key characteristics of stereoscopic depth perception. This section reviews our current understanding of the ways in which single cortical neurons selective for binocular disparity may contribute to the perception of stereoscopic depth. Finally, there is a brief concluding section that aims to highlight gaps in our current knowledge and point out directions for future research. This chapter is inevitably highly selective and incomplete. Its purpose is to focus on recent developments and to identify some issues that may be within our grasp during the next 10 years or so.

The groundwork of any account of stereoscopic depth is the perceptual and psychophysical investigations initiated in the nineteenth century by Wheatstone, inventor of the mirror stereoscope (Wheatstone, 1838, 1852). Although others, notably Leonardo da Vinci, had previously understood that the right and left eyes obtain slightly different views of the visual scene, Wheatstone appreciated that presenting images to the left and right eyes in a way that mimicked the natural viewing geometry could create a sense of binocular depth. This set off a string of nineteenth-century investigations, which are summarized in von Helmholtz (1909/1962). Figure 49.1 summarizes how objects at different depths give rise to binocular disparities.

A critical concept is *binocular correspondence*. Locations at the same distance on the retinas from the left and right foveas are said to be in *anatomical correspondence*. Psychophysically, the concept of correspondence is more complex: one commonly adopted definition is pairs of points on the left and right retinas that generate the same sense of visual direction when stimulated monocularly (see Howard and Rogers, 1995, for a summary of these issues). Importantly, the perception of

an object with binocular depth in front of or behind the binocular fixation point depends on the visual stimulation of *noncorresponding* points on the left and right retinas (Fig. 49.1*B,C*).

Our understanding of how single neurons support this visual function began in the 1960s, when Hubel and Wiesel (1962) discovered binocular summation within the striate cortex. Soon afterward, it was established that some of these striate cortical neurons possess receptive fields that are not in exact correspondence between the two eyes (Barlow et al., 1967; Bishop et al., 1971; Nikara et al., 1968). The connections of some of these binocular cortical neurons from the left and right eyes are organized such that the neuron responds best when an object is further than the binocular fixation point (Fig. 49.1*B*). Other neurons respond best when the object is nearer than the binocular fixation point (Fig. 49.1*C*). The small inset panels in Figure 49.2 show a collection of tuning curves measured for single V1 neurons in the macaque monkey. Each curve shows the firing rate of one neuron plotted against the disparity of the stimulus. The curves have been chosen to illustrate the range of tuning types encountered in V1.

Neurons with this type of receptive field are candidates for a physiological mechanism that is responsible for binocular stereopsis. Deviations from exact correspondence have two possible forms (Fig. 49.3). In one form (position encoding), the centers of the receptive fields occupy noncorresponding locations on the left and right retinas (Barlow et al., 1967; Ohzawa et al., 1990). Figures 49.1*B* and *C* show the shifts in retinal locations of a binocular object at different distances: this mechanism matches these shifts in retinal stimulation with an equivalent shift in the centers of the left and right eyes' receptive fields. In the other form (phase encoding), the centers are in corresponding locations but the exact profile of the receptive field differs between the left and right eyes (Ohzawa et al., 1997). Either type of difference endows the binocular visual system with a fundamental sensitivity to stereoscopic depth by making the neuron's response stronger at some disparities than others (Fig. 49.3). A detailed discussion of these properties is presented in Chapter 48 of this volume.

FIGURE 49.1. Diagrams illustrating the definitions of binocular disparity used in this chapter. In all diagrams, the optic center of each eye is shown with a solid circle •, the positions of the left and right foveas (F_L and F_R , respectively) are shown with solid arrows, the directions of binocular gaze are indicated with solid lines, and the visual directions of nonfixated objects are indicated with dashed lines. *A*, The simplest case, in which the two eyes fixate a single object, *O*. *B*, Object *O* remains in the same location, but the eyes have rotated inward toward the midline to fixate a new point closer to the observer than *O*. The projection lines of *O* now fall on noncorresponding retinal points. The retinal projection of *O* is to the right of the fovea in the left eye and to the left of the fovea in the right eye. *C*, Object *O* is again in the same location, but the eyes have rotated outward away from the midline to fixate a point farther away from the observer. The retinal projection of *O* is now to the left of the fovea in the left eye and to the right of the fovea in the right eye. *D*, The eyes now fixate object *O* with a second object, *N*, at a different depth from the observer. The angles α and β between *O* and *N* are unequal in the two eyes, and the difference $\beta - \alpha$ is the relative disparity between *N* and *O*. The value $\beta - \alpha$ is also the absolute disparity of *N* because the observer is fixating *O*. *E*, When the binocular gaze is shifted to a nearer point, *O* and *N* both have different absolute disparities. However, the relative disparity between *O* and *N* is unaltered.

Disparity selectivity

Whichever of these two forms of selectivity is present (or a mixture of them), a system of binocular disparity based on retinal noncorresponding points is firmly locked to the coordinate frames for each retina. As Figure 49.1 illustrates, when the eyes converge or diverge to inspect a new target, mechanisms locked to noncorresponding points register a new disparity value for an object *O* that remains at a fixed distance from the observer. The geometric projection lines for object *O* alter as the binocular fixation point moves closer or farther in depth. By fixating *O*, the visual system brings the object to corresponding points on the left and right retinas, hence a disparity of zero (Fig. 49.1*A*). Converging closer than *O* gives *O* a *far* disparity, and converging farther than *O* gives *O* a *near* disparity. Thus, when the disparity of *O* is measured in terms of retinal noncorresponding points, its disparity is subject to fluctuation as the eyes move, despite the fact that it is actually at a constant distance from the observer. Most physiological studies of disparity selectivity have explored within this framework, which may be termed *absolute disparity* (Cumming and Parker, 1999).

Another way of describing binocular disparity has been current in the literature on the psychology of depth perception. Here the emphasis has been not primarily on noncorresponding points in retinal coordinates but on the difference in the retinal projections of two visible objects at different depths from the observer, for example, points *O* and *N* in Figure 49.1*D*. The angles that are subtended by the gap between *O* and *N* are, of course, different in the left and right eyes. Figure 49.1*E* shows that this difference is not substantially affected by the vergence angle of the eyes (at least to the extent that the eyes may be assumed to rotate around their true optical centers, which is reasonable for small rotation angles). This measure of disparity has been termed *relative disparity* and is in fact equal to the difference in the absolute disparities of the two visible points under consideration.

An estimate of relative disparity can only be achieved by the nervous system if there are at least two features that can be seen in the visual field. By comparison, the nervous system can estimate the absolute disparity of a single point in an otherwise empty visual field. Absolute and relative disparity are associated with different visual and oculomotor functions. Absolute disparity is an important parameter in controlling disparity-driven vergence movements (Rashbass and Westheimer, 1961), whereas the finest stereoacuties are obtained with stimulus arrays that include relative disparity (Andrews et al., 2001; Westheimer, 1979). Most compelling is a demonstration by Erkelens and Collewijn (1985) and Regan et al. (1986). Observers view a display with two depth planes defined by a relative disparity between them. A

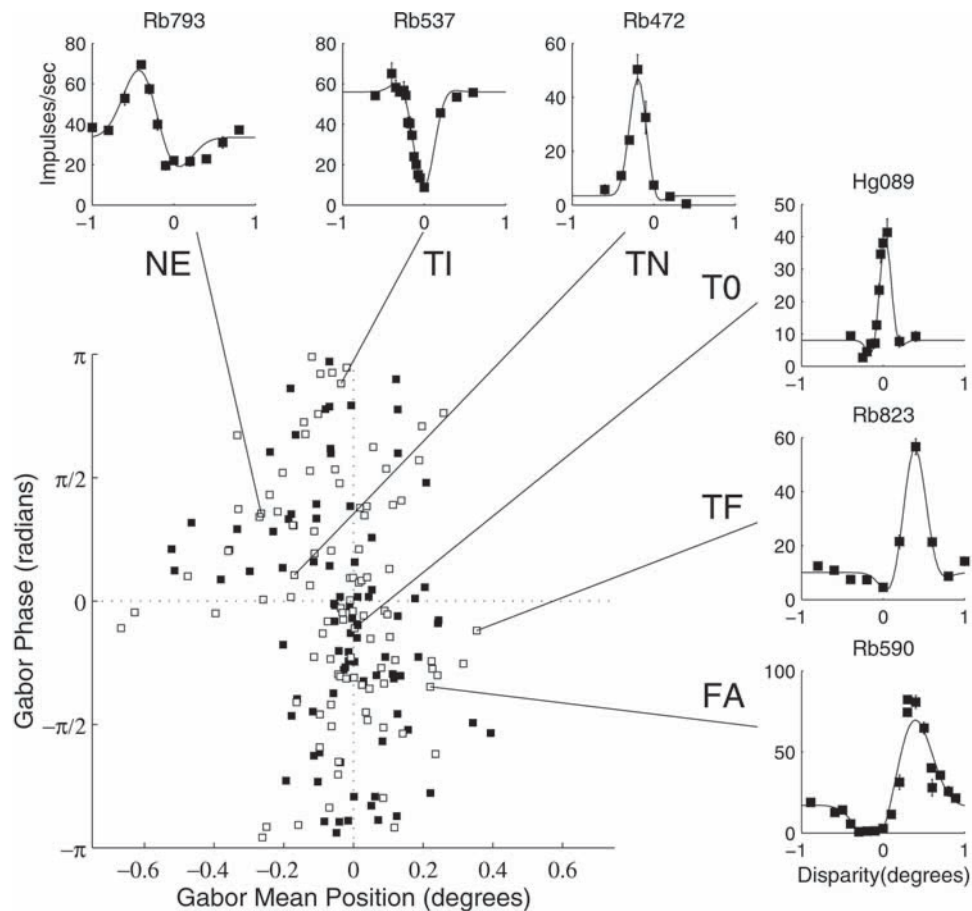

FIGURE 49.2. The small inset panels show six examples of disparity-tuning curves recorded from single neurons in macaque V1. The smooth curves through the data points are Gabor functions (Gaussian multiplied by sinusoid). The main plot shows the values of position disparity (in degrees of disparity, reflecting the esti-

mated position of the peak of the Gaussian) and phase disparity (in phase angle, reflecting the estimated phase of the sinusoidal component of the Gabor function). Data are shown for 180 neurons recorded from V1 of two macaque monkeys. (From Prince et al., 2002a.)

change in the absolute disparity of the entire display causes a human observer to track the change with vergence movements of the eyes, but no perceptible change of depth is generated. On the other hand, movement of one of the planes in depth relative to the other gives rise to a vivid sense of motion in depth.

Disparity-selective neurons have been identified not just within the striate cortex but also throughout the visual areas of the extrastriate cortex (Cumming and DeAngelis, 2001). This makes it clear that the discovery of a specialized set of neurons responsible for stereoscopic depth perception has to go beyond the identification of disparity selectivity in single neurons. We need a specific comparison between the perceptual properties of stereoscopic vision and the properties of single neurons studied in neurophysiological experiments. Considerable progress toward this goal has been made in recent years.

V1 and its response properties

Cortical area V1 is the first site in the brain at which information from the two eyes is brought together by means of specific excitatory connections designed to create high precision for binocular disparity. Some of these single neurons carry highly accurate signals. Such neurons can encode an alteration in the disparity of a stimulus with an accuracy that rivals that of psychophysical observers (Prince et al., 2000). This is remarkable given that psychophysical observers should be potentially able to access information from all the neurons in the relevant cortical areas at their disposal in performing the same task.

Recent quantitative measurements provide a basis for estimating the total range of disparities processed by V1 neurons and how the resources of V1 are applied, in terms of both numbers of neurons and the signaling capability of neuronal firing. Figures 49.2 and 49.4 show the distribution

FIGURE 49.3. The disparity-tuning curves at the right are generated by a computational model of the binocular receptive field (Ohzawa et al., 1990). The random-dot stereo image is received and filtered by the receptive field structures for the left and right eyes, illustrated by the receptive field profiles marked L and R and the gray inset panels in which ON regions of the receptive field are white and OFF regions are dark. The outputs of the left and right eyes' receptive fields are added linearly and then passed through a half-wave rectifier. The computational model simulates the repeated presentation of dynamic random-dot stereograms by presenting many different patterns of dots at one disparity and taking the overall average response to each disparity. Each disparity-tuning curve plots these computed responses on the ordinate against the disparity of the stimulus (in arbitrary units) on the abscissa. The top row shows the shapes of tuning curve predicted by the position-shift model (Ohzawa et al., 1990). In this case, the left eye and right eye have the same arrangement of ON and OFF zones

and are related by a simple translation. The disparity-tuning curve has even symmetry. The bottom row shows an alternative way of generating disparity tuning. Here the location of the ON and OFF zones is different in the left and right eyes, whereas the overall centers of the receptive fields remain in the same position with respect to one another. This type of disparity tuning is called *phase disparity* because when the left eye and right eye receptive fields are described by a Gabor function (the product of a Gaussian multiplied by a sinusoid, as seen in the figure), the rearrangement of the ON and OFF zones is achieved by means of a shift in the phase of the sinusoidal component that describes the receptive field. The resultant tuning curves for disparity are odd-symmetric rather than even-symmetric. Binocular receptive fields that contain a mixture of both position-shift and phase-shift mechanisms generate disparity-tuning curves that are intermediate between odd and even symmetry (see Fig. 49.2 for examples). (From Prince et al., 2002a.)

of peak disparities for neurons recorded at eccentricities within 5 degrees of the fovea. The data are from Prince et al. (2002a) and are plotted separately for the two types of mechanism identified earlier in this chapter and in Chapter 48 of this volume. The horizontal axis (position disparity) shows the scatter of peak disparities for interocular differences in receptive field location, while the vertical axis (phase shift) shows the scatter of peak disparities generated by interocular differences in the profile of the receptive field. To allow a direct comparison, Figure 49.4 expresses the phase shifts in units of visual angle equivalent to position disparities (see Prince et al., 2002a, for details). The scatter of peak disparities for V1 receptive fields is approximately Gaussian, with a total range of just over 0.5 degree.

Figure 49.5 shows the neuronal activity pooled across 180 disparity-tuned neurons from cortical area V1 in the near-foveal part of the visual field as a function of the stimulus disparity. The neuronal activity has been pooled in a way that reflects the statistical reliability of the signals from indi-

vidual neurons. These data have again been analyzed separately for the two types of interocular difference in receptive fields (position and phase). Taken as a whole, the population of V1 neurons has the greatest potential for discrimination near the fixation plane at zero disparity, a finding that is consistent with a wide range of psychophysical data. The V1 population remains functionally effective in disparity discrimination over a range of about ± 1 degree of disparity. This is consistent with the largest values of stereoscopic disparity that can be processed psychophysically by human and macaque observers with random-dot stereograms (Glennerster, 1988; Prince et al., 2002a).

Despite these close correspondences between the properties of the neuronal population in V1 and psychophysical measures of the range and sensitivity of binocular disparity mechanisms, there are several respects in which the properties of V1 neurons are fundamentally inconsistent with many of the perceptual properties of binocular stereoscopic vision. We will therefore now focus on some important

FIGURE 49.4. The scatter plot shows the same data as Figure 49.2, except that the phase shifts have been converted to an equivalent visual angle rather than a phase angle. This allows a direct comparison of the relative importance of phase and position disparity, which may be viewed by inspecting the histograms above and to the right. The different symbols in the scatter plot indicate whether the binocular receptive fields are best characterized by an interocular difference in receptive field location (position disparity) or receptive field profile (phase shift): \triangle , phase shift only; \bullet , position shift only; \blacksquare , position and phase shift; \square , either phase or position but not both; \blacktriangle , neither phase nor position. (From Prince et al., 2002a.)

discrepancies between the behavior of V1 neurons and stereo-depth perception.

V1 NEURONS RESPOND TO ABSOLUTE, NOT RELATIVE, DISPARITY As mentioned above, psychophysical judgments of stereoscopic depth by humans and macaques are most sensitive when relative disparity information is included in the visual stimulus. By contrast, V1 neurons respond to absolute disparity (Cumming and Parker, 1999). Disparity-tuning curves of V1 neurons were measured with a stimulus that contained relative disparity information, so that if there were any receptive field structures sensitive to relative disparity, they would be adequately stimulated. The V1 tuning curves were examined in two conditions. Each condition included a different amount of absolute disparity that was added to the entire stimulus array (including the binocular fixation point) with a tightly controlled feedback loop that took into account the state of convergence of the eyes. The extra absolute disparity mimics the sensory effect of a convergent or divergent eye movement away from the binocular fixation point. Hence it is important to monitor vergence and adjust

FIGURE 49.5. Sensitivity of the population of V1 neurons to changes in disparity. The abscissa plots the disparity of the dynamic random-dot stimulus, while the ordinate shows the ability of the population of V1 neurons to signal a change from the tested disparity. The neuronal sensitivity is estimated by first taking the square root of the neuronal firing and pooling across neurons the absolute value of the slope of the disparity-tuning curve (the ordinate scale is the square root of spikes per second per degree of disparity). The plot shows separately the contributions of phase shift and position disparity mechanisms, which are similar.

The justification for taking the square root of the neuronal spike counts is that the variance of neuronal spike counts tends to rise more or less proportionately with the mean spike count. Without a square root transform, the firing rates pooled across neurons would be biased toward those neurons with high mean firing rates. Such neurons are inherently also highly variable. Thus a square root transform gives a more equal weighting to all statistically significant signals, regardless of the mean firing rate of the neurons (see Appendix A in Prince et al., 2002b, for details).

the visual stimulus appropriately to keep the added absolute disparity at the desired value.

When an extra amount of absolute disparity is added to the display, a receptive field that is fundamentally responsive to absolute disparity should simply respond on the basis of the absolute disparities in the display. A mechanism that is fundamentally responsive to relative disparity should respond entirely on the basis of the relative disparities in the display. The situation is like that in Figure 49.1E, where the relative disparity between O and N is not affected by the vergence angle of the eyes. For a neuron that is selective for relative disparity, its response should not be affected by the addition of extra absolute disparities to the display. For neurons in V1, the results are unambiguous: all disparity-selective neurons in V1 are fundamentally responsive to absolute disparity (Cumming and Parker, 1999). Thus these neurons code disparity in terms of retinal correspondence.

V1 NEURONS RESPOND TO LOCAL DISPARITY, NOT STEREOSCOPIC DEPTH The way in which the visual system sorts out which features on the left retina correspond to those on the right retina and how the visual system derives depth signals from these binocular matches has been a topic of considerable research, both psychophysically and computationally. A fairly simple stimulus array highlights the main issues. Consider the case of a simple stimulus consisting of four dots in a horizontal row presented to both the left and right eyes in a stereoscope (Fig. 49.6). The human subject perceives a horizontal row of four dots all in the same depth plane. This appears unremarkable until one appreciates that, since every dot is identical to every other, there is actually no particular factor within the stimulus that forces this specific perceptual interpretation (Julesz, 1971; Marr and Poggio, 1976). Numerous other patterns of pairing between left and right eyes are possible, even if one applies the constraints that there should be no unmatched dots left over and that each dot should match only once. The latter constraint is doubtful for human vision in view of the possibility of multiple matching of features in Panum's limiting case, in which two similar dots in one eye and a single dot in the other lead to a sensation of stereoscopic depth.

Computational arguments have been made based on a number of principles, two of which are (1) that the visual system tends to select the smoothest possible disparity field and/or (2) that the visual system allows only unique, rather than multiple, matches between a feature in one eye and a feature in the other. In practice, we are not certain which of these is more significant for the mammalian visual system, although undoubtedly they are close to the truth since the principles reflect the geometric structure of natural scenes.

Without needing to understand exactly which principles are most significant, we can use a stimulus with multiple repeating features to probe different levels of stereoscopic depth processing in the cerebral cortex to discover whether true stereoscopic matching of features has been achieved at any particular neuronal site. For example, in macaque V1, a variant of the four-dot stimulus has been used to examine whether V1 neurons respond primarily to local disparity or binocular depth. In the stimulus used by Cumming and Parker (2000), a drifting sinusoidal grating was placed within a sharp circular window, with both grating and window having the same disparity (Fig. 49.6). This stimulus has the appearance of a flat surface with the bars of the grating at the same depth as the window. However, V1 neurons that are tuned to binocular disparity respond whenever there are appropriate contours in the left and right eye receptive fields of the neuron, even though the disparity that generates the response actually corresponds to a binocular match that forms no part of the psychophysical observer's percept. In other words, V1 neurons behave as if they are sensitive to

FIGURE 49.6. The upper diagram shows the 16 possible pairings of 4 identical dots presented to the left and right eyes. The lower diagram shows the windowed sinusoidal grating stimuli used by Cumming and Parker (2000) to test whether V1 neurons can identify globally correct stereoscopic matches. The crosses represent the binocular fixation point, and the rectangular boxes placed within the grating patches indicate a binocular cortical receptive field tuned to zero disparity. Even though a psychophysical observer perceives the grating patch to be at a nonzero disparity, V1 neurons tuned to zero disparity respond well to this stimulus because the local luminance information over the receptive field is also consistent with a stimulus of zero disparity.

all 16 possible pairings of the dots in Figure 49.6 rather than just the 4 pairings that correspond to the percept. In this sense, V1 neurons do not extract the global stereoscopic percept from this configuration.

V1 NEURONS RESPOND TO DISPARATE STIMULI THAT DO NOT GENERATE A SENSE OF STEREOSCOPIC DEPTH In normal viewing of a natural three-dimensional scene, features that are visible in both the left and right eyes' images generally have the same contrast polarity in each image. Thus a bright feature in one eye corresponds geometrically to a bright feature in the other eye and similarly for dark features. The

major exception to this occurs with a specular highlight, where the mirror-like reflection may send light directly along the line of sight to one eye and not to the other. This unusual circumstance creates a condition in which very different contrast values are presented to the two eyes. When artificial stereoscopic images are viewed under laboratory conditions, the presence of features that are of opposite contrast polarity (a bright dot in one eye paired with a dark dot in the other eye) has either a deleterious or a completely disruptive effect on stereo processing as measured psychophysically. If the feature of opposite contrast in the two eyes is a pair of isolated bars or dots, then the thresholds for detecting stereoscopic depth are raised substantially (Cogan et al., 1993, 1995; Cumming et al., 1998). Notably, when the features are binocularly fused, the percept is classically described as *lustrous* (von Helmholtz, 1909/1962), consistent with an association with specular highlights. In the case of random-dot stereograms that have a moderately dense packing of dots, the sense of stereopsis is completely destroyed by binocular anticorrelation: psychophysically the depth threshold is immensurable, and there is no segregation of one region from another purely on the basis of a difference in disparity.

These psychophysical responses are in contrast to the behavior of a simple disparity-detecting mechanism that gives a reasonable model for V1 neurons by computing the correlation between spatially localized regions in the left and right eyes' images. When two features have the same contrast and shape in the left and right eyes' images, the local correlation between the images will be highly positive. Introducing binocular anticorrelation by inverting the contrast of just one of these features does not simply reduce the correlation between the left and right images to zero but actually makes the correlation highly negative. Any model like the binocular energy model of Ohzawa et al. (1990), which is based on multiplication of spatially filtered versions of the left and right eyes' images, shows an inversion of its disparity tuning under binocular anticorrelation (Cumming and Parker, 1997). Disparities that are maximally effective with correlated images become maximally suppressive with anticorrelated images and vice versa.

When the disparity tuning of V1 neurons to binocularly correlated images is compared with the tuning to anticorrelated images, many neurons show an inversion of the tuning curve, as predicted by the binocular energy model (Cumming and Parker, 1997). However the amplitude of the anticorrelated response is often smaller than that of the correlated response, and indeed, some tuning curves do not show a simple inversion. At the behavioral level, ultra-short-latency vergence movements show an inverted response with binocularly anticorrelated patterns. Thus a large field of binocularly anticorrelated random dots with far disparities actually causes a transient convergence rather

than the divergence that would be generated with binocularly correlated random-dot patterns (Masson et al., 1997). Hence, these fast vergence eye movements may be driven directly from sensory detectors that register a simple correlation over a large region of the left and right eye' images. A particularly close match has been observed between the characteristics of these vergence movements and the tuning properties of neurons in the extrastriate medial superior temporal area (MST) (Takemura et al., 2001). However, some of the disparity-tuning properties of MST neurons may be derived from neurons at earlier stages in the visual pathways.

Psychophysically, it is possible to identify a stage in binocular processing at which disparity-detecting mechanisms invert their response under binocular anticorrelation (Neri et al., 1999). This observation is in sharp contrast with the perceptual effect of anticorrelated stimuli placed at nonzero disparities. As mentioned above, anticorrelated stimuli with spatially isolated features such as single bars or edges do give rise to a sense of depth. In the case of random-dot stereograms, a sense of binocular depth is generated at low dot densities and is absent at moderate to high dot densities (Cogan et al., 1993; Cumming et al., 1998). The critical observation is that when anticorrelated disparities do generate a sense of binocular depth, the perceived depth is always in the direction predicted by the geometric arrangement of the features (Cumming et al., 1998; Read and Eagle, 2000). Thus a binocularly anticorrelated bar with near disparities gives rise to the perception of a feature that is closer to, not farther from, the subject than the binocular fixation point.

This response is not predicted from a disparity detector based on simple correlation and appears to require the initial generation of a monocular response to contour that is independent of contrast sign before stereoscopic processing (Ziegler and Hess, 1999). Stereopsis from such responses are confined to single isolated features, and the visual system appears to be unable to derive any sense of depth from the more crowded and complex arrangements of dots in anticorrelated random-dot stereograms with the same facility.

In summary, V1 neurons show evidence of disparity-specific responses to stimuli that are ineffective in generating a percept of stereoscopic depth. We may conclude that it is insufficient simply to activate disparity-specific neurons in V1 to perceive stereo depth: there must be a further stage at which the pattern of activation of neurons within V1 is evaluated and tested for consistency prior to the generation of a stereoscopic depth percept.

The role of extrastriate cortex

The evidence that has been reviewed at this point indicates that V1 is important for the initial registration and analysis

of binocular disparity. There are some close matches between the performance of the V1 population of neurons and the psychophysical capabilities of the visual system. However, for a complete explanation of many of the perceptual qualities of binocular stereoscopic depth, it is necessary to look outside V1 in the extrastriate cortex. Evidence concerning the responses of the various extrastriate areas is sparse at the moment, although identification of sites is now of critical importance.

The satisfactory identification of sites will require the application of multiple techniques (single-unit recording, electrical microstimulation, functional magnetic resonance imaging (fMRI) and other imaging methods, visual psychophysics) in combination with tests for the perceptual significance of cortical responses of the kind discussed above for V1. Such experiments are aimed chiefly at providing a neuronal basis for the perceptual psychology of binocular stereopsis. However, the outcome will have implications reaching beyond this issue. For example, early developmental experience has been thought to induce normal binocular function, primarily due to actions upon the striate cortex. Thus, the effect of disrupted visual experience has been interpreted principally in terms of changes in striate connectivity, with extrastriate sites being affected only consequentially due to alterations within V1. Since we can now determine that there must be extrastriate sites that act importantly upon striate signals to generate a complete sense of binocular depth, the discovery of these sites becomes a priority, not only for perceptual psychology but also for the developmental neurobiology of binocular vision.

THE BEGINNINGS OF RELATIVE DISPARITY Since we know that cortical area V1 responds fundamentally to absolute disparity, while psychophysically humans and monkeys are most sensitive to stimuli that include relative disparities, one criterion for interesting extrastriate sites is that they show a specific sensitivity to relative disparity. In both cortical areas V2 and the lateral division of the middle superior temporal area (MSTl), there are reports of neurons that are sensitive to the manipulation of relative disparity as a parameter (Eifuku and Wurtz, 1999; Thomas et al., 2002). Since the evidence from each study is of a rather different nature, they will be described separately before being compared.

There are a number of possible experimental designs for testing for the presence of sensitivity to relative disparity. At the heart of one class of these designs is an approach that establishes criteria for designating a region of the receptive field that may be reasonably termed the *center* and then designating a region immediately adjacent to it that may be termed the *surround*. The experiment then places pairs of stimuli of different disparity in the center and surround and looks for an interaction between the responses of the center and the surround, such that the response to center stimula-

tion is differentially altered by stimuli of different disparity in the surround. The center is generally defined either with respect to the *minimum response field* (Henry et al., 1969) or by obtaining an estimate of the summation area of the center with a stimulus of uniform disparity that is centered on the receptive field and then measuring the neuron's response as a function of stimulus diameter.

With this approach, Thomas et al. (2002) observed, for a proportion of neurons in cortical area V2, that the disparity preference of the center region of the receptive field can be shifted to a different value by changing the disparity of the surround. The direction of the shifts is consistent with a sensitivity to relative disparity. Thus when the disparity of the surround is altered to indicate a surface closer to the subject, the disparity preference of the center shifts in the same direction. The ability to modulate the disparity preference of the center is greater when the surround stimulus is given a disparity close to the tuning preference of the center. In other words, the effect of the surround is strongest when its disparity is close to the natural tuning profile for the center mechanism. This may reflect the fact that psychophysical sensitivity for relative disparity is most acute for small differences in disparity between the two regions to be compared. Only rarely did the neurons studied by Thomas et al. (2002) show magnitudes of shift in the disparity preference of the center consistent with a tuning curve wholly dominated by relative disparity. Nonetheless, in comparison with neurons in V1 (Cumming and Parker, 1999), those in V2 show an impressive transformation of neuronal sensitivity to disparity.

Using a different approach, Eifuku and Wurtz (1999) also examined the modulation of center responses by the disparity of the surround. These authors studied the MSTl. They concentrated on varying the disparity difference between center and surround and examining the effect on firing rate rather than the tuning preference of the neurons. They found that the firing pattern of some neurons was more strongly affected by the relative disparity between the center and surround rather than the absolute disparity of either alone. Although there were strong changes in firing in these experiments, it is not entirely clear that these results represent the same kind of sensitivity to relative disparity found by Thomas et al. (2002).

First, in Eifuku and Wurtz (1999), the range of disparities over which modulation takes place is very large, up to 3 degrees of disparity. At such large disparities, the perceptual sensitivity to relative disparity is weak and the stimuli would very likely be diplopic. Second, while the observations are consistent with a shift in disparity preference of the type found by Thomas et al. (2002), they are also consistent with simpler forms of interaction such as a simple modulation of the gain of the center response by the disparity of surround. Demonstration of a true selectivity for relative disparity (as

opposed to merely a change in response when relative disparity is manipulated) requires a measurable multiplicative interaction between the disparities of the center and the surround upon the response of the neuron rather than an additive effect of each alone. A multiplicative interaction provides the ability to respond invariantly to relative disparity over a range of absolute disparities.

There are other ways in which sensitivity to relative disparity may be significant. Neurons in a number of extrastriate cortical areas are sensitive to the shapes of contours defined by disparity alone (von der Heydt et al., 2000). Some of these neurons exhibit the same selectivity for the orientation of the contour whether they are stimulated with luminance-defined or disparity-defined contours. The mechanisms by which this is achieved are unknown, but sensitivity to relative disparity (Thomas et al., 2002) could feasibly be involved. However, to achieve a segregation of one region from another for contour requires no specific signal about whether one region is in front of or behind another. In this respect, segregation is different from relative disparity (see Fig. 49.7 for a stereogram that illustrates how binocular information can yield segregation without a specific depth difference).

Another role for neuronal signals about relative disparity is in the generation of neuronal receptive fields that are sensitive to the three-dimensional structure of the disparity fields. Some way further forward from V2, in the inferotemporal cortex, there are neurons whose firing rate codes

the curvature of disparity fields (Janssen et al., 2000). The curvature preference of these neurons is maintained over a range of absolute depth values and two-dimensional locations within the visual field. However, it should be emphasized that even these neurons also have some sensitivity to the parameters of two-dimensional location and absolute depth, like the neurons found in V2.

Issues relating to the processing of relative disparity have also recently been addressed in human subjects using fMRI of the brain. Interpretation of the BOLD (blood oxygenation level dependent) response is more complex since it is an indirect measure of pooled neuronal activity, some of which may be nonspiking activity. For this reason, it is harder to link BOLD responses to changes in a sensory parameter such as disparity: the BOLD response has inherently less precision because the cortical signal is pooled over spatial location and time and reflects the metabolic demands of neuronal processing. It is hard to determine which aspects of the stimulus are responsible for the measured response and relate them to the signals in single neurons. For example, it is clear that there are measurable cortical activations generated by contours between spatial regions of the visual field that differ in depth (Mendola et al., 1999). Like the single-unit physiology of von der Heydt et al. (2000), some of these activations probably reflect a generalized response to visual contours rather than to the difference in depth (as in Fig. 49.7).

Backus et al. (2001) used a pair of binocular depth planes whose separation in depth was varied parametrically. The upper and lower limits for the perception of binocular depth were measured psychophysically, and the cortical activation of several extrastriate areas was assessed by comparing the specific activation generated by the two-plane stimulus relative to the general activation created by the one-plane stimulus. Backus et al. argued that cortical areas with specific sensitivity to relative disparity would be more strongly activated by the two-plane rather than the one-plane stimulus and, indeed, the limits of the psychophysical performance correspond rather well with the range of disparities that generate the specific activation. The degree of specific activation for the two-plane stimulus was strongest in cortical area V3A, but several other visual cortical areas also showed signs of specific activation.

Indices of perceptual signals

Another approach to examining the coding of disparity and binocular depth involves studies in which awake, behaving macaques perform a specific binocular depth task while single neurons are recorded simultaneously. The trial-by-trial neuronal responses can then be compared individually with the psychophysical responses of the animal. A general overview of this approach and its application to perceptual

FIGURE 49.7. Random-dot stereogram showing the ability of binocular correlation without a sensation of depth to generate segregation of one image region from another.

processing is available elsewhere (Parker and Newsome, 1998). With one exception already discussed (Prince et al., 2000), the majority of studies that have used this approach to study binocular depth have been performed in middle temporal cortical area V5.

Cortical area V5/MT has been associated for a number of years with a significant role in the perception of visual motion (Movshon et al., 1986; Newsome et al., 1989; Salzman et al., 1990). Although the presence in V5/MT of neurons with selectivity for binocular disparity was discovered at an early stage (Maunsell and Van Essen, 1983) in the exploration of this area, only recently has this knowledge been consolidated through a detailed quantitative study (DeAngelis and Newsome, 1999). It appears that (1) about two-thirds of the neurons in this area show significant selectivity for binocular disparity, (2) the tuning curves are typically odd symmetric in their tuning characteristics about the fixation plane, and (3) there is evidence for a functional clustering of different tuning types, such that neurons preferring “near” or “far” disparities appear to be encountered together.

As previously acknowledged, the presence of neurons with particular tuning properties, even the organization of those tuning properties into a columnar structure, does not constitute adequate evidence for the direct involvement of those neurons in perceptual processing. However, there are now several compelling lines of evidence for a link between the activation of these disparity-specific neurons in V5/MT and binocular depth perception. Such a link does not necessarily mean that a unique role for V5/MT in the perception of binocular depth has been established. The current evidence allows for the possibility of similar links being established for other cortical areas. Even so, it is somewhat surprising to learn that the evidence linking the activity of V5/MT neurons to particular perceptual processes is as strong for binocular depth as it is for visual motion.

There are three main lines of evidence, two of which indicate strong correlations between neuronal activity and perceptual state and the third of which seeks evidence of a more causative nature. The first line of evidence compares the basic sensitivities of the individual neurons against the psychophysical performance of the macaque monkey: this is the comparison of neurometric and psychometric performance (Parker and Newsome, 1998). This comparison has been made for two binocular depth tasks.

In the first of these tasks, the sensitivity to binocular disparity is probed by exploiting the fact that the perceptual ambiguity of structure-from-motion stimuli can be resolved by adding a controlled amount of binocular disparity to the figure. Consider the side view of a transparent cylinder that rotates about its principal axis and is depicted by dots randomly placed on the surface of the cylinder (Fig. 49.8). This cylinder is ambiguous in its direction of rotation if the cylin-

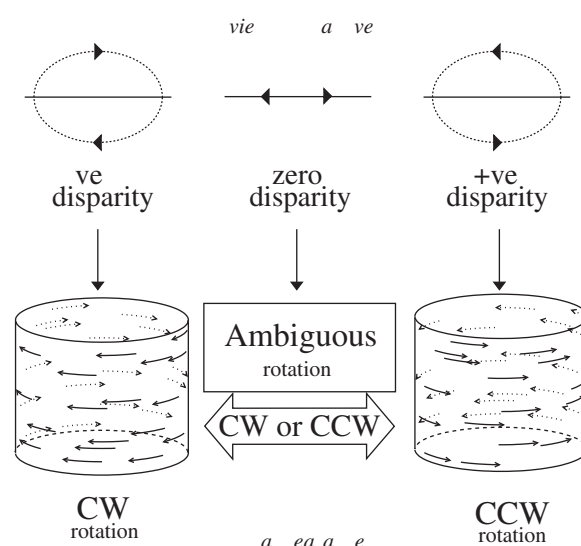

FIGURE 49.8. Diagram of a cylinder depicted by moving patterns of dots. When all the dots have the same binocular disparity (zero) as in the center panel, the direction of rotation of the pattern is inherently ambiguous (see Ullman, 1979, for discussion). Addition of a pattern of disparities that separates the front and rear surfaces of the cylinder fixes the direction of rotation, either as clockwise (left) or counterclockwise (right).

der is viewed monocularly or all the dots are at the same binocular depth plane. This ambiguity is inherent in the motion information, which is insufficient to fix the direction of rotation (Treue et al., 1991). The addition of a binocular disparity that separates the front and rear surfaces determines the direction of rotation. Thus psychophysical observers can be trained to report the direction of rotation of a cylinder stimulus with small amounts of binocular disparity present. The sensitivity of a psychophysical observer to binocular disparity can therefore be assessed in terms of the smallest amount of disparity that makes the direction of rotation unambiguous.

V5/MT neurons respond vigorously to these cylinder stimuli (Bradley et al., 1998; Dodd et al., 2001). In the majority of cases, the neurons' firing changes monotonically as stereoscopic depth is used to separate the front and rear surfaces of the cylinder. This response is much as would be expected for neurons that are conjointly selective for both the visual motion and the binocular disparity in the stimulus, with an odd-symmetric tuning curve for binocular disparity. Analysis of the performance of the neurons in discriminating one direction of rotation of the cylinder from the other shows that single neurons in V5/MT are highly sensitive to binocular disparity. The average neuron was only 1.24 times less sensitive than the psychophysical performance of the macaque monkeys that carried out simultaneous judgments on the stimuli used to test the neurons (Krug et al., 2001).

A broadly similar conclusion has been reached for a quite different form of depth task. In this task, a plane of binocular dots is presented at a relatively coarse disparity, either closer to or farther from the fixation plane. The presence of the plane is disguised by the addition of binocularly uncorrelated dots. The task for the macaque monkey is to identify on any individual trial whether the correlated dots are in the closer or the farther depth plane. The psychophysical performance is assessed by finding the proportion of binocularly correlated dots that are required to sustain this judgment (DeAngelis et al., 1998). A recent study (Uka and DeAngelis, 2001) has compared the sensitivity of single neurons against psychophysical performance on this task. In this case the single neurons were, on average, close in sensitivity to the psychophysical observer.

The second line of evidence that links the activity of V5/MT neurons to the perception of stereoscopic depth arises from an analysis of the trial-by-trial covariation between neuronal firing and behavioral choice in a psychophysical experiment (Parker and Newsome, 1998). This covariation is expressed in terms of a measure called *choice probability*, which takes a value of 0.5 when there is a random association between the neuronal response and behavioral choice and increases to 1 if the neuronal response predicts every psychophysical response. It is a measure of how well an ideal observer would perform in predicting the behavioral response from the firing pattern of a single neuron (Fig. 49.9).

In the earlier work on the sensitivity of V5/MT neurons to visual motion, the choice probability in a direction discrimination task was 0.56 (Britten et al., 1996). This value

was statistically different from 0.5, but it represents a relatively weak association between behavioral choice and neuronal activity. In the same brain area, when macaque monkeys are making perceptual judgments about the direction of rotation of an ambiguous cylinder stimulus, the choice probability is much stronger (0.67; see Dodd et al., 2001). For the task used by DeAngelis et al. (1998), which involves the detection of the depth of a plane of binocularly correlated dots, the choice probability was 0.59 (DeAngelis and Uka, 2001).

Choice probability is inherently a measure of correlation rather than causation, so these differences in measured values must be interpreted with some caution. For example, it would be a mistake to assume that activity in V5/MT is necessarily more strongly associated with binocular depth than with motion analysis simply because the observed choice probabilities are stronger. There are a number of cognitive factors, such as attention, task difficulty, degree of training on the task, and so on, that might affect the measures of choice probability. Equally, at the neuronal level, there are important factors such as the size and connectivity of the neuronal populations activated by these different stimuli, the strength of neuronal activity generated by different stimuli, and the degree of correlation in firing patterns between different members of the active population (Shadlen et al., 1996).

One study has investigated evidence for a causal link between the activation of V5/MT neurons and perceptual decisions about binocular depth (DeAngelis et al., 1998). In this case, electrical microstimulation of a small region of cortex was applied at the same time as a visual stimulus was

FIGURE 49.9. The firing of a single V5/MT neuron to 30 trials in which the macaque monkey was required to judge the direction of rotation of the ambiguous zero-disparity stimulus shown in the middle of Figure 49.8. The impulse counts on each trial are coded with solid symbols when the monkey made a clockwise (CW) judgment about the ambiguous cylinder and open symbols when the monkey made a counterclockwise (CCW) judgment. This neuron fired more strongly to CW rotations with unambiguous cylinders.

The left-hand panel shows histograms of impulse counts, the middle panel shows the individual impulse counts coded by choice on individual trials, and the right-hand panel shows the calculation of choice probability (CP) as the area under the solid curve. The solid curve is constructed using the same principle as the analysis of receiver operating characteristic (ROC) curves in signal detection theory (see Britten et al., 1996; Dodd et al., 2001, for details). (From Dodd et al., 2001.)

presented. When the electrical stimulation was applied in a region of the cortex where the typical neuronal preference was for near disparities, the macaque monkey's perceptual decisions were shifted to generate more "near" decisions. Interestingly, the effects of electrical microstimulation on this task were strongest in those regions of the cortex that had the strongest tuning for binocular disparity. Note, however, that the stimulus and psychophysical task used in these experiments is unlikely to make demands on fine-grained stereoscopic acuity, since the paradigm involves the detection of a minimum level of binocular correlation of dots that have coarse disparities and are located either closer to or farther from the binocular fixation point.

In summary, the evidence linking activity in V5/MT to some aspects of binocular depth judgments must be considered impressively strong. The responses of neurons in this area are individually reliable enough to sustain binocular depth judgments. Their responses sometimes covary tightly on a trial-by-trial basis with perceptual decisions about binocular depth. Artificial activation of this region of cortex influences binocular depth judgments. On the other hand, many V5/MT neurons respond to binocularly anticorrelated patterns in a way broadly similar to the behavior of V1 neurons, even though these patterns do not result in a coherent depth percept. Specifically, it is clear that there are neurons with statistically significant choice probabilities that also modulate strongly to the binocular disparity of anticorrelated random-dot patterns. The first criterion is generally regarded as evidence in favor of a link between neuronal activity and perceptual judgments, while the second criterion suggests that the same neurons carry signals that are not associated with psychophysical depth perception (Krug et al., 2000). It may be that the links between neuronal activity and perceptually relevant signals can be dynamically formed and broken in ways that remain to be determined. Clearly, further experimental investigations are required to resolve these issues. Comparative data from several extrastriate cortical areas will be needed before a more complete picture will emerge.

Concluding remarks

Our understanding of how binocular vision yields a sense of stereoscopic depth is in a time of transformation. We have acquired a solid understanding of the contribution of V1 neurons to this process, and we have a good working model of the functional organization of the binocular receptive fields of these neurons. No doubt our picture of the binocular mechanisms of V1 neurons will continue to be refined and amended. However, it is clear that a bigger task is to gain a deeper understanding of the roles of neurons in the extrastriate visual cortex. Present work has established several aspects of binocular processing that still require a full

explanation at the neuronal level. For example, it is still unclear which neuronal sites support the unambiguous resolution of matching of binocular features from the left and right inputs. In other cases, such as the emergence of a representation of relative disparity, we can already identify an important role for V2, which may be enhanced and further processed by other extrastriate areas.

A speculative argument can be advanced for a binocular pathway concerned with three-dimensional shape, perceptual segregation of different regions of the visual field, and relative disparity judgments that originates in V2 and projects presumably via V4 to regions of inferior temporal cortex. Processing in this pathway depends strongly on accurate establishment of binocular corresponding features between the eyes and on the ability to process fine-grained stereoscopic depth differences.

A different pathway may be concerned with integration of motion and stereo information. This includes V5 (MT), MST, and potentially V3 or V3A. This pathway includes the capability of responding more rapidly to stimuli that change in depth. It may therefore make use of signals based on simpler measures such as interocular correlation (as explored by DeAngelis et al., 1998) and therefore show inversion of disparity tuning curves with binocularly anticorrelated stimuli. A faster responding sensory pathway would also be more naturally selected for the control of binocular eye movements, particularly fast, stereotyped responses (Masson et al., 1997).

The distinction being drawn here has its roots in similar distinctions about fine and coarse stereoscopic processing that have been advanced at various times on the basis of psychophysical and computational arguments (e.g., Mallot et al., 1996). The current evidence suggests that both pathways may have a role to play in perceptual judgments about stereoscopic depth, although the involvement of each pathway is almost certainly task dependent. Mapping these various distinctions onto a coherent neuronal framework remains a task for the future.

Acknowledgments

I thank Kristine Krug for a critical reading of this chapter. Work in our laboratory is supported by the Wellcome Trust and the Royal Society.

VII DETECTION AND SAMPLING

50 Formation and Acquisition of the Retinal Image

DAVID R. WILLIAMS AND HEIDI HOFER

THE QUALITY OF VISION ultimately rests on the properties of both the eye and the brain. For complex visual tasks such as inferring the objects in a three-dimensional visual scene, mechanisms in the brain are obviously paramount in establishing visual performance. However, for simpler tasks such as visual resolution, fundamental constraints on performance often arise in the eye itself. This chapter evaluates the roles for spatial and color vision of early stages of visual processing, beginning with the formation of the retinal image and followed by the acquisition of that image by the photoreceptor mosaic. The chapter focuses on foveal vision, where visual resolution is highest. Discussions of the off-axis optical and neural performance of the eye can be found elsewhere (Jennings and Charman, 1981; Navarro et al., 1993; Packer and Williams, 2003; Thibos, 2000; Williams et al., 1996).

Retinal image formation

Though its optical components are made of living tissue instead of glass, the eye forms a remarkably good retinal image. The quality of this image depends on diffraction at the pupil, aberrations in the cornea and lens, light scatter in the optical media, and the optical properties of the retina. Fourier optics succinctly describes the effects of diffraction and aberrations. For an excellent treatment of Fourier optics in imaging systems generally, see Goodman (1996). See Thibos (2000) or Packer and Williams (2003) for treatments pertaining to the eye.

THE WAVE ABERRATION Figure 50.1*A* shows a perfect and an aberrated eye forming a retinal image of a distant object such as a star. The parallel light rays arriving at the eye from the star can be described alternatively as a series of planar wave fronts. The wave front is always perpendicular to each ray at the point of intersection. The optics of a perfect eye transform this planar wave front into a spherical wave front which collapses to form a compact light distribution on the retina. The perfect eye delays light traveling through different parts of the pupil so that all the light takes exactly the same time to reach the retinal location where the image of the star is formed.

In the aberrated eye shown in Figure 50.1*B*, the wave front is not delayed by the proper amounts and the wave front inside the eye departs from its ideal spherical shape. It fails to collapse to a compact point at the retina, and blurring is inevitable. Aberrations arise from several sources, such as a misshapen cornea or lens, and these errors add. The contributions of the cornea and lens to these errors are often compensatory, especially in young eyes, so that the overall optical quality of the eye is superior to that of either element alone (Artal et al., 2001). We can sum all the errors experienced by a photon passing through the cornea and lens and assign the sum to the point in the entrance pupil of the eye through which the photon passed. It is convenient to express the total error in a unit of distance, such as micrometers (μm), indicating how far the distorted wave front departs at each point in the entrance pupil from the ideal wave front. A map of the eye's entrance pupil that plots the error at each entry point is the eye's wave aberration. The wave aberration captures in one function all the aberrations for a particular wavelength of light that ultimately influence image quality at a particular location on the retina. Figures 50.2*A–D* are wave aberrations for four typical human subjects. Like a fingerprint, the wave aberration is different in different people, though there is often some degree of mirror symmetry between eyes of the same person (Liang and Williams, 1997; Porter et al., 2001). Figure 50.2*E* shows the wave aberration for an ideal eye, which is zero at every point in the pupil.

DECOMPOSING THE WAVE ABERRATION INTO INDIVIDUAL ABERRATIONS To understand more clearly what is wrong with the optics of an individual eye, one can decompose the wave aberration into a number of component aberrations. A Zernike decomposition is used in much the same way that Fourier analysis is used to decompose an image into spatial frequency components. Zernike polynomials are defined on the unit circle, which approximates the natural shape of the eye's pupil. Figure 50.3 shows the pyramid of Zernike modes, akin to the periodic table of elements. Three modes, piston, tip, and tilt, that cap the pyramid have been omitted because these modes do not influence image quality. Modes are characterized by their *radial order*, which refers to the

exponent that describes how the function behaves in the radial direction from the center of the pupil.

Figure 50.4 shows the average magnitude of these modes in a normal population (Porter et al., 2001, see also Castejon-Mochon et al., 2002). The higher-order monochromatic aberrations were measured with a Shack-Hartmann wave front sensor in a population of 109 normal subjects for a 5.7 mm pupil size. The magnitude corresponds to the absolute value of the Zernike coefficient associated with each Zernike mode. Each Zernike coefficient is the root mean square deviation of the wave front from the ideal wave front for each particular Zernike mode expressed in microns. The largest monochromatic aberration of the eye is typically defocus, followed by astigmatism. These are the only aberrations that conventional spectacles and contact lenses correct. However, normal eyes have many monochromatic aberrations besides defocus and astigmatism (Berny and Slansky, 1969; Howland and Howland, 1977; Liang and Williams, 1997; Liang et al., 1994; Sergienko, 1963; Smirnov, 1961; van den Brink, 1962; Walsh and Charman, 1985; Walsh et al., 1984; Webb et al., 1992). Generally speaking, Figure 50.4 shows that aberrations corresponding to more rapidly varying errors across the pupil (i.e., higher radial order) have smaller amplitudes and make a smaller contribution to the total wave aberration for normal eyes.

THE PUPIL FUNCTION The retinal image is made up of light that arrives from many different locations in the pupil. In addition to depending on the eye's aberrations, the quality of the retinal image depends on how much light entering

each location in the pupil actually gets caught by the retinal receptors. The pupil function succinctly captures both the wave aberration and the variation of the effectiveness of light at different points in the pupil. The pupil function is

$$P(\eta, \zeta) = P_0(\eta, \zeta) \cdot \exp\left(i \frac{2\pi}{\lambda} W(\eta, \zeta)\right)$$

where (η, ζ) are two-dimensional spatial coordinates in the entrance pupil and λ is the wavelength of light used to measure the eye's wave aberration, $W(\eta, \zeta)$. $P_0(\eta, \zeta)$ is the amplitude transmittance across the eye's optics, the truncating effect of the iris being the most important. The

FIGURE 50.1. *A*, Retinal image formation for an aberration-free eye. Parallel rays from a distant point source converge inside the eye to a single point on the retina. If light is described as a wave, image formation consists of a planar wave front incident on the cornea that is transformed into a spherical wave front, which collapses to a single point on the retina. *B*, In the case of all real eyes, aberrations deviate the rays so that they do not converge to a point. Alternatively, the wave front is distorted from the ideal spherical shape, and the retinal image is blurred.

FIGURE 50.2. *A–E*, Wave aberrations of real eyes are shown in *A–D*; the flat wave aberration of an ideal, aberration-free eye is shown in *E*. The pupil diameter was 5.7 mm. *F–J*, The point spread functions computed from the wave aberrations shown in *A–E*. *K–O*, The result of convolving the point spread function with the letter

E, which subtended 0.5 minute of arc. Note the increased blur in the real eyes compared to the diffraction-limited eye. The calculations were performed assuming white light, axial chromatic aberration in the eye, and that a wavelength of 555 nm was in best focus on the retina.

FIGURE 50.3. The pyramid showing each of the Zernike modes in radial orders 2 through 5, along with their names and their designation (OSA Standard). Tip, tilt, and piston, which would normally cap the pyramid, have been excluded because they do not influence image quality.

FIGURE 50.4. Mean absolute root mean square (RMS) values for 18 Zernike modes as measured from a population of 109 normal human subjects for a 5.7 mm pupil. The percentages above some modes indicate the percentage of the total wave aberration variance accounted for by each mode. The inset excludes the first Zernike mode corresponding to defocus and has an expanded ordinate to illustrate the magnitudes of higher-order aberrations.

variation in the absorption of the cornea and lens across the pupil is small enough in the normal eye that it can usually be ignored. However, because of the antenna properties of cones, the quantum efficiency of the retina depends on the entry point of light in the pupil. Though this effect, known as the *Stiles-Crawford effect*, is caused by the optics of the retina, it is equivalent to reducing the amplitude transmittance toward the margin of the entrance pupil (see Chapter 53). Therefore, the generalized pupil function for the eye includes the directional sensitivity of the retina in $P_0(\eta, \zeta)$.

THE POINT SPREAD FUNCTION In evaluating the quality of an imaging system such as the eye, it is often useful to characterize the system's point spread function (PSF). The PSF describes the distribution of light in the retinal image when the eye is viewing a distant point source, such as a star, and provides a complete description of image quality at that retinal location for a given wavelength of light. Figures 50.2*F–J* show the PSFs corresponding to the wave aberrations of Figures 50.2*A–E*, respectively. Because of aberrations in real eyes, the PSFs are broader and more irregular than the aberration-free PSF for the same 6 mm pupil size, shown in Figure 50.2*J*.

The PSF is the squared modulus of the Fourier transform of the pupil function. That is,

$$\begin{aligned} PSF(x, y) &= |\mathfrak{F}(P(\lambda d \eta, \lambda d \xi))|^2 \\ &= \mathfrak{F}(P(\lambda d \eta, \lambda d \xi)) \cdot \mathfrak{F}(P(\lambda d \eta, \lambda d \xi))^* \end{aligned}$$

where the Fourier transform is given by

$$\mathfrak{F}(f(\eta, \xi)) = \iint f(\eta, \xi) \cdot \exp[+i2\pi(x\eta + y\xi)] d\eta d\xi$$

This is of fundamental importance, because it allows us to compute the retinal image of a particular object, a single point of light, based on knowledge of the pupil function. Knowledge of the retinal image of a single point of light allows us to compute the retinal image of any object, as we describe later. This is a very powerful result, because it provides a firm quantitative link between aberrations in the eye and their impact on the retinal image.

DIFFRACTION An analysis based solely on geometrical optics might lead one to suppose that the PSF in the aberration-free eye of Figure 50.2*f* would be a single point. But even in this case, the light is spread out somewhat across the retina due to diffraction at the pupil, an inevitable consequence of the wave nature of light. The PSF shown in Figure 50.2*f* has a bright central core, called the *Airy disk*,

surrounded by dimmer rings. The PSF can be described quantitatively by

$$I(r) = [2\mathcal{J}_1(\pi r)/\pi r]^2$$

where $I(r)$ is normalized intensity as a function of distance r from the peak and \mathcal{J}_1 is a Bessel function of the first kind. The radius of the PSF, r_0 , expressed in radians and measured from the peak to the first point at which the intensity is zero, is given by

$$r_0 = 1.22\lambda/\alpha$$

where λ is the wavelength of light and α is the diameter of the circular pupil. Because the width of the diffraction-limited PSF is proportional to wavelength and inversely proportional to pupil diameter, the retinal image quality of this ideal eye is optimum at large pupil sizes and short wavelengths. Figure 50.5 illustrates the inverse relationship between PSF diameter and pupil size for an aberration-free eye.

LIGHT SCATTER In addition to blurring by diffraction and aberrations, the eye's PSF is blurred by light scatter in the anterior optics and retina (Vos, 1963). The sources of intraocular scattered light are (1) forward scatter from the

FIGURE 50.5. PSFs for an ideal, aberration-free eye limited only by diffraction for various pupil diameters. Note that the diameter of the PSF is inversely proportion to pupil diameter. (Courtesy of Austin Roorda.)

cornea, (2) forward scatter from the lens, (3) forward scatter from the retina, and (4) back scatter from the fundus. Roughly a quarter of the scatter comes from the cornea, another quarter from the retina, and the remaining half from the lens. Since most of the forward scattering is by relatively large particles, the scattered light in the eye does not show a strong wavelength dependence (Wooten and Geri, 1987).

Scatter tends to contribute predominantly to broaden and increase the skirt of the PSF. This has the effect of adding a veiling illumination to the retinal image, reducing image contrast at relatively low as well as high spatial frequencies. In the young eye, scatter is not a major source of image blur. It becomes important primarily in the aging eye (Guirao et al., 1999; Westheimer and Liang, 1995), or in the young eye when the observer is required to detect a relatively dim object in the vicinity of a much brighter object. The PSF due to scatter can be summed with the PSF due to diffraction and aberrations, at which point the retinal image can be computed for any object, as described below.

COMPUTING RETINAL IMAGES Once we have the PSF, the retinal image for any arbitrary object can be computed either in the spatial domain or in the frequency domain. In the spatial domain, the intensity distribution of the image, $I(x, y)$, is the convolution of the PSF with the intensity distribution of the object, $O(x, y)$. That is,

$$I(x, y) = \text{PSF}(x, y) \otimes O(x/M, y/M)$$

where M is the magnification between the object and image planes. The convolution of two functions $f(x, y)$ and $g(x, y)$ is

$$f(x, y) \otimes g(x, y) = \iint f(x, y) \cdot g(r - x, s - y) dx dy$$

In practice, the computation of the retinal image is more efficient in the spatial frequency domain. In that case, the intensity distribution of the object, $O(x, y)$, is Fourier transformed to provide the object Fourier spectrum, $\sigma(f_x, f_y)$. That is,

$$\sigma(f_x, f_y) = \mathfrak{F}(O(x, y))$$

The object Fourier spectrum is then multiplied by the optical transfer function (OTF) of the eye to give the image Fourier spectrum:

$$i(f_x, f_y) = \text{OTF}(f_x, f_y) \cdot \sigma(Mf_x, Mf_y)$$

By taking the inverse Fourier transform of the image spectrum, one obtains the retinal image

$$I(x, y) = \mathfrak{F}^{-1}(i(f_x, f_y))$$

The OTF is the autocorrelation of the pupil function. Alternatively, the OTF can be computed by taking the Fourier transform of the PSF. The OTF is complex, consisting of two parts, a modulation transfer function (MTF) and a phase transfer function (PTF). The MTF indicates how faithfully the contrast of each spatial fre-

quency component of the object is transferred to the image. The PTF indicates how individual spatial frequency components of the object have been translated in the retinal image.

ESTIMATES OF THE POINT SPREAD FUNCTION AND MODULATION TRANSFER FUNCTION Figure 50.6 illustrates how the PSF changes with pupil diameter for a typical human eye when both aberrations and diffraction are taken into account. At small pupil sizes, aberrations are insignificant and diffraction dominates. The PSF takes on the characteristic shape of the Airy pattern, with a wide core and little light in the skirt around it. At larger pupil sizes, aberrations dominate. The PSF then has a small core but reveals an irregular skirt that corresponds to light distributed over a relatively large retinal area. A pupil size of roughly 3 mm in diameter represents a good compromise between blur due to diffraction and aberrations (Campbell and Gubisch, 1966). In this case, the full width at half height of the PSF is approximately 0.8 minute of arc, corresponding to nearly twice the width of a cone at the foveal center.

Retinal image quality is often represented by the MTF instead of the PSF, mainly because only relatively recently has it been possible, with the advent of wave front sensing, to recover the PSF. Only the MTF was accessible with earlier methods of measuring the optical quality of the eye, such as laser interferometry and the double pass technique (Artal et al., 1995). The MTF by itself is not as complete a description of the eye's optics as the PSF, because it does not include the PTF. Image quality in the human eye depends on the PTF when the pupil is large (Charman and Walsh, 1985). Furthermore, accurate phase information is important for the perception of complex scenes (Piotrowski and Campbell, 1982). Nonetheless, the MTF has its uses, especially in situations where the contrast sensitivity of the eye is involved. In that case, knowledge of the MTF of the optics allows the segregation of optical and neural factors in visual performance.

The solid curves in Figure 50.7 show MTFs for a diffraction-limited eye with pupil diameters ranging from 2 to 7 mm calculated for a wavelength of 555 nm.

Figure 50.7 also shows the mean monochromatic MTFs (*dashed lines*) computed from the wave aberration measurements for 14 eyes made with a Shack-Hartmann wave front sensor (Liang and Williams, 1997). For small pupil sizes, the MTF is high at low spatial frequencies owing to the absence of light in the skirt of the PSF. For large pupil sizes, however, the MTF is reduced at low spatial frequencies due to the large skirt in the PSF that aberrations produce. However, at high frequencies, the MTF is higher than that for small pupils due to the narrower core of the PSF. The implication of this is that although a 2 to 3 mm pupil is commonly said to represent the best trade-off

FIGURE 50.6. PSFs for a typical real eye for various pupil diameters. Defocus and astigmatism have been zeroed. Note that diffraction controls the PSF shape for small pupils, whereas aberrations dominate for large pupils. (Courtesy of Austin Roorda.)

between diffraction and aberrations, there is no single optimum pupil size. The optimum size depends on the task. Smaller pupils minimize optical aberrations for visual tasks involving low spatial frequencies. Larger pupils transmit high spatial frequencies for tasks that involve fine spatial detail even though they suffer more aberrations. If the goal is to resolve very fine features in images of the retina, then larger pupils transfer more contrast. With increasing pupil diameter, the difference between the diffraction-limited and real MTFs grows due to the decrease in the contribution of diffraction to retinal blur and the increase in the role of aberrations.

RETINAL IMAGES IN POLYCHROMATIC LIGHT In everyday viewing situations, the eye is confronted with broadband light instead of monochromatic light. The assessment of retinal image quality then demands that the effects of chromatic aberration be taken into account. Chromatic aberration arises because the refractive index of the ocular medium increases with decreasing wavelength. Consequently, any light rays incident on the cornea will generally be bent more if the wavelength is short than if it is long. See Thibos (1987) for a review of chromatic aberration in the eye. There are two kinds of chromatic aberration, axial and transverse. The main effect of axial chromatic aberration is to cause the

Zernike polynomial corresponding to defocus to vary with wavelength. All the other aberrations retain roughly the same amplitudes when expressed in microns (Marcos et al., 1999). Across the visible spectrum from 400 to 700 nm, the difference of focus caused by axial chromatic aberration is about 2.25 diopters. Transverse chromatic aberration can manifest itself either as a lateral displacement of a single point in a scene or as a magnification difference of an extended object. In the typical human eye, transverse chromatic aberration does not reduce image quality very much in the fovea.

The blur produced by chromatic aberration does not have especially important effects on spatial vision. The largest aberrations in human eyes are defocus and astigmatism, followed by the aggregate effect of all the remaining, higher-order monochromatic aberrations. Chromatic aberration is not as large as the combined effect of the higher-order aberrations, and its influence on vision is less pronounced. Campbell and Gubisch (1967) found that contrast sensitivity for monochromatic yellow light was only slightly greater than contrast sensitivity for white light. Visual performance on spatial tasks usually depends very little on the S cones, the cone class that would generally experience the greatest retinal image blur due to axial chromatic aberration. Moreover, the proximity of the L and M absorption spectra means

FIGURE 50.7. MTFs calculated for eyes with pupils ranging from 2 to 7 mm. In each panel, the solid line shows the MTF for an eye whose optics suffer only from diffraction, $\lambda = 555$ nm. The dashed lines show the mean monochromatic MTFs of 14 normal human eyes. MTFs were computed from wave aberration measurements obtained with a Hartmann-Shack wave front sensor and a 7.3 mm pupil (Liang and Williams, 1997). The dotted lines show the MTFs expected in white light, taking into account the axial but not the transverse chromatic aberration of the eye. The eye was assumed

to be accommodated to 555 nm, and its spectral sensitivity was assumed to correspond to the photopic luminosity function. The MTFs were calculated without defocus and astigmatism by setting the appropriate Zernike terms in the wave aberration to zero. This is not quite the same as finding the values of defocus and astigmatism that optimize image quality, as one does in a conventional clinical refraction. Had such an optimization been performed, the white light and monochromatic MTFs would have been more similar.

that the deleterious effects of axial chromatic aberration will be similar for both cone types. The reduced spectral sensitivity of the eye at short and long wavelengths also reduces the deleterious effects of chromatic aberration. In fact, the 2 diopters of defocus produced by chromatic aberration will have an effect on image quality similar to that of 0.15 diopter of monochromatic defocus, an amount that is close to the limit of what can be detected (Bradley et al., 1991). A less widely recognized reason that chromatic aberration is not more deleterious is that it is overwhelmed by the numerous monochromatic aberrations. These aberrations, most of which spectacles fail to correct, dilute the impact of axial chromatic aberration (Marcos et al., 1999; Yoon and Williams, 2002).

Figure 50.7 compares the MTFs in monochromatic (*dashed curves*) and broadband (*dotted curves*) light. These curves were obtained by computing the separate MTFs at each wavelength and then computing from these the mean MTF, weighting the influence of each separate MTF by the photopic luminosity function.

Retinal image acquisition

SPATIAL FILTERING BY THE CONE APERTURE Once light passes through the optics of the eye, it must pass through the retina on its way to the photoreceptors that transduce the retinal image. Foveal cones enjoy relatively unperturbed access to the retinal image because the inner retina and its associated vasculature have been swept aside to form the foveal pit. The photoreceptors themselves blur the retinal image by averaging light within their collection area (Miller and Bernard, 1983). The size of the human foveal cone aperture has been estimated psychophysically in humans to correspond to about half of the anatomical diameter (MacLeod et al., 1992). This estimate probably represents the lower bound of its true size. Even under the assumption that the cone aperture corresponds to the size of a foveal cone ($\sim 2.5 \mu\text{m}$), it is half the size of the eye's optical PSF for an aberrated eye with a 3 mm pupil. Therefore, under normal viewing conditions, the spatial resolution of the eye is not limited by the spatial frequency bandwidth of the cone aperture (Williams, 1985).

PHOTORECEPTOR TOPOGRAPHY Color and spatial vision at high light levels is subserved by 4 to 5 million cones (Curcio

et al., 1990; Osterberg, 1935) that are distributed unevenly across the retina. Cone density peaks at an average of 200,000 cones/mm² at the center of the fovea, then falls sharply to one-half maximum at less than 0.2 degree of eccentricity, to one-tenth maximum at 1 degree of eccentricity, and to 5000 cones/mm² or less near the edge of the retina. Foveal cones are set in a lattice which has an approximately triangular packing arrangement, as illustrated in Figure 50.8. The mean center-to-center spacing of the most central cones has been measured anatomically at 2.24 μ m (27 seconds of arc) (Curcio et al., 1990) and interferometrically (see below) in the living human eye at 2.7 μ m (32 seconds of arc) (Williams, 1988).

OBSERVATIONS WITH LASER INTERFEROMETRY An especially effective way to investigate image acquisition by the retina is with the use of laser interferometry. Interference fringes are formed on the retina by passing all the light through two small point sources imaged near the eye's pupil. Because the eye's wave aberration is constant at the small spatial scale of these point sources, the blurring effects of the eye's optics are avoided (Arnulf and Dupuy, 1960; Campbell and Green, 1965; Le Grand, 1935; Williams, 1985). When the two beams from a single laser overlap at the retina, they interfere with each other, producing an interference fringe with a sinusoidal luminance profile whose spatial frequency is proportional to the beam separation. The spatial frequency of the interference fringe is limited only by the size of the pupil. In the case of an 8mm pupil, the cutoff exceeds 200 c/deg in visible light. Normal observers viewing inter-

ference fringes can resolve the regular stripes of the fringe up to frequencies in the range from 45 to 70 c/deg, depending on the observer and whether steps have been taken to reduce laser speckle, which otherwise masks interference fringes (Williams, 1985). At higher spatial frequencies, many observers report seeing a scintillating pattern of irregular stripes that are not present in the original image (Byram, 1944; Campbell and Green, 1965; Williams, 1985). Perhaps the first report of this phenomenon was that of Bergmann (1858), who reported seeing similar effects when viewing gratings without the benefit of interferometry. Figure 50.9 shows drawings of the appearance of high-frequency fringes from several sources.

Figure 50.10 demonstrates the origin of this phenomenon using a simulation first suggested by Yellott (1982). When the spatial frequency exceeds the resolution limit of about 60 c/deg, a lower-frequency, distorted moiré pattern occurs that is indistinguishable from the regular, higher-frequency pattern that is actually imaged on the mosaic. This moiré pattern can be exploited to study the topography of the photoreceptor mosaic in the living human fovea (Williams, 1988).

The subjective observations of interference fringes that exceed the limit of visual resolution can be well described by a two-stage model (Tiana et al., 1991). The first stage samples the continuous retinal image with the photoreceptor mosaic, and the second stage reconstructs the sampled image with a postreceptoral, low-pass spatial filter that accepts spatial frequencies up to the resolution limit and rejects those above it. At spatial frequencies above about 60 c/deg, the spatial filter rejects the original

FIGURE 50.8. Image of the center of the living human fovea obtained with the Rochester Adaptive Optics Ophthalmoscope. Because of the 1 degree field of view of the instrument, this larger image was constructed by merging a number of overlapping images centered at different locations. The height of the image is 0.98

degree and its width is 2.2 degrees, extending from 0.7 degree temporal to 1.5 degrees nasal retina. Note the increase in cone spacing with increasing distance from the foveal center. (Courtesy of Matt MacMahon and Heidi Hofer.)

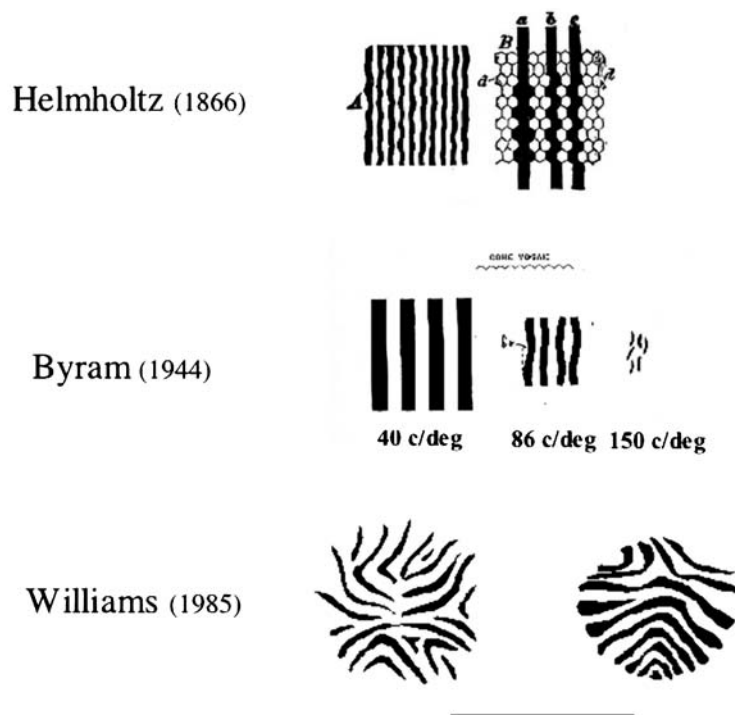

FIGURE 50.9. Drawings from three different authors of the appearance of high-frequency gratings, illustrating distortions in the appearance of the gratings caused by aliasing.

FIGURE 50.10. Simulation of aliasing in which a 30, 60, 90, and 120 c/deg fringe is superimposed on the foveal cone mosaic. Cone locations, taken from a tangential section of primate fovea, are represented as points. The 30 c/deg grating is adequately sampled by the mosaic, and the 60 c/deg grating is near the Nyquist limit. When the limit is exceeded, the reader interprets the image as a low-frequency, distorted moiré pattern instead of a high-frequency grating. At 120 c/deg, the grating period roughly equals the cone spacing, which produces a very coarse alias.

grating and passes the moiré patterns generated by the cone mosaic.

This phenomenon is closely related to the sampling theorem (Shannon, 1949). In its simplest form, to reconstruct a one-dimensional signal from a set of regularly spaced samples, the sampling rate must be equal to or greater than twice the highest frequency in the signal. Put another way, the highest spatial frequency that is adequately sampled, known as the *Nyquist limit*, is half the sampling frequency. Aliasing, which is essentially the creation of a low-frequency moiré pattern, results from exceeding the Nyquist limit. The sampling theorem is often applied to the cone mosaic, despite the fact that the mosaic is neither regular nor one-dimensional. The cone mosaic is a disordered two-dimensional sampling array. See Peterson and Middleton (1962) for a discussion of two-dimensional sampling. In the case of the foveal cones, the packing geometry is regular enough to produce moiré patterns that look like zebra stripes, while outside the fovea, aliasing takes on the appearance of two-dimensional spatial noise.

The optical quality of the eye plays a major role in preventing foveal cone aliasing from disrupting visual experience under normal viewing conditions. Figure 50.11 shows the relationship between the eye's MTF for various pupil sizes and the foveal cone Nyquist limit. The optics of the eye filter out those spatial frequencies above ~ 60 c/deg that exceed the Nyquist limit of the foveal cone mosaic, and these

are the frequencies that could produce aliasing. This relationship between optics and mosaic is often described as one in which they are matched, first articulated by Helmholtz (1896). While this is approximately true for the fovea, the optics are substantially superior to the grain of the peripheral mosaic and especially that of subsequent neural sampling arrays en route to the brain. The spatial frequency spectra of natural visual scenes generally have amplitudes that decline as the inverse of spatial frequency (Field, 1987). This allows the optics to provide higher contrast in the retinal image at sub-Nyquist frequencies without encountering aliasing. Snyder et al. (1986) argued convincingly that evolution should drive the cutoff frequency of the eye's optics to frequencies higher than the Nyquist limit. This is because the resulting improvement in image contrast at spatial frequencies below the Nyquist limit more than offsets the deleterious effects of any aliasing of spatial frequencies above the Nyquist limit.

The Nyquist limit is not an impenetrable barrier beyond which the eye cannot possibly resolve (Ruderman and Bialek, 1992; Williams and Coletta, 1987). Spatial sampling does not obliterate contrast in the retinal image above the Nyquist frequency in the same way that spatial filtering drives the contrast to zero above the cutoff frequency set by diffraction. The sampling process by itself usually has no effect on image contrast. Instead, by reducing the dimensionality of the image, it introduces ambiguity simply because the signal between the sample points is unknown. The original object becomes only one of an infinite number of objects that could have generated the observed distribution of quantum catches. It is then up to postreceptoral processes, probably involving the use of a priori information, to interpret the ambiguous image. Experimental support for the idea that the Nyquist limit is not impenetrable comes from Williams and Coletta (1987), who showed that observers could reliably discriminate the orientation of gratings at spatial frequencies 50% greater than the Nyquist limit in the parafoveal retina. Subsequent unpublished experiments by David Brainard in my laboratory showed that spatial frequency discrimination was exceedingly poor for frequencies above the Nyquist limit. Nonetheless, limited orientation information is preserved at supra-Nyquist spatial frequencies.

Appealing solely to the Nyquist limit of the sampling theorem oversimplifies the mechanisms that actually set the resolution limit. Strictly speaking, the retina and brain as well as the cone mosaic share the responsibility for setting the visual resolution limit. This point has been made with intriguing experiments that show perceptual consequences of interference fringes that exceed the resolution limit (He and MacLeod, 2001; Macleod and He, 1993). If foveal grating resolution were determined by cone sampling alone, then one would expect the highest spatial frequency inter-

FIGURE 50.11. The relationship between the eye's modulation transfer function for 2, 4, and 6 mm pupils and the foveal cone Nyquist limit and sampling rate. Because the modulation transfer is greatly reduced at frequencies in excess of the Nyquist limit, the eye's optics protect vision from aliasing under normal viewing conditions.

ference fringe that can be resolved to increase with increasing contrast until the Nyquist barrier is reached and remain constant thereafter. Surprisingly, this is not always the case. In a previously unpublished experiment in my laboratory, an observer adjusted the spatial frequency of a fixed-contrast interference fringe to find the highest spatial frequency at which a grating could be seen in foveal vision. Figure 50.12 shows these settings with filled-circle symbols for various fringe contrasts. Also shown are forced-choice contrast sensitivity measurements (filled-square symbols), in which observers could detect gratings at very high spatial frequencies due to aliasing by the cone mosaic (Williams, 1985) and nonlinear distortion (He and MacLeod, 1996; Sekiguchi et al., 1991). The striking thing about the acuity settings is that, for contrasts above about 15%, acuity declines significantly with increasing contrast. Very high contrast stimuli near the resolution limit have a dazzling appearance, including a change of hue that is diminished at reduced contrast.

The nervous system is not able to represent these stimuli, faithfully, possibly because such high spatial frequencies at such high contrast are not experienced in normal viewing. We know that adults reared with cataracts have impressively poor visual performance even when their optics are restored (Fine et al., 2002; Gregory, 1990). Amblyopia demonstrates how restricted visual experience during development can lead to permanent neural deficits. It is plausible that the data in Figure 50.12 illustrate a kind of amblyopia in normal eyes, an amblyopia that is revealed only when the normal optics are improved. It would be of some interest to know whether

FIGURE 50.12. Forced-choice contrast sensitivity for laser interference fringes (632.8 nm) (*squares*). Fringes can be detected beyond the resolution limit due to nonlinearities in the retina as well as aliasing by the cone mosaic. *Circles* show acuity for resolving regular stripes in interference fringes obtained with the method of adjustment. The highest settings slightly exceed the Nyquist limit for this observer of about 56 c/deg, which may be an example of supra-Nyquist resolution. As fringe contrast is increased above about 15%, acuity actually declines rather than increases. This may be due to the fact that the visual system of this observer developed without exposure to such high-contrast stimuli at such high spatial frequencies and lacks the capacity to represent such stimuli.

extended experience with high-frequency interference fringes can improve resolution.

TRICHROMATIC SAMPLING AND CHROMATIC ALIASING So far, we have considered sampling by the cone mosaic without distinguishing between different classes of cone. The normal cone mosaic is composed of three submosaics of cones, L, M, and S, as shown in Figure 50.13. Unlike color film, which samples each location in the image with three emulsions, the retina samples the image with only one spectral sensor at each location. This means that at a local spatial scale, the retina is color blind. Because the sampling density of each submosaic is necessarily lower than the sampling density of the mosaic as a whole, chromatic aliasing can arise at lower spatial frequencies than the Nyquist limit for the mosaic as a whole.

Holmgren (1884) noticed that the hue of stars varied from instant to instant, a fact he attributed to selective excitation of different cone classes as the point of light moved across the mosaic. This observation is a form of chromatic aliasing and has led to a number of investigations that probe the cone mosaic with small spots (cf. Cicerone and Nerger, 1989; Krauskopf, 1978; Vimal et al., 1989). This color fluctuation is never very salient, because the optics of the eye blur the point of light across several cones. It has recently become possible to use adaptive optics (Liang et al., 1997) to reduce

the diameter of the spots of light to less than the diameter of an individual cone. Under these conditions, Heidi Hofer at the University of Rochester has shown that the chromatic fluctuations are greatly increased.

Chromatic aliasing can also be observed when viewing spatially extended stimuli as well as sharply focused points of light. High-contrast patterns such as black and white lines with spatial frequencies between 10 and 40 c/deg sometimes appear to contain splotches of desaturated color (Brewster, 1832; Erb and Dallenbach, 1939; Luckiesh and Moss, 1933; Skinner, 1932). Williams et al. (1991) have named this effect *Brewster's colors* after the first person to have described them. The visual system is remarkably resistant to the effects of chromatic aliasing. In those cases in which it can be detected at all, it is subtle and fleeting. The visual system has apparently evolved the capacity for color discrimination without any substantial cost for spatial vision under natural viewing conditions. The statistics of natural scenes make high-contrast, high spatial frequency signals rare events, optical blurring in the eye reduces the potential for aliasing, and clever postreceptor processing based on prior information about natural visual scenes may also tend to hide the apparently haphazard organization of the trichromatic mosaic.

S cones are of particular interest because they sample the foveal retinal image especially coarsely, accounting for less than 10% of the cone population (Ahnelt et al., 1987; Bumsted and Hendrickson, 1999; Curcio et al., 1991; de Monasterio et al., 1981, 1985; Roorda and Williams, 1999; Wikler and Rakic, 1990; Williams and Collier, 1983; Williams et al., 1981b). Correspondingly, the resolution of gratings seen only by S cones is one-fourth to one-sixth that of the luminance mechanism fed by L and M cones (Stromeyer et al., 1978; Williams and Collier, 1983), and S cone aliasing is seen above the resolution limit. In the human fovea, S cones are randomly arranged, at least in local patches of retina, so that aliasing appears as spatial noise instead of the more regular zebra stripe-like patterns seen in foveal vision with interference fringes. A widely accepted explanation for the sparse sampling by S cones is that chromatic aberration blurs the short-wavelength retinal image enough that the sparse sampling is adequate to capture the retinal image seen by the S cone mosaic (Yellott et al., 1984).

In most though perhaps not all human foveas, S cones are absent in the central 20 minutes of arc (Williams et al., 1981a). It is especially striking that this is not subjectively obvious since it renders us tritanopic within the most acute portion of our visual field. The brain must be equipped with sophisticated mechanisms capable of hiding this gaping chromatic blind spot from us (Brainard and Williams, 1993; Magnussen et al., 2001). A priori information presumably plays a role.

FIGURE 50.13. Images of the cone mosaics of 10 subjects with normal color vision, obtained with the combined methods of adaptive optics imaging and retinal densitometry. The images are false colored so that blue, green, and red are used to represent the S, M, and L cones, respectively. (The true colors of these cones are yellow, purple, and bluish-purple). The mosaics illustrate the enormous variability in L/M cone ratio. The L/M cone ratios are *A*, 0.37, *B*, 1.11, *C*, 1.14, *D*, 1.24, *E*, 1.77, *F*, 1.88, *G*, 2.32, *H*, 2.36, *I*, 2.46, *J*, 3.67, *K*, 3.90, *L*, 16.54. The proportion of S cones is relatively

constant across eyes, ranging from 3.9% to 6.6% of the total population. Images were taken either 1 or 1.25 degrees from the foveal center. For two of the 10 subjects, two different retinal locations are shown. Panels *D* and *E* show images from nasal and temporal retinas respectively for one subject; *J* and *K* show images from nasal and temporal retinas for another subject. (Images *C*, *J*, and *K* are from Roorda and Williams, 1999. All other images were made by Heidi Hofer.) (See color plate 30).

Because the sampling densities of the L and M cone submosaics are lower than the density of the mosaic as a whole, one might expect to find a reduction in the acuity of the separate L and M cone submosaics. However, there is no measurable difference in contrast sensitivity or acuity when the L and M cones are isolated compared to conditions in which they operate together (cf. Brindley, 1953; Williams, 1991). This is true even when laser interference fringes are used to exclude blurring by the optics of the eye. To be sure, resolution declines when the density of cones in the submosaic becomes sparse enough. The S cone submosaic is a case in point. Nonetheless, relatively large density losses have no obvious effects on grating acuity (Geller et al., 1992). This is almost certainly due to the disordered arrangement of L and M cones, which creates small clumps of like-type cones whose spacing is much less than the average spacing of that submosaic. These clumps may

be sufficiently large and common to subserve better than expected acuity, especially with extended stimuli such as large patches of grating. Only when one cone class is greatly underrepresented, as in some heterozygous carriers for congenital X-linked protanopia, is resolution clearly affected in cone-isolating conditions (Miyahara et al., 1998). Presumably, visual stimuli that are more localized, such as vernier targets, would be better suited to reveal a deficit due to the coarser grain of the separate L and M cone submosaics.

VARIATION IN CONE RATIO AND COLOR VISION A wealth of evidence shows that the ratio of L to M cones is highly variable in the normal population (Bowmaker and Dartnall, 1980; Dartnall et al., 1983; Hagstrom et al., 1997; Jacobs and Deegan, 1997; Jacobs et al., 1993; Roorda and Williams, 1999; Rushton and Baker, 1964; Vimal et al., 1989;

Yamaguchi et al., 1997). This is illustrated in Figure 50.13, which shows images of the cone mosaic obtained with adaptive optics in the retinas of ten different eyes. The L/M cone ratio ranges from 0.37 to 19.5. Gunther and Dobkins (2002) found evidence that chromatic contrast sensitivity was depressed slightly in subjects with extreme ratios of L to M cones estimated with flicker photometry. Nonetheless, it is striking how little difference the ratio of L to M cones makes for vision, except when the ratio becomes extreme. Due to the similarity of the M and L cone spectra, the photopic luminosity function changes relatively little with large changes in the L/M cone ratio (cf. Jacobs and Deegan, 1997). Color appearance, at least for large stimuli where aliasing is not an issue, seems not to depend on the L/M ratio (Brainard et al., 2000; Miyahara et al., 1998; Neitz et al., 2002). The subjective boundaries between hues are apparently set by factors other than cone numerosity. As Pokorny and Smith (1977) proposed, the balance point of color opponent mechanisms may be determined by the average chromaticity in natural scenes. This would be a more efficient choice for the visual system since it would minimize the metabolic cost of transmitting neural signals about the most common colors in the world, reserving resources for departures from the average. Neitz et al. (2002) have recently reported some experimental support for this view, showing that the color boundary between red and green, unique yellow, can undergo modification over a period of many days of exposure to an altered chromatic environment. Presumably, this same mechanism explains the constancy of color vision despite the large spectral changes in the lens with age (Werner, 1996).

THE LIMITS OF HUMAN VISION An optical engineer, undertaking to design the human eye, would not have chosen the same parameters for optical quality and sampling that evolution has created in the eye. The coarse and random sampling performed by the three cone submosaics would generally be unacceptable in a digital camera that has the optical quality of the eye. It must be that central mechanisms for object recognition are especially good at rejecting sampling artifacts, and it seems likely that experience with visual scenes during development is used to create representations that hide the grain of the neural visual system from us under ordinary viewing conditions.

Given the tolerance the visual system has for undersampling, it is natural to wonder how much normal vision could be improved by improving the optics of the eye (Charman, 2000; Williams et al., 2001). Laser interferometry shows that grating resolution does not improve much. In practice, interferometry is limited to the presentation to the retina of a small number of monochromatic gratings of different spatial frequency and orientation. Adaptive optics, on the other

hand, can increase the retinal image contrast of any arbitrary stimulus with any spectral properties. Adaptive optics, unlike interferometry, is subject to blurring by diffraction. Nonetheless, it can be used to correct the eye's higher-order monochromatic aberrations as well as defocus and astigmatism. Correcting higher-order aberrations in normal eyes increases contrast sensitivity by roughly a factor of 2 on average at high frequencies (Yoon and Williams, 2002). In the average eye, correcting higher-order aberrations will produce a benefit only when the pupil is large. With a 6 mm pupil, the higher-order aberrations are roughly equivalent to one-third of a diopter of defocus (Guirao et al., 2002). Of course, this benefit is highly variable, depending on the amount of higher-order aberrations in the eye. There are large individual differences in higher-order aberrations, just as there are for astigmatism.

It is advantageous to correct higher-order aberrations in eyes that have large amounts of these aberrations, and the recent excitement in wave front sensing and wave front correction with customized contact lenses and refractive surgery offers the possibility of substantial benefit in these people. However, in eyes with good optical quality already, the benefit of correcting higher-order aberrations comes with some costs in addition to the possibility of aliasing. Color artifacts associated with chromatic aberration are increased. It is possible to detect the chromatic fringing caused by chromatic aberration in normal viewing conditions, and the accommodative mechanism can sometimes use this effect to pick the direction with which to accommodate (Fincham, 1951; Kruger and Pola, 1986). Correcting monochromatic aberrations in broadband light makes chromatic aberration even more visible. White targets seen through adaptive optics reveal quite pronounced blue-green fringes when the eye is slightly myopic and reddish fringes when the eye is slightly hyperopic. Long-term exposure to chromatic fringes makes them less visible (Held, 1980), and it is possible that adaptation could reduce the visibility of this effect as well.

Another possibly negative effect of correcting the monochromatic aberrations of the eye is that the depth of field is reduced. This is illustrated in Figure 50.14, which shows the Strehl ratio of the eye's PSF as a function of light vergence. These data were calculated from wave aberration measurements of 13 eyes, assuming an equal energy spectrum and axial chromatic aberration in the eyes. Pupil size was 6 mm. Note that correcting monochromatic aberrations increases image quality over a range of about 1.25 diopters, but outside this region, image quality is actually lower with correction than without it. If the eye's chromatic aberration is also corrected, the benefits when focus is optimized are even greater but the depth of focus is even smaller. The true cost of this loss of depth of field in everyday vision has not been explored.

FIGURE 50.14. The Strehl ratio of the eye's PSF as a function of light vergence.

The parameters that the eye has evolved for image formation and image acquisition seem to be well balanced in the best human eyes so that improvement in any single parameter does not create large improvements in visual performance and can even come at a cost.

Acknowledgments

The authors wish to thank Antonio Guirao, Jason Porter, and Geunyoung Yoon for their contribution to the chapter. Williams' laboratory is supported by National Institutes of Health Grants EY01319 and EY07125 and the National Science Foundation Science and Technology Center for Adaptive Optics, managed by the University of California at Santa Cruz under cooperative agreement No. AST-9876783.

51 Thresholds and Noise

THEODORE E. COHN

A NATURAL WAY TO describe the quality of a visual detection system is to specify the least amount of light that can be seen. This concept was formalized by Fechner (1860) in the mid-nineteenth century and persists with us today. The concept was given a name, *threshold*, which has evolved in meaning as understanding of threshold phenomena has increased. Most importantly, we have begun to understand the nature of the threshold and its relation to noise.

The title of this chapter is redundant. In vision there cannot be thresholds without noise. With noise, vision is limited. Without noise, the only limit is the grain of light itself; a single photon is the irreducible threshold. And while the concept of *noise* has only recently crept into our thinking about threshold, it is central to the discussion. Noise is ubiquitous. It is intrinsic to all light sources, it arises as a result of pupil instability, and it is characteristic of all cell membranes, including those of neurons, and of all chemically mediated synapses.

In this chapter I trace the concept of the threshold to its most recent embodiment. Related topics will be examined: physiological thresholds and psychophysical thresholds, dependence of threshold upon adaptation level, target size, duration and color; threshold models, and key unexplored problems. The discussion begins with three different definitions of threshold: the classical one due to Fechner, the traditional concept that replaced it, and finally the modern version.

The classical (Fechnerian) threshold

Fechner is said to have borrowed a concept from Hebart, that of a *limen* or limit below which intensity is too small to be seen (Boring, 1942). Thus energy at or below the limen is unseen, while that above the limen is seen. This concept is shown schematically in Figure 51.1A. Measurement, by techniques that Fechner himself introduced, disproved the elegance of this concept immediately. No such unique limit can be found experimentally. Instead, the limit gives the appearance of whimsy: it is sometimes at one value, sometimes at another, and always both changing and unpredictable. Figure 51.1B illustrates this modified classical threshold for three different instances: low, medium, and high. The evidence for this modified theory is that some intensity that is not (reported as) “seen” on one occasion may be seen on the next, and one that was seen might not be seen later.

One can imagine that for repeated examples, the measured frequency seen will equal the fraction of occasions on which threshold, defined in this way, is exceeded. Thus, the measured frequency seen averages over a multiplicity of instances, and the result is a curve that rises from zero or a few instances seen and asymptotes at 100% seen. Instances of reports of seen intensity when no stimulus has been delivered have been known since the time of Fechner. Thus the frequency of reports seen may rise from a nonzero value at zero contrast. As will be seen below, there are two different ways of dealing with such events. One assumes that they are guesses and then modifies all seen events by a putative guess rate. The other approach treats these as noise-caused events and uses them to gain a greater understanding of the relevant noise.

Figure 51.2 shows an example of such a frequency seen curve (also termed a *psychometric function*—see the later section “The Psychometric Function”) and, on the same abscissa, the putative probability density of the threshold value. In a sense, then, this traditional concept of the threshold incorporates a sort of noise, a random variability of the value of the threshold. The conclusion that Fechner and the entire vision community reached, and that held for 100 years, was that of a randomly varying limen or threshold. The inclusion of randomness in this model may have been the first acknowledgment that noise had to play a role in threshold, though this was not explicit. How then to quantify or estimate the threshold?

The traditional threshold

A threshold that varies randomly over time is best described by its typical value, hence the search for a mean or average. In a yes/no task, the probability with which a presented stimulus will be judged to be present usually varies monotonically with the stimulus intensity. This function is called the *psychometric function*. The (traditional) threshold is defined by convention. It is taken as the intensity that leads to a probability of detection of some prescribed value that is usually, though not always, 0.50. That intensity can be determined by a number of means. The most obvious method is to fit the psychometric function with a reasonably smooth curve and to interpolate. More modern approaches abound, and all have the merit of shortening the time it takes to conduct an experiment to make the determination. Usually these

FIGURE 51.1. *A*, Schema for Fechner's idea of (classical) threshold. The abscissa is contrast, and the ordinate is a dichotomous variable indicating "seen" or "not seen." A contrast above the threshold level is seen; otherwise it is not seen. *B*, Modified threshold schema for the case where the threshold can vary from time to time. Coordinates are as in *A*. Three arbitrary instances are illustrated. The (traditional) threshold theory holds that the level of contrast above which a target is seen varies at random.

techniques, called *adaptive staircases*, lead rapidly to a threshold estimate by using information gained during the trials to structure subsequent trials. The reader is referred to studies by Watson and Pelli (1983) and by King-Smith et al. (1994) and to a review by Klein (2001) for details.

The modern threshold

The traditional threshold concept described above rests on the premise that it is the manifestation of a noise-limited process wherein the noise is randomness in the location along the intensity (or contrast) continuum of the intensity limen. This conceptualization is what scientists call a *model*. It supplants Fechner's classic threshold model of a static

barrier that intensity has to exceed in order for a stimulus to be seen. The premise may be false. Tanner and Swets (1954) disproved the premise of a threshold below which no information was available with two elegant experiments. One showed that false alarms, assertions by the observer that a stimulus had been seen when none was present, cannot be guesses in the sense that some information must have guided the choice. The other showed that a second choice in a multialternative detection task could be accomplished with better than chance success when the first choice was wrong. Under the threshold assumption, a wrong first choice implies that the threshold could not have been exceeded, so the success of a second choice could not have been better than chance. That other sources of noise might enter into the

FIGURE 51.2. Frequency of the seen curve (solid) for a traditional threshold observer. Another name for this function is *psychometric function*. The abscissa is target contrast. The ordinate is frequency seen, the fraction of trials on which the observer reports that the target is seen. The dashed curve shows the presumed underlying probability distribution of the threshold level that would have led to the solid frequency seen curve.

picture (e.g., that another model might supply a better description) illustrates a general approach to threshold matters. Suppose that for a given visual system one could specify a set of noises and transformations that limit the ability to perceive light. Then one could define the threshold intensity as that intensity which enabled the observer to achieve a specified level of performance in a detection task.

Theory—thresholds implied by the irreducible noise implicit in light

Instead of asking what the magnitude of the threshold is, it has been argued (Barlow, 1958; Rose, 1948) that one should first ask what it should be. Here's the logic. Suppose that we could develop an analytic approach to finding the level of performance that a given stimulus could allow. This performance level would assume that processing is ideal and that the only limitation on detection comes from noise that accompanies or is intrinsic in the stimulus. If that calculation could be achieved, then we would have a benchmark against which to compare the performance of any observer, whether human or machine, animal or neuron. In Rose's and Barlow's terms, the disparity between real measured performance and the superior ideal performance defines the *logical space* (Rose's term) within which models may be constructed or mechanisms sought. This strategy has been deployed during recent years and has led to some very powerful advantages, which include (1) the ability to model quantitatively the internal noise sources of real observers, (2) the ability to ascribe sensory deficiency to one or more candidate causes, and (3) the ability to define processing efficiency, which is a measure of performance that can be

largely independent of stimulus contrast. In order to illustrate these matters, I present below a development of ideal observer processing of a light stimulus plus degradations of that ideal observer that may serve to help model real observers. The development begins with an irreducible source of noise that exists in all visual detection situations. This is the point of departure for several seminal papers in the area of thresholds and noise, those of Hecht et al. (1942), Rose (1948), Barlow (1956), and Sakitt (1972).

THE QUANTUM FLUCTUATION LIMIT Consider a detection task in which an increment in intensity, ΔI [quanta/DEG²/SEC/NM], is to be detected in the presence of a background, I [quanta/DEG²/SEC/NM]. Assume a duration T [SEC], an area, A [DEG²], and a rectangular window in the wavelength domain of width Γ [NM]. Predicted performance can be formulated for the quantum fluctuation-limited ideal observer (Cohn, 1976a; Tanner and Clark-Jones, 1960). The derivation of this relationship is straightforward. Detectability is conventionally defined (Tanner and Birdsall, 1958) as the difference of means of two hypothesis distributions divided by a common standard deviation. In the present case, the distributions are approximately Gaussian (see below). Adding the approximation that for ΔI small compared to I , the standard deviations are nearly the same ($\sim\sqrt{\{ATI\Gamma\}}$), this detection problem reduces to one in which means are different by $\Delta IAT\Gamma$. Then

$$d' = \frac{\Delta IAT\Gamma}{\sqrt{ATI\Gamma}} \quad (1)$$

The means and standard deviation used in this computation are real numbers without units.

A note on units: In equation 1 the numerator and denominator are without units, the former being the difference of Poisson means (which are not necessarily integers) and the latter being the square root of the Poisson variance, which is also without units. In later equations, variables have been manipulated to isolate ΔI on one side of the equation. Its dependence on such variables as A , T , and so on should be viewed as numerically correct, with each such variable retaining its original units. A scale change (e.g., specifying T in minutes instead of seconds) would be reflected by a constant in the expression related to the square root of the scaling constant.

Graham (1989) has pointed out the useful insight that the factor that multiplies ΔI can be thought of as the sensitivity of the observer. This is because it is the inverse of the threshold (see development below that leads to equation 3).

Anticipating conclusions that real data to be described below will compel, I also present a modified ideal photon detector prediction for an observer with two imperfections likely in human eyes: a nonzero dark light, D [events/DEG/SEC], and an imperfect quantum efficiency, p ($0 < p < 1$).

1.0). Hecht et al. (1942) anticipated the latter, and the former was anticipated by Barlow (1956). The dark light, D , reflects events that exist, by assumption, at the level of the photopigment. It can also be expressed in units of quanta at the locus of the cornea by accounting for the attenuation from cornea to photopigment (reflection, absorptions, scatter, and imperfect catching) that is conveniently summarized as quantum efficiency (Rose, 1948).

Quantum efficiency is taken here as the fraction of quanta incident at the cornea used by the observer. Thus, a number of factors including corneal reflection, media absorption (Hecht et al., 1942), macular pigment absorption (Hammond et al., 1998), photopigment depletion (Reeves et al., 1998), photoreceptor optical cross-section (Curcio et al., 1990; Øesterberg, 1935), and photopigment catching (Hagins, 1955) all are subsumed under this single parameter. The predicted detectability, d' , is given by

$$d' = \frac{p\Delta IAT\Gamma}{\sqrt{pATT(I + D + p)}} \quad (2)$$

For an ideal observer ($p = 1.0$; $D = 0$), this reduces to equation 1.

In order to formulate the predicted threshold increment, ΔI , one adopts a convention for detectability at threshold. A convenient choice is $d' = 1.0$, which corresponds to an error rate in a yes/no task of close to 24%. Then

$$\Delta I = \sqrt{\{(I + D + p)/(pATT)\}} \quad (3)$$

which, for the ideal observer (for whom $D = 0$ and $p = 1.0$), is

$$\Delta I = \sqrt{I + ATT} \quad (4)$$

PREDICTED SQUARE-ROOT LAWS Equation 4 expresses jointly what have come to known as the *square-root laws of quantum fluctuation-limited detection performance*. Each such law is obtained by examining the relation between ΔI and one of the independent variables, I (DeVries-Rose), A (Piper's), T (Piéron's), or Γ (unnamed). Each of these will be considered in turn and compared to empirical evidence that relates to it. First, however, a variety of other traces of quantum fluctuation limitations will be described as they figure in the quest for evidence that the human approaches the limit set by the variability in light itself.

THE QUANTUM FLUCTUATION FINGERPRINT Quantum fluctuations, variability in the number of arriving quanta that can be caught in a given space-time-wavelength interval, present the fundamental limitation for thresholds and as such, need to be better understood. While the matter of their importance at absolute threshold has been known since the classic work of Hecht et al. (1942), their importance above absolute threshold has not. The fingerprints devolve from the quantum nature of light. The primary fingerprint is the set of four square-root laws that are developed above. Others

come about in detection situations, and all have their origin in the variable nature of light.

The number of photons caught in a fixed space-time-wavelength interval is random, and its probability distribution can be shown for most light sources to be described as Poisson. The Poisson distribution has one free parameter, the mean. All other higher-order moments are simple functions of the mean, the variance being numerically equal to it. In a detection task as described above, an increment, ΔI , will raise the mean and thus the variance. A convenient way to appraise theoretical detection predictions is to use the receiver operating characteristic (ROC) of signal detection theory (Tanner and Swets, 1954). The ROC curve plots hit rate versus false alarm rate for a detection situation. Theoretical curves for the simplest case of a deterministic signal in additive Gaussian noise are straight lines of unity slope in coordinates for which z -scores corresponding to hit and false alarm rates are plotted.

As Poisson ROC curves are well approximated by Gaussian curves (Thibos et al., 1979), one can picture the effects of this added variance. One effect is that the photon count distribution for the increment stimulus has more variance and the increment is thus less detectable than the decrement, which has lower variance. This translates to a higher increment threshold for the same contrast or modulation. Thus, the approximation that led us to equation 4 obscures this feature.

A second-order effect is that the ROC curve changes shape in response to that extra variance for increments. Variance affects slope, and the result is that the ROC slope (on z -coordinates) is less than 1.0 for increments and greater than 1.0 for decrements. Finally, a tertiary effect is seen in the last fingerprint, an elusive one that has been seen only in physiological preparations involving single cells. The quantal nature of light means that only discrete integer values can be coded. Nonetheless, the nervous system may superimpose a more fine-grained code (for example, with more than one action potential per photon). The result is that some adjacent categories of response are indistinguishable and will show concave cusps. Examples may be seen in both Cohn et al. (1975) and Cohn (1983). To sum up, quantum fingerprints are as follows:

- (First-order) Square-root laws
- (First-order) Increment threshold larger than decrement threshold. Thibos et al. (1979) give this expression:

$$d' = \left| \frac{\Delta I}{I} \right| \frac{\sqrt{IAT\Gamma}}{(1 - (\Delta I/I))^{1/4}} \quad (5)$$

where $\Delta I < 0$ for decrement contrast

- (Second-order) ROC slope >1.0 for decrements and <1.0 for increments. Thibos et al. give this expression:

$$\text{Slope} \cong \left(1 + \frac{\Delta I}{I}\right)^{1/6} \quad (6)$$

- (Third-order) ROC cusps

Figure 51.3 shows theoretical ROC curves for increment and decrement detection that reveal each of the quantum fluctuation fingerprints save for the square-root laws.

Measurement of the square-root laws

In this section I describe, in order, studies that bear on the approach of human observers to the predictions of the square-root laws. It will be seen that obedience to these laws is not ubiquitous. More significantly, no conditions have yet been described in which all of these laws can be shown to hold (Barlow, 1958). Nonetheless, the point where human performance approaches that predicted by these laws proves to be a useful starting point to understand what forces influence visual thresholds and, in particular, what noise might be limiting.

FIGURE 51.3. Quantum fluctuation fingerprint. ROC curves on probability coordinates are presented. The ordinate is the z -score transform of the probability of a hit (target presented and seen) for an ideal photon detector. The abscissa is the z -score transform of the false alarm probability. A background of 10 quanta with contrast of +6 or -6 quanta is assumed. The upper curve is for the six-photon decrement. The lower curve for the six-photon increment. Elements of the fingerprint manifest here include (1) decrement

THRESHOLD VERSUS INTENSITY: THE DEVRIES-ROSE LAW Evidence for this square-root law has been described since the two named investigators derived it (DeVries, 1943; Rose, 1948). The attempt to verify it empirically has always failed in a global sense (Fig. 51.4), although it is equally true that a small range of low backgrounds always presents a good fit.

Figure 51.4 displays data that are typical of a number of studies. The resulting data are alternatively referred to as *Threshold versus Intensity (TVI) curves*, as *increment threshold curves*, or as *Stiles curves*. These data are taken from Barlow (1977). The threshold on the ordinate ($I = 0$) is actually the absolute threshold. Under some conditions (Baumgardt and Smith, 1965), the threshold declines from the absolute threshold for values of I near the absolute threshold (this behavior is seen in other settings, such as masking, where the function is termed the *dipper*; see “The Psychometric Function”). At low backgrounds the increment threshold rises, often with a slope (log-log coordinates) near 0.5. At higher backgrounds the slope increases to approximately 1.0, and

threshold (detectability 2.5) less (greater) than increment threshold (detectability 1.6); (2) decrement ROC slope > 1.0 ; (3) increment ROC slope < 1.0 ; (4) cusps can occur when the precision of coding exceeds that of the target (see the lower left of the decrement curve). The primary quantum fluctuation fingerprint, the several square-root laws, would be seen if the ROC curves had been parameterized in any of the independent variables, A , T , Γ , or I .

FIGURE 51.4. TVI curves. The abscissa is log background intensity, $\log I$. The ordinate is log threshold, $\log \Delta I$. The TVI function shows a slight threshold reduction below absolute threshold at very low backgrounds, then a threshold rise roughly corresponding to

the DeVries-Rose law (line). Squares are averages of the several thresholds at a given background. (Data transcribed from Barlow, 1977).

this is the Weber law domain. Aguilar and Stiles (1954) showed conditions (blue test on a red background) in which the slope becomes asymptotically infinite for a narrow range of backgrounds above the Weber regime, and this has been interpreted as evidence for saturation of the photoreceptor elements (rods) responsible for the detection. Ultimately, when cones become engaged, and this is a strong function of both stimulus conditions and retinal locus, at least the early elements of the sequence of domains are repeated.

In order to interpret this behavior, it is most convenient to study the relation of these empirical data to the data expected of the ideal observer that are shown as a solid line in Figure 51.4. It is apparent that ideal performance lies closest to the empirical thresholds in the DeVries-Rose domain. Thus, one wants to find physiological explanations for the shortfall there first, for under those conditions it is logical to assume that the deficiencies, as compared to the ideal, are the least complex (Barlow, 1977). Other phenomena are certain to be at play, for the threshold increases further beyond what an extrapolation would lead one to expect, both at lower and higher backgrounds.

EXPLAINING THRESHOLDS IN THE DEVRIES-ROSE REGIME
Start with an assumption. Suppose that the only limit on sensitivity in this domain is due to quantum fluctuations, as DeVries and Rose thought. Then the shortfall in the DeVries-Rose regime is explained most parsimoniously by an inability to use all of the available quanta (Barlow, 1957a,b; Rose, 1948). This deficiency may arise from one or more of several physical processes (e.g., reflection, absorption, scattering, imperfect photon catching in photopigment), and possibly physiological ones, and was very clearly anticipated by Hecht et al. (1942; see their “corrections”) in their landmark paper on absolute threshold. It is quantified as the ratio of photons apparently used in the task to the number of those

presented at the cornea. This ratio is termed *detective quantum efficiency* and is given the designation F . Values of F determined by Barlow are not so low as to defeat a formulation that rests solely on quantum fluctuations, but they are close. Complete concordance would require that the detective quantum efficiency determined by psychophysical means approached approximately the quantum losses calculated (or measured) by physiological-optical means. Barlow (1977) estimated that 30% of photons incident at the cornea were absorbed in photopigment, considerably more than what Hecht et al. thought (10%). But the highest reported detective quantum efficiency in a psychophysical task thus far is Barlow’s for rods and is about 7%. This leaves room for other sources of noise or information loss. Hallett’s (1987) refinement, which assumes a slowly changing response characteristic, places the value closer to 10%.

DECREMENT THRESHOLDS IN THE DEVRIES-ROSE REGIME

Two studies (Patel and Jones, 1968; Short, 1966) measured both increment and decrement thresholds at backgrounds just above absolute threshold. Their findings were quite similar. At the lowest backgrounds, the decrement threshold was smaller than the increment threshold. Example data are shown in Figure 51.5. Prior to understanding the quantum fluctuation fingerprint, there were two ways to think about such a finding. One could imagine either that OFF neurons in the visual pathway were more sensitive (had a higher quantum efficiency) or that ON neurons were noisier (manifested their own internal noise). The former cannot be true for optical reasons because both pathways use the same photoreceptors. However, OFF neurons might indeed receive input from more photoreceptors.

DARK LIGHT: ANOTHER NOISE AT ABSOLUTE THRESHOLD

Barlow (1956) advanced an explanation for the low back-

FIGURE 51.5. Thresholds for increments and equal-contrast decrements. The abscissa is log background intensity, and the ordinate is log threshold. Filled symbols incate decrements and open symbols represent increments. Stimuli were $\frac{1}{4}$ degree in diameter and 50msec duration. The dashed line shows the DeVries-Rose square-root law. At higher backgrounds increment thresholds are virtually equal to decrement thresholds, and data are better fit by a curve of higher slope tending toward Weber's law. (After Patel and Jones, 1968.)

ground inefficiency which he termed *dark light*. As is apparent in Figure 51.4, some factor besides quantum loss must be at play at the lowest backgrounds, where the noise inherent in the background cannot be expected to pose a significant barrier to detection. Traditionally, vision researchers have thought of the zero background condition as a unique circumstance, concerning which they have referred to the *absolute threshold problem*. This means that some process has caused threshold to be finite, and not infinitesimal, and the researchers in the field have since wondered what this process is. Barlow supplied a prescient answer. He hypothesized the existence of thermally caused spontaneous isomerization of photopigment that presented a “background” of neural activity (indistinguishable from that caused by light) which added to the real-light background, I . If so (and much contemporary evidence, including that obtained from photoreceptor recording, is consistent with this view), it is as if the background against which the stimulus must compete is the sum of the dark light, D , and the real light, I . Then the absolute threshold cannot be infinitesimal (as the extrapolation of the DeVries-Rose law would imply), but rather finite, and determined by the magnitude of the dark light. That magnitude has been estimated by a number of means and amounts, on average, to a fraction of a photon-like event per second per photoreceptor (Sakitt, 1972).

There is a subtlety involved in the units of dark light. If, as often is the case, it is estimated as the background, I , for which a curve fitting asymptotic low background performance intersects with one that fits asymptotic high background performance, then its units are specified as if at the input (e.g., at the cornea where I is estimated). But this must

be corrected by another estimated parameter, that of the quantum efficiency, p . This is because events due to light compete (or are intermingled) with those due to dark light in the photopigment. And because quantum efficiency may have a physiological component, comparing rods to cones can be hazardous (Barlow, 1957a) because rods may differ from cones in that regard.

APPLICATIONS OF THE DARK LIGHT CONCEPT A number of researchers have used the simple model of processing described above to infer the cause of less than normal sensitivity as occurs in ocular disease. Suppose, for example, that an observer suffered from excessive dark light, D , but her quantum catching was ideal ($p = 1.0$). In that case, thresholds would be higher, as shown in equation 3, which is repeated here:

$$\Delta I = \sqrt{\{(I + D \div p) \div (pAT\Gamma)\}} \quad (3)$$

For $I \sim D$, thresholds are elevated. For high backgrounds, $I \gg D$ and thresholds are normal. Now, in contrast, assume that $D = 0$ and consider the effect of a quantum catching inefficiency, as evidenced by $p \neq 1.0$. Equation 3 becomes

$$\Delta I = \sqrt{\frac{I}{AT\Gamma}} \quad (4)$$

Whether for small or large I , thresholds are raised by a multiplicative factor ($1 / \sqrt{p}$). Thus the first situation is manifest in a TVI curve that is elevated over the normal but only for low backgrounds. The second one is elevated for all backgrounds.

Hood (1988) has pointed out that one's model of how the TVI curve becomes shaped determines how one interprets the shape changes that occur in conditions of abnormality. While he focused on the development of normal thresholds through childhood and while his model contained no quantum fluctuation noise, his point is well taken.

HIGH BACKGROUND INEFFICIENCY Now consider the high background condition which leads to Weber's law. Here thresholds are markedly higher than predicted for an ideal photon detector, even one with a quantum efficiency less than unity. What could explain this deficiency of processing? An attractive explanation is found in the very earliest work of Rose (1948). He appreciated that physiological elements couldn't possibly match their dynamic range to the span of energy that impinges on the eye between noon and night. He thus hypothesized gain control in neural elements and pointed out that internal noise processes might become more prominent as the background level goes up and thus gain goes down. Shapley and Enroth-Cugell (1984) formalized this notion. With fairly simple assumptions, it causes a system that is dominated by quantal noise at low levels to become dominated by internal noise at high levels.

Suppose for simplicity that the system gain is set by a photon counter that estimates the background intensity level by averaging the photon catch over a sufficiently long period of time, say several minutes. Let this average level be given by \bar{I} [unitless]. One convenient gain would normalize the photon input at any given moment by this average. If an internal noise follows the gain control, then a new performance prediction would be

$$d' = \left(\frac{\Delta I}{\bar{I}} \right) \frac{AT\Gamma}{N} \quad (7)$$

where N is the standard deviation of the (late) noise process in units of quanta. Solving for ΔI when $d' = 1.0$ leads to Weber's law. Hence, we may view the increased thresholds in this range of backgrounds as being due both to quantum inefficiency and to a combination of internal noise and gain control that together lessen the influence of the externally originating quantum fluctuations. It follows that under some conditions both quantal and internal noise may be manifest in performance.

Hornstein et al. (1999) nicely illustrated this principle for a photoreceptor operating at a single adaptation level. They showed that the gain is so low at high temporal frequencies that internal noise dominates even at a low enough background, one for which quantal noise dominates for low frequencies. The evidence for this conclusion relates to the statistical nature of the neural responses, which are treated above (see "The Quantum Fluctuation Fingerprint") in the general case.

To this point we have seen that only two types of inefficiency suffice to explain low background thresholds, and the addition of a third type, the combination of proximal internal noise and gain control, suffices to explain performance at higher backgrounds.

THE LOW BACKGROUND SENSITIZATION A number of early studies reported that low background increment thresholds were in some cases less than the absolute threshold. Barlow's data in Figure 51.4 show a subtle form of this effect. The theory immediately advanced to explain this phenomenon (Baumgardt and Smith, 1965) was little more than a repetition of its description. The term, *facilitation*, given to this phenomenon was intended to convey the idea that a bit of light would drive neurons into a more receptive state, thereby requiring fewer photons to achieve a criterion change in response. The problem with such a theory is that it leaves out the symmetrical requirement that false alarms, positive responses in the absence of a stimulus, also should rise. If so, it is not clear that sensitivity can be improved.

Nachmias (1966) pointed out that this was not the only possible answer and argued that it was possible that the additional photons from the background merely had the effect of showing an observer where to look for those from the

target. Data described by Baumgardt and Smith showing that the smaller the size of the background light the greater the advantage of turning it on support Nachmias' conjecture. This historical sidelight is nonetheless of contemporary relevance because of its similarity to dipper phenomena (see the section "The Psychometric Function" below).

The reader will appreciate that an absolute threshold experiment is conducted in the dark. While there may be a small central fixation mark of sufficient luminance to stimulate cones (for the purpose of allowing steady central fixation), observers are not generally equipped to handle an instruction of the sort "expect the stimulus 17 degrees to the right of fixation." But a weak background can illuminate elements of the background plane that would allow an observer to remember where to look and to actually use that information. Sensitization, as a concept, is similar to the concept of the transducer nonlinearity that arises in the context of departures from ideal observer performance in simple detection tasks at any background. This will be elaborated below. Suffice it to say here that a definitive study to separate these two explanations of sensitization has not been reported. A simple one would be to replicate the phenomenon while measuring ROC curve parameters. Uncertainty can leave a trace on the ROC curve. This could lead to an unequivocal finding.

AREA AND THRESHOLD Another of the square-root laws of quantum limited performance implicit in equation 2 arises from quantum fluctuations. This law relates area to threshold. Perhaps the most complete account can be found in Barlow's early paper on increment threshold (1957b). The empirical relation is shown in Figure 51.6. Threshold falls in inverse proportion to area for small areas and for large areas is constant with area. Adopting the same rationale as for the TVI function, one imagines the ideal photon detector theoretical relation as lying below that of the real detector and being a line on log-log coordinates with slope $-1/2$. Then one can see that the measured threshold is closest to that predicted at the part of the empirical curve where the function bends from one of slope $= -1$ to one of slope $= 0$. The most economical explanation of the departure from theory is the quantum (in)efficiency which is represented in these coordinates as simply a constant added to the curve at all areas. If so, the question becomes: what forces cause the threshold to escalate so rapidly with area for low areas and to remain fixed for high areas? Before answering this question, it is well to examine the classical treatment of the empirical function at small areas.

LOW AREA THRESHOLDS Low area thresholds depart strongly from those extrapolated from performance at middle areas. This function, of slope -1.0 on log-log coordinates, has been referred to as *Ricco's law* after its first dis-

FIGURE 51.6. Area-threshold relationship. The abscissa is the log target area, and the ordinate is log threshold. Successive curves indicate successively higher backgrounds. The solid line (slope = -0.5) is the square-root law for the ideal photon detector, Piper's law. The dashed line (slope = -1.0) shows Ricco's law. Measured human thresholds lie closest to predicted thresholds in the Piper's law range. It is thus assumed that human processing is most efficient there, and the next step is to identify causes for larger than extrapolated thresholds at both lower and higher areas.

coverer (Ricco, 1877) and is said to be consistent with "perfect" or "total" summation because of reciprocity between area and threshold. The largest area for which Ricco's law holds is said to be the *Ricco area* or the *area of complete summation*, and for the record, this area declines as the adaptation level increases. That Ricco's is a law of perfect summation appears to be a contradiction to the quantum fluctuation model, in which performance is perfect by assumption and threshold varies with the square root of the background. How can this apparent contradiction be resolved?

Thus one has to contend not only with the question of why Ricco's law is not a law of ideal performance, but also with what brings it about. It will be seen that the explanation for the latter is also the explanation for the former. Barlow (1958, 1964) was careful to outline the key implicit assumption in the formulation of the square-root laws that may have broken down in this case. The assumption is that the human observer integrates only those photons that fall in the area, A , designated for the target. Suppose that the assumption is not true (Rosell and Wilson, 1973) and that, in fact, the observer is unable to sum photons over areas smaller than a particular area, A_{\min} (Barlow termed this deficiency a *mismatching loss*). One might think of this area as that of the smallest receptive field. The consequence of such an inability is that more photons are gathered from the background than is necessary or desirable. Those photons, and their Poisson fluctuations, constitute noise that makes detection of the target more difficult than it would otherwise have been. This consequence is embodied in a modified detection equation

$$d' = \frac{\Delta I A T \Gamma}{\sqrt{A_{\min} T \Gamma}} \quad (8)$$

from which Ricco's law immediately follows. Then A_{\min} , which is essentially Ricco's area, is actually *the smallest area of complete summation*, not the largest. There is a more modern way of viewing this phenomenology. In considering that the early vision is characterized by filters, one might ask what effect these filters should have on ideal detection performance. The answer is that filters in the spatial domain at low backgrounds are low-pass. This means that high-frequency information fails to gain admission to the signaling pathway. A low-pass system is one that approximately integrates high frequencies. If the area over which it integrates is too large, it collects too many background photons; thus, the threshold is compromised and is higher than it would otherwise be. It is worth mentioning at this point that Ricco's law ensues at zero background in the dark, and one might wonder how this phenomenon is embraced by a modified ideal observer theory. The answer, as described above, is due (as so many are) to Barlow (1958). A too-large integration area will gather dark light from photoreceptors untouched by the target. This raises the threshold because of the noise or variability of the photoreceptors due to the dark light.

Application of this insight is useful. It has been reported that senescence leads to increased Ricco's areas (Scheffrin et al., 1998). On the interpretation that Ricco's area reflects a deficiency of processing, one then interprets such a finding as indicating the possibility of an increased minimum summing area.

THRESHOLDS AT LARGE AREAS A comparable argument can be made for the processing deficiency that is measured at high areas. Suppose that there is an area beyond which the eye cannot integrate. Such an area is not apparent in practice unless one considers that there is an upper limit on receptive field size, which appears to be finite. If one accepts that argument, then constant threshold as area increases is expected. If one does not, the filter explanation provides some respite. At even low backgrounds, the spatial contrast sensitivity function is bandpass. For large areas with their predominantly low spatial frequencies, the eye acts not as an integrator but as a differentiator, seeking contrast in distinction to light. It is as if there is a maximum area, A_{\max} , over which photon integration can occur. If so, equation 1 becomes

$$d' = \frac{\Delta I A_{\max} T \Gamma}{\sqrt{I A_{\max} T \Gamma}} \quad (9)$$

The result is independence of performance, and thus of threshold, from area A , for areas greater than A_{\max} .

At high backgrounds, different phenomenology emerges. If backgrounds are high enough that internal gain controls

effectively minimize the quantum fluctuations in comparison to internal noise processes, \mathcal{N} , performance measures have different dependence upon area. In this instance, Ricco's law emerges for low areas because it is only the noise in the proximal neuron(s) that matters, and that noise, an internal noise arising at or near that level, would not depend on area. At high areas, there would be no areal dependence by the same arguments advanced above: the brain is simply unable to integrate photons over areas larger than A_{\max} .

DURATION AND THRESHOLD The situation for duration is quite similar to that for area. In a sense, each is the dual of the other. Empirical threshold-versus-duration curves are shown in Figure 51.6 as adapted from Barlow (1958). The prediction of the ideal photon detector is again a line with slope = $-1/2$ on log-log coordinates termed *Piéron's law*. Thresholds of the human observer lie closest to those of the ideal where the empirical data themselves fall close to a slope of $-1/2$. Explaining the shortfall in processing quality evidenced by thresholds elevated from those extrapolated from middle durations requires two separate explanations, one at low duration and one at high duration.

At low duration we must ask why ideal performance has failed, and the attractive possibility is that the human observer is simply unable to fix her attention upon epochs shorted than a minimum duration, T_{\min} . If so, and by analogy to the area-threshold relationship, too many background quanta are summed and equation 1 becomes

$$d' = \frac{\Delta I T \Gamma}{\sqrt{A T_{\min} I \Gamma}} \quad (10)$$

This expression is the embodiment of the ubiquitous Bloch's law, which, like Ricco's law, is not a law of perfect integration under conditions where quantum fluctuations are the main limitation on performance. Thus it is important to avoid the temptation to refer to the largest duration for which Bloch's law holds as the integrating time of the eye. The integrating time is more properly the largest duration for which Piéron's law holds.

The physiological concept of a receptive field, so useful above in appraising low area thresholds, is not duplicated in the temporal domain. Instead one can rest on the concept of the *temporal impulse response*, which is especially long for small receptive fields.

At large durations, we have a situation likewise similar to that in the area-threshold relation. Most often, threshold is fixed at high durations, although there is evidence in some studies of a minimum threshold at middle durations (e.g., Swanson et al., 1987) which appears to be related to biphasic photoreceptor impulse responses (or, equivalently, the bandpass frequency response).

CHROMATIC EXTENT AND THRESHOLD The following description refers to phenomena that have not, to this author's knowledge, been explicitly studied. Consider the relation implicit in equation 4 between threshold, ΔI , and wavelength extent, Γ . As with area and duration, an increase in wavelength extent should lower the threshold according to a square-root law. The task would be to detect an increment of area A , of duration T , and of a specified wavelength extent and specified center wavelength superimposed on a white background. Can we imagine limitations similar to those for area or for duration that might limit the observer and thus raise thresholds? Consider first scotopic vision. In the case of small values of wavelength extent, because rod photoreceptors are the initial receptive elements and because they are broadband, they will have to sum wavelengths from beyond the band of interest. According to the concept of *univariance*, an absorbed photon is treated the same way irrespective of its wavelength. In this case, we could say that we have a minimum band limitation. If that minimum band extent is G , then G will replace Γ in the denominator of the performance prediction and a linear law, not a square-root law, would be expected. In the case of stimuli with large wavelength extent, the picture does not change. So for rods we predict a linear law, showing no sign (e.g., no square-root relationship) of quantum-limited behavior.

Cones may present a different picture. Even though the receptive elements are broadband, computation that takes advantage of different absorption in different cones could be used to exclude wavelengths beyond those in the stimulus band. In that case, and if the photon count is low, it might be possible to observe square-root law behavior. While some authors have argued that quantum fluctuations have little bearing on behavior above absolute threshold (Hecht, 1942; Massof, 1987), that assertion has not been proven. In fact, quantum fluctuation fingerprints may be seen in detection data where cones are involved. Two simple examples are these: both first- and second-order quantum fluctuation effects have been described for cones. Cohn (1976a) has shown that decrement threshold is less than increment threshold in rod-free fovea and when the color of the target can be seen, and has also shown that the decrement ROC curve slope is greater than unity.

The psychometric function

Perhaps the most fundamental relation that appears explicitly in the relations described above (equations 1, 2, and 5 to 9) is the psychometric function. The more traditional definition is that of the frequency-seen (which is but one component of d') versus the contrast. [The reader is referred to Klein's (2001) extensive recent review of the recent psychometric function literature.] The psychometric function is

defined here as the relation between observer performance, d' , and signal contrast as expressed by ΔI . As can be seen, the prediction for the ideal observer or for a nonideal observer with a number of different possible flaws (e.g., dark light, quantum inefficiency, internal noise) is simple proportionality between ΔI and contrast. The constant of proportionality is dependent on all of the aforementioned parameters, including especially observer parameters of efficiency and dark light and signal parameters of area, duration, background, and wavelength extent.

The first test of this proportionality prediction was that of Tanner and Swets (1954), and the result was a marked failure. Instead of simple proportionality between d' and contrast, measured d' was better described as a power function of contrast $\sim(\Delta I)^r$, where $r > 2.0$. (A value of $r = 1.0$ would have exactly matched the prediction.) In other words, weak signals were disproportionately hard to see. A subsequent test (Nachmias and Kocher, 1970), however, was intriguing. Placing the signal to be detected on top of a contrast pedestal of identical time course and spatial extent (which would not alter the prediction) did indeed lead to a proportional relationship.

Two major classes of explanation (Cohn and Lasley, 1985) have been advanced to explain this difference between predicted and measured performance for human observers. At the same time, some investigators have explored the relation for single neurons. Below I describe both the explanations and the physiological findings and their interrelation.

THE NONLINEAR TRANSDUCER EXPLANATION Nachmias and Sansbury (1964) were the first to describe this possibility. They reasoned that a physiological nonlinearity early in the system attenuated weak signals and that the psychometric function shape merely mirrored the shape of the transducer nonlinearity. Taking equation 5 as a point of departure is necessary because one needs a late internal noise source to make this explanation work (Lasley and Cohn, 1981). Suppose that contrast was attenuated by a nonlinearity:

$$f(\Delta I) = (\Delta I)^r \quad (11)$$

Then the relation becomes

$$d' = \left(\frac{\Delta I}{I} \right)^r \frac{AT\Gamma}{N} \quad (12)$$

Equation 12 applies only to low-contrast signals. It is not meant to convey a prediction for large-contrast signals for those should lead to saturation. But even for small signals, it is intriguing beyond its ability to fit data. Suppose that one sought the predicted area- or duration-threshold relationship for near-threshold increments. Rearrangement in equation 12 leads to a relationship in which threshold is predicted to be proportional to area or duration to the $1/r$ power. Since many authors have estimated r to be 3 and above (cf.

Graham, 1989), the ubiquitous existence of Ricco's and Bloch's laws would tend to refute this nonlinearity hypothesis should it emerge under the same conditions.

THE UNCERTAINTY EXPLANATION Tanner (1961) proposed that observer uncertainty, analogous to a similar phenomenon observed in radar detection apparatus, could be the cause of an accelerating psychometric function. The uncertainty explanation, in brief, suggests that the observer does not know which of a number of directions to attend to, or to which of a number of possible times (equally, the observer may have been told these particulars but may be unable to use the information fully). In recent years, vision scientists have been more explicit about what it means to be looking in various places or at various times, referring to relevant (signal-containing) and irrelevant neural channels or mechanisms (cf. Pelli, 1985). In either case, it has been shown theoretically (Peterson et al., 1954) and empirically (see Cohn and Lasley, 1985, for a summary) that weak signals will suffer disproportionately (presumably because strong signals point themselves out both for time and for location.)

A line of research that extends from Tanner's (1961) paper to the present day has sought to demolish one or the other of these opposing theories of the nonlinear psychometric function. Dispassionate reading of these papers leads to the conclusion that despite pronouncements as to the demise of one or the other theory (cf. Foley and Legge, 1981; Lasley and Cohn, 1981) consensus has not been achieved.

PHYSIOLOGICAL PSYCHOMETRIC FUNCTIONS (NEUROMETRIC FUNCTIONS) As both alternative explanations for the nonlinear psychometric function may point to visual pathway elements, one is naturally led to inquire how those elements behave. Data exist for photoreceptors, for retinal ganglion cells, and for cortical neurons. Photoreceptors are known to exhibit a nonlinear (saturating) response characteristic (Cohn, 1983; Lillywhite and Laughlin, 1979; Schnapf et al., 1990), but that does not necessarily translate to a nonlinear neurometric function. It is worthwhile to distinguish these two response indicators. The magnitude of the response is not the only determinant of the sensitivity of response. Response magnitude must be compared with response variability, or noise, this being the rule for threshold problems.

Both the near linearity of the predicted neurometric function and the disparity between increment and decrement detectability have been observed in neurometric functions for photoreceptors and for retinal ganglion cells. Locust photoreceptors do not exhibit a linear response characteristic. Instead, they show marked saturation, as would be expected. Nonetheless, for contrasts where saturation occurs, detectability is still nearly proportional to contrast (Cohn, 1983). Also, increment detectability is inferior to decrement

detectability, and by an amount that is predicted from the number of quanta that the photoreceptor is catching (Hornstein et al., 1999). But photoreceptors are the first neural element in the perceptual chain. One might wonder if this phenomenology persists at higher levels where nonlinearities and other sources of noise and information loss may be important. Half of the answer was shown early (Cohn et al., 1975), where class IV dimming retinal ganglion cells of *Rana pipiens* showed both the second-order quantum fluctuation fingerprint (ROC slope > 1.0 for contrast decrements) and the first-order (De Vries-Rose) square-root law.

OFF-center (brisk, sustained) cat retinal ganglion cells also showed these results and, in addition, showed a first-order fingerprint, that increment threshold (for stimuli confined to the receptive field center) is greater than decrement threshold (Levick et al., 1983). Of course, one might think that such a finding reflects little more than a preference of the OFF-center neuron for negative contrast in the receptive field center. But two findings argue against that possibility. First, the same finding emerges, paradoxically, in the receptive field center of the ON-center neuron. For that neuron, decrement stimuli are seen with higher detectability than equal-contrast increment stimuli. This result suggests that ON cells are more sensitive to OFF stimuli than to ON stimuli owing to quantum fluctuations. The second finding is that the neuron in question uses so many of the quanta available in its receptive field that there is no statistical room for a source of variance greater than, or even approximately equal to, that due to quantum fluctuations to determine the threshold of the cell. Two surprising but robust conclusions follow from this. Under the conditions of test, and for those very sensitive cells, the “spontaneous activity” of the cell is

actually the code of the background quantum catch and is not spontaneous in any sense. Moreover, quantum utilization is high, (close to the quantal attenuation determined densitometrically (Bonds and Macleod, 1974) that it is necessary to conclude that each photoreceptor in the receptive field sends signals to the neuron.

Cortical neurons are generally thought to respond in a highly nonlinear fashion, and it might seem impossible to expect that any could even approximate the linear neurometric function prediction. The primary reason is that many such cells show no spontaneous activity and thus show no response for weak stimuli, an extreme version of *weak signal suppression*. Nonetheless, the available literature shows the existence of neurons that do obey the proportionality prediction. Tolhurst et al. (1983) have published response summaries for a number of complex cells. Figure 51.7 shows some data from one such cell which exhibited a significant spontaneous discharge. Such a cell is a candidate for processing a low-contrast stimulus, as cells with no spontaneous firing cannot do so. Despite a tendency for the literature to pronounce cortical neurometric functions to be nonlinear, departures from simple proportionality in a cell such as this are so small as to be unconvincing.

Added external noise as an analytic tool

Since the deployment of signal detection methods in the 1950s, scientists have found that using external noise (noise that is generated in the stimulus domain) has analytic and strategic advantages in the search for an accurate characterization of the system under study. The most fundamental of these approaches pits external noise against internal

FIGURE 51.7. Neurometric function for a complex cell. The abscissa is target contrast for a sinusoidal grating moving across the receptive field of a complex cell. The ordinate is the detectability as extracted from ROC curves fitted to measured distributions of action potentials counted following the stimulus, a single cycle passing one point on the retina. The line is the prediction of proportionality between detectability and contrast of an ideal photon

detector. It is fit by eye with the constraint that detectability must be identically zero for zero contrast. Photoreceptors (Cohn, 1983) and retinal ganglion cells (Cohn et al., 1975; Levick et al., 1983) show nearly identical proportional behavior, except that at low backgrounds, the quantum fluctuation causes a slight reduction of increment detectability, and amplification of decrement detectability can be measured. (Data from Tolhurst et al., 1983.)

noise. When external noise of sufficient magnitude is introduced, the threshold is, of course, raised. When raised enough, by enough noise, the threshold that remains is limited solely by the external noise, and internal noise may be eliminated from formulations. The noise power at which performance is halved (or threshold is doubled) is the one for which the internal noise can be viewed as equivalent to the external noise when it is referred to the input (Cohn, 1976b; Nagaraja, 1964; Pelli and Farell, 1999). External noise can also be used to strategic advantage. Cohn and Macleod (1999) showed a noise probe technique that allowed them to characterize the summation properties of the visual system.

Threshold behavior as an indicator of sensory deficiency

While the identification of the components of normal human vision is far from complete, a number of these components are agreed upon. It is clear that quanta available at the cornea are not fully utilized and that dark light dominates real backgrounds at low light levels. It is also likely that the combination of gain control and proximal internal noise sets the detection limit at higher backgrounds. Considerable evidence suggests that intrinsic uncertainty as to stimulus parameters characterizes normal visual behavior (Cohn and Lasley, 1985; Pelli, 1985; Tanner, 1961). This specificity of knowledge places scientists in a position of good leverage. If the question is why a particular human visual nervous system is deficient compared to normal, each of the information-losing components in the extant model becomes a candidate for the locus of a site-specific deficiency. Then a strategic series of measurements is capable of revealing the nature of a given deficit. Hood (1988) has employed this strategy to study the nature of the deficiency that is erased by development using electroretinographic thresholds. Werner et al. (2001) have employed it to examine the nature of the age-related deficiency in psychophysical thresholds. It should be apparent that the accuracy of the model directly determines the validity of the conclusions drawn from its use. In particular, a model of threshold that ignores noise is not complete and thus cannot be expected to fully capture behavior.
